2023 Annual Meeting of the American Society for Bone and Mineral Research

October 13-16, 2023

The *Journal of Bone and Mineral Research* (ISSN: 0884-0431 [print]; 1523-4681 [online]) provides a forum for papers of thehighest quality pertaining to bone, muscle, and mineral metabolism. Manuscripts are published on the biology and physiology of bone and muscle, relevant systems biology topics (e.g., osteoimmunology), and the pathophysiology and treatment of sarcopenia,and disorders of bone and mineral metabolism. All authored papers and editorial news and comments, opinions, findings, conclusions or recommendations in the *Journal* are those of the author(s) and do not necessarily reflect the views of the *Journal* and its publisher, nor does their publication imply any endorsement.

The JOURNAL OF BONE AND MINERAL RESEARCH (ISSN: 0884-0431), is published monthly on behalf of the American Society for Bone and Mineral Research by Wiley Subscription Services, Inc., a Wiley Company, 111 River St., Hoboken, NJ 07030-5774. Periodical Postage Paid at Hoboken, NJ and additional offices.

Postmaster: Send all address changes to JOURNAL OF BONE AND MINERAL RESEARCH, John Wiley & Sons Inc., C/O The Sheridan Press, PO Box 465, Hanover, PA 17331. **Information for subscribers:** The *Journal of Bone and Mineral Research* ispublished in 12 issues per year. Institutional subscription prices for 2023 are: Print &Online: US$1481 (US), US$1481 (Rest of World),€1064 (Europe),£908 (UK). Prices are exclusive of tax. Asia-Pacific GST, Canadian GST and European VAT will be applied at the appropriate rates. For more information on current tax rates, please go to www.wileyonlinelibrary.com/tax-vat. The price includes online access to the current and all online back files to January 1st 2012, where available. For other pricing options, including access information and terms and conditions, please visit www.wileyonlinelibrary.com/access. **Commercial Reprints:** Beth Ann Rocheleau, Reprints and Eprints Manager, Rockwater, Inc., PO Box 2211, Lexington, SC 29072, USA; Tel: +00 (1)803-359-4578; Fax: +00 (1)803-753-9430; E-mail: asbmr@rockwaterinc.com. For submission instructions, subscription and all other information, visit: www.jbmr.org

The *Journal of Bone and Mineral Research* is the official journal of the American Society for Bone and Mineral Research, 2001 K Street, NW, 3rd Floor North, Washington, D.C. 20006, USA. **Advertising:** Address advertising inquiries to Joseph Tomaszewski, Advertising Sales Executive, Wiley, 111 River St., Hoboken, NJ 07030, (201) 748-8895 (Tel); jtomaszews@wiley.com (email). Advertisements are subject to editorial approval and must adhere to ASBMR's advertising policy as specified here: https://onlinelibrary.wiley.com/page/journal/15234681/homepage/Advertise.html. Publication of the advertisements in JBMR® is not an endorsement of the advertiser's product or service or the claims made for the product in such advertising. **Disclaimer:** No responsibility is assumed, and responsibility is hereby disclaimed, by the American Society for Bone and Mineral Research, the *Journal of Bone and Mineral Research*, and the Publisher for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of methods, products, instructions or ideas presented in the *Journal*. Independent verification of diagnosis and drug dosages should be made. Discussions, views and recommendations as to medical procedures, choice of drugs and drug dosages are the responsibility of the authors. Advertisers are responsible for compliance with requirements concerning statements of efficacy, approval, licensure, and availability. The *Journal of Bone and Mineral Research* is a **Journal Club™** selection. The Journal is indexed by *Index Medicus, Current Contents/Life Science, CABS (Current Awareness in Biological Sciences), Excerpta Medica, Cambridge Scientific Abstracts, Chemical Abstracts, Reference Update, Science Citation Index*, and Nuclear Medicine Literature Updating and IndexingService.

GUIDELINES FOR ABSTRACT READERS

The JBMR® Supplement 1 Abstracts serves as a compiled version of the Abstracts. Authors submit their own abstracts and are charged a fee to do so. Each abstract must be sponsored by a current ASBMR member. Authors are responsible for the accuracy of the content that they post. Authors are responsible for ensuring compliance with applicable human subject and animal subject procedures. When an abstract is submitted, one person is identified as the Presenting Author, the person who is expected to present the abstract at the ASBMR Annual Meeting.

The ASBMR depends upon the honesty of the authors and presenters and relies on their assertions that they have had sufficient full access to the data to be and are convinced of its reliability. The ASBMR expects that authors and presenters:

- Will disclose any conflicts of interest, real or perceived.
- Should disclose any relationship that may bias one's presentation or which, if known, could give the perception of bias.
- Will affirm, for any study funded by an organization with a proprietary or financial interest, that they had full access to all the data in the study.
- Are responsible for the content of abstracts, presentations, slides, and reference materials.
- Keep the planning, content and execution of abstracts, speaker presentations, slides, abstracts and reference materials free from corporate influence, bias or control.
- Should give a balanced view of therapeutic options by providing several treatment options, whenever possible, and by always citing the best available evidence.
- Should disclose when any commercial product is not labeled for the use under discussion or that the product is still investigational.

The ASBMR:

- Will note those speakers who have disclosed relationships, including the nature of the relationship and the associated commercial entity.
- Will peer-review the abstracts according to categories, but only to determine which will be selected for oral presentation, for poster presentations or for any awards. Abstracts are not otherwise subject to any quality or content review by ASBMR or JBMR®.
- Expects the audience for the Abstracts to be researchers, physicians and other health and allied health professionals.
- Protects the Abstracts by copyright, and prohibits the reproduction, distribution or transmission of the abstracts without the express written permission of ASBMR.
- Embargoes the Abstracts for public release in written, oral or electronic communications – until the start time of the session in which the presentation is being made at the ASBMR Annual Meeting

Disclaimer. All authored abstracts, findings, conclusions, recommendations or oral presentations are those of the author(s) and/or speaker(s) and do not reflect the views of the American Society for Bone and Mineral Research or imply any endorsement. No responsibility is assumed, and responsibility is hereby disclaimed, by the American Society for Bone and Mineral Research for any injury and/or damage to persons or property as a matter of products' liability, negligence or otherwise, or from any use or operation of methods, products, instructions or ideas presented in the abstracts or at the ASBMR Annual Meeting. Independent verification of diagnosis and drug dosages should be made. Discussions, views and recommendations regarding medical procedures, choice of drugs and drug dosages are the responsibility of the authors and presenters.

GENERAL MEETING INFORMATION

ASBMR 2023 Annual Meeting Location

All ASBMR sessions will take place in the Vancouver Convention Centre, Vancouver, BC, Canada, West Building, unless otherwise stated. The Vancouver Convention Center is located at 1055 Canada Place, Vancouver, BC, V6C 0C3, Canada.

Annual Meeting Evaluation

The ASBMR 2023 Annual Meeting Evaluation will be accessible online starting Thursday, October 19. An email will be sent to all meeting attendees who provided their email addresses at the time of registration. The email will provide a hyperlink to the online evaluation site. It will also to be accessible via the ASBMR website at https://www.asbmr.org/annual-meeting. We strongly encourage and welcome all attendees to provide us with feedback on the meeting. Your input is very important to us.

Registration Hours

Registration desks will be open for new registrants and material pick-up in the Vancouver Convention Center in the Ballroom Lobby during the following hours:

Thursday, October 12 ..... 7:00 am – 6:00 pm
Friday, October 13 ..... 7:00 am – 6:00 pm
Saturday, October 14 ..... 7:00 am – 6:30 pm
Sunday, October 15 ..... 7:30 am – 6:00 pm
Monday, October 16 ..... 7:30 am – 12:00 pm

Discovery Hall Hours

Exhibits are located in the ASBMR Discovery Hall on the Exhibition Level, Exhibit Halls A and B of the Vancouver Convention Center. Please note that children aged 16 and under are not permitted in Discovery Hall at any time.

Friday, October 13 ..... 6:00 pm – 7:30 pm
Saturday, October 14 ..... 9:30 am – 4:30 pm
Sunday, October 15 ..... 9:30 am – 4:30 pm

Future ASBMR Annual Meeting Dates

ASBMR 2024 Annual Meeting
Metro Toronto Convention Centre, Toronto, ON, Canada
September 27-30, 2024

ASBMR 2025 Annual Meeting
Washington State Convention Center, Seattle, WA, USA
September 4 - 8, 2025

DISCLOSURE POLICY

The ASBMR is committed to ensuring the balance, independence, objectivity and scientific rigor of all its individually sponsored or industry-supported educational activities. Accordingly, the ASBMR adheres to the requirement set by ACCME that audiences at jointly-sponsored educational programs be informed of a presenter's (speaker, faculty, author, or planner) academic and professional affiliations, and the disclosure of the existence of any significant financial interest or other relationship a presenter or their spouse has with any proprietary entity over the past 12 months producing, marketing, re-selling or distributing health care goods or services, consumed by, or used on patients, with the exemption of non-profit or government organizations and non-health care related companies. When an unlabeled use of a commercial product, or an investigational use not yet approved for any purpose, is discussed during the presentation, it is required that presenters disclose that the product is not labeled for the use under discussion or that the product is still investigational. This policy allows the listener/attendee to be fully knowledgeable in evaluating the information being presented. The On-Site Program book will note those speakers who have disclosed relationships, including the nature of the relationship and the associated commercial entity.

Disclosure should include any affiliation that may bias one's presentation or which, if known, could give the perception of bias. This includes relevant financial affiliations of a spouse or partner. If an affiliation exists that could represent or be perceived to represent a conflict of interest, this must be reported in the abstract submission program by listing the name of the commercial entity and selecting the potential conflict(s) by clicking in the box next to the relationship type. Disclosures will be printed in the program materials. These situations may include, but are not limited to: 13. Grant/Research Support; 14. Consultant; 15. Speakers' Bureau; 16. Major Stock Shareholder; 17. Other Financial or Material Support.

ABSTRACT PRESENTATION KEY

Metastatic Breast Cancer Cells Induce Osteocyte Senescence Contributing to Osteolytic Bone Destruction *Japneet Kaur[1], Manish Adhikari[1], Hayley Sabol[1], Aric Anloague[1], Sharmin Khan[1], Lowry Barnes[1], Jeffrey Stambough[1], Michela Palmieri[1], Olivia Reyes-Castro[1], Elena Ambrogini[2], Maria Jose Almeida[2], Charles O'Brien[3], Intawat Nookaew[1], Jesus Delgado-Calle[1]. [1]University of Arkansas for Medical Sciences, United States. [2]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, United States. [3]Univ of Arkansas for Medical Sciences, United States

Breast cancer (BCa) bone metastases cause extensive bone destruction and are typically incurable. We studied the impact of BCa bone metastasis on osteocytes (Ots) - recently identified as key cells of the tumor niche - using single-cell RNA sequencing (scRNAseq). First, we injected murine E0771 BCa cells or PBS into 8-wk female NuTRAP reporter mice crossed with Dmp1-8kb-Cre mice and, after 2 wks, sorted Dmp1-8kb-GFP+ cells to study Ots. Bioinformatic analyses showed that Ots from BCa bone metastases had upregulation of genes enriched in GO terms linked to senescence, senescence-associated secretory phenotype (SASP), and inflammatory response, and had an increased senescence/SASP score compared to naïve mice. Histology revealed 4 times more p16+ (RNAscope) and senescence-associated distension of satellites (SADS)+ (centromere-FISH; 2 vs 14%) Ots, hallmarks of cellular senescence, in the cortical bone of BCa-bearing mice. Conditioned media (CM) from E0771 or human MDA-MB-231 BCa cells increased senescence-associated ?-galactosidase activity and upregulated senescence-related genes p16, p21, Mmp13, and Il6 in cultured Ocy-454 cells. Remarkably, MDA-MB-231 BCa cells led to similar gene expression changes in ex vivo organ cultures of human bone. Collectively, these results support the idea that signals from metastatic BCa cells cause Ot senescence. Next, we treated 8-wk female mice with intratibial E0771 BCa tumors with a cocktail of the senolytics (D+Q) Dasatinib (5 mg/kg) and Quercetin (50mg/kg) once a wk, starting two days after tumor inoculation. D+Q, known to eliminate senescent cells, prevented the histological increases in p16+ and SADS+ Ots induced by BCa cells. D+Q did not affect tumor burden but decreased lytic lesions and preserved cancellous bone mass (30% higher vs untreated BCa-mice). scRNAseq showed Ots from BCa-bones had elevated Rankl, Mmp13, Il6, Lgals3, Serpine2, Cd9, and Vegfa, and reduced Cthrc1 expression, suggesting increased osteoclastogenic potential. Consistent with this, D+Q restored the elevated p21, p16, and Mmp13 mRNA levels and reduced by 40% the increase in CTX in bones-bearing BCa cells cultured ex vivo. D+Q did not affect P1NP levels, which remained decreased in bones with BCa cells, suggesting senolytics preserved bone by inhibiting resorption. Our data demonstrate that metastatic BCa cells change the bone microenvironment and cause Ot senescence, which in turn induces osteoclastogenesis and osteolytic disease.

Local and Systemic Effects of Dickkopf-1 During Breast Cancer Progression by Limiting NK Cell-Mediated Killing *Seunghyun Lee[2], Biancamaria Ricci[2], David Clever[2], Roberta Faccio[3]. [2]Washington University in St.Louis, . [2]Washington University in St.Louis, United States. [3]Washington University in St Louis School of Medicine, United States

Elevated levels of the Wnt inhibitor dickkopf-1 (Dkk1) are detected in breast cancer patients and correlate with the progression of bone metastases. We found that breast cancer patients with progressive metastatic bone disease unresponsive to standard-of-care therapies have higher Dkk1 levels than patients with stable disease. Intriguingly, serum Dkk1 levels do not always correlate with Dkk1 expression in cancer cells. Thus, it is important to understand the source and role of Dkk1 in breast cancer to better identify patients that could benefit from Dkk1-targeted therapies.In this study, we used mice orthotopically injected with PyMT, EO771, and 4T1 breast cancer lines. Although Dkk1 was not expressed in these cells, Dkk1 serum levels were upregulated in all models. Strikingly, Dkk1 neutralizing antibody (?-Dkk1) significantly reduced tumor growth in the primary site and in the bone compared to IgG, in all models.To understand the source of Dkk1 in the tumor-bearing mice, we examined Dkk1 transcripts in the bone and tumor stroma. Dkk1 was highly expressed by the osteoblasts (OBs) in the bone and to a less extent by the cancer-associated fibroblasts (CAFs) in the tumor stroma. To address the role of bone- versus CAF-derived Dkk1, we generated mice with specific deletion of Dkk1 in the OBs (OsxCre;Dkk1fl/fl), or CAFs (Fsp1Cre;Dkk1fl/fl and aSMACreERT2;Dkk1fl/fl). To our surprise, all models showed a significant reduction in primary tumor growth. Furthermore, WT mice co-injected with PyMT and Dkk1 KO CAFs showed reduced tumor growth compared to mice co-injected with Dkk1 WT CAFs. These results suggest systemic and local effects of Dkk1.To understand how Dkk1 supports tumor growth, we performed bulk RNAseq on tumor cells isolated from IgG and ?-Dkk1 treated mice. Intriguingly, immune response-related pathways were upregulated in the ?-Dkk1 treated tumors. Supporting the involvement of immune cells, ?-Dkk1 did not reduce tumor growth in the NSG immune-compromised mice. Next, we treated tumor-bearing mice with ?-Dkk1 and depleting antibodies against T or NK cells. Surprisingly, only NK cell depletion abrogated ?-Dkk1 anti-tumor effects. Further confirming that Dkk1 directly affects NK cells, we found that the NK cell killing efficiency against PyMT tumor cells in vitro was significantly reduced by recombinant Dkk1.In sum, our data show that Dkk1 exerts local and systemic effects to promote tumor progression by modulating the killing efficiency of NK cells.

1003

PD-1 blockade disrupts bone microarchitecture and compromises bone strength in breast cancer bone metastasis *GWENYTH JOSEPH[1], Lawrence A. Vecchi III[2], David Kell[3], Sasidhar Uppuganti[2], Margaret Durdan[4], Wei Chen[2], David Harrison[2], Jeffry Nyman[2], Megan Weivoda[5], Rachelle Johnson[2]. [1], United States. [2]Vanderbilt University Medical Center, United States. [3]Vanderbilt University, United States. [4]University of Michigan, United States. [5]Mayo Clinic, United States

Immune checkpoint blockade (ICB) enables anti-tumor immunity by blocking immunoregulatory receptor-ligand interactions [e.g., programmed cell death protein 1 (PD-1) and its ligand (PD-L1)]. ICB has revolutionized cancer treatment but has lower efficacy in patients with bone metastases, and bone loss and increased fracture risk are reported in patients receiving treatment. To study mechanisms of ICB-induced bone loss, we inoculated 8-week-old WT female C57Bl/6 mice with E0771 mouse mammary carcinoma cells by intracardiac injection and treated with IgG or ?-PD-1 for 2 weeks (n=6-10), at which point the mice were euthanized due to paralysis. Tumor naïve mice were included to assess the baseline skeletal phenotype following 2 or 4 weeks of ?-PD-1 treatment (n=10). In tumor naïve mice, 2 weeks of ?-PD-1 treatment reduced BMD by DXA compared to IgG treatment (4%, p=0.04); after 4 weeks, BV/TV by ?CT was lower in ?-PD-1-treated mice compared to IgG controls (17%, p=0.04), consistent with reports of bone loss in patients receiving ICB therapy. We observed a similar reduction in BV/TV in young, adult, and aged PD-1 KO female mice compared to WT controls (n=5, 32-81%, p<0.01). We also assessed bone strength in tumor naïve mice by 3 point bending and saw no effect from ?-PD-1. As with tumor naïve mice, E0771-inoculated mice had reduced BMD (8%, p=0.04); in contrast, ultimate strength was lower in E0771-inoculated ?-PD-1 treated mice and 8-week-old PD-1 KO mice (n=7) compared to controls (12-16%, p<0.005). Thus, PD-1 blockade only weakens the bone if tumor cells are present. Importantly, flow cytometric analysis of the bone marrow revealed a similar number of tumor cells in ?-PD-1-treated mice compared to IgG controls, suggesting the impact of PD-1 blockade on bone strength is not due to changes in tumor burden. Serum CTX-1 was also elevated in E0771-inoculated PD-1 KO mice vs WT controls (1.8-fold, p=0.04), suggesting elevated bone resorption. CD8+ effector memory T cells, capable of promoting IFN?-mediated osteoclastogenesis in chronic inflammation, were also enriched in the bone marrow in tumor naïve and tumor bearing ?-PD-1 treated mice (1.4-1.8-fold, p<0.03), as was Ifng (5.8-8.2-fold, p<0.002). These data suggest that PD-1 blockade compromises bone microarchitecture by promoting infiltration of T cells that enhance bone resorption, and the presence of bone metastases reduces bone strength and increases fracture risk in the setting of immune checkpoint blockade.

Bimodal Bone-Targeted Therapy Repairs Damage Bone and Overcomes Drug Resistance in Multiple Myeloma *Hayley Sabol[1], Manish Adhikari[1], Cody Ashby[1], Aric Anloague[1], Japneet Kaur[1], Sharmin Khan[1], Michela Palmieri[1], Lawry Barnes[1], Elena Ambrogini[1], Venkatesan Srinivasan[2], Alison Frontier[2], Frank H. Ebetino[2], Jesus Delgado-Calle[1]. [1]University of Arkansas for Medical Sciences, United States. [2]University of Rochester, United States

Multiple myeloma (MM) remains incurable due to drug-resistant cells and disease relapse. Further, MM induces high bone resorption, increasing fracture risk, and osteoblast suppression, which impedes the restoration of damaged bone. Thus, drug resistance and bone repair remain major challenges in MM. Because Notch signals promote MM growth and bone destruction, and Wnt inhibition suppresses osteoblasts, we postulated that a bimodal therapy inhibiting Notch (bone-targeted ?-secretase (GS) inhibitor; BT-GSI) and activating Wnt signaling (anti-Sclerostin; Scl-Ab) should decrease tumor burden and repair bone. To test this idea, we injected OPM2 human MM cells, which have the high-risk t(4;14) translocation linked to poor prognosis/survival, in the tail vein of NSG mice. After 1wk, mice had tumor engraftment and decreased bone mass (20%). We then randomized mice to groups receiving BT-GSI (2.5mg/Kg, 3x/wk), Scl-Ab (100mg/Kg, 1x/wk), or a combination of both. After 3wks, all untreated mice bearing MM tumors died. Scl-Ab did not improve tumor burden or survival. In contrast, BT-GSI, alone or with Scl-Ab, decreased tumor burden by 75% and improved survival (9/11 alive). Untreated mice had a 40% decrease in bone mass, 53% CTX increase, and 40% P1NP reduction. BT-GSI reduced CTX by 58% but did not improve bone mass. However, Scl-Ab, alone or with BT-GSI, increased bone mass (70%) and restored P1NP to naïve controls. Remarkably, the bimodal therapy also reduced tumor growth (85%) and CTX (75%) and elevated P1NP (55%) in human bones bearing OPM2 cells cultured ex vivo. Because Notch signals also promote chemoresistance, we next assessed if the expression of genes of the Notch activator GS complex (PSEN1, PSENEN, APH1, or NCSTN) correlates with therapeutic responses in MM in patients using the CoMMpass database (n=750). Newly diagnosed MM patients with high vs. low expression of these genes had worse responses to Bortezomib (BOR)-based therapies. We then studied if inhibiting GS with BT-GSI improves responses to Bortezomib (BOR) in an ex vivo bone

organ culture established with BOR-resistant MM cells. BT-GSI reduced MM growth by 30% and doubled BOR's anti-MM efficacy (35% vs 70%, BOR alone vs BOR+BT-GSI, respectively). Our data demonstrates that a bimodal bone-targeted therapy based on Notch inhibition and Wnt activation is a safe and clinically relevant approach to control tumor growth, repair damaged bone, and improve therapeutic responses to chemotherapy in MM.

Targeting tumor innervating neurons via chemical and genetic approaches to improve osteosarcoma disease progression *Sowmya Ramesh[1], QIZHI QIN[3], Lingke Zhong[3], Ankit Uniyal[4], Masnsen Cherief[1], Mary Archer[1], Leslie Chang[3], Yun Guan[4], Edward F. McCarthy[5], Thomas Clemens[6], Aaron James[3]. [1]Department of Pathology, Johns Hopkins University, United States. [3]Johns Hopkins University, . [3]Johns Hopkins University, United States. [4]Department of Anesthesiology and Critical Care Medicine, Johns Hopkins University, United States. [5]Department of Orthopedics, Johns Hopkins University, United States. [6]University of Maryland, Baltimore, United States

Osteosarcoma (OS) is a bone malignancy affecting young adults. Bone pain is a common symptom in OS patients, however the importance of abnormal sensory innervation in OS progression remains unclear. Here, we perturbed nerve signaling using a combination of transgenic-mice and FDA-approved local analgesic to mitigate pain and OS growth. TrkAF592A mice carry a point mutation in Ntrk1 gene, resulting in inactive signaling upon small-molecule treatment. Human 143B OS cells (1x106) were injected into the tibia and assayed for OS growth for 4wks using caliper measurements. Innervation was assessed using pan-neuronal marker Beta III Tubulin (TUBB3) immunostaining and vascularity was assessed using Endomucin (EMCN). Molecular changes were studied using single cell-RNA sequencing (scRNA-seq) of the OS xenograft tissue. Bupivacaine liposomes (B-LNP) was used as a neurotoxic agent. Along with OS cells, Scid mice received tibial injection of 10mg/kg B-LNP while the sham received saline (PBS). Behavioral test of mechanical sensitivity was conducted using von Frey filament (0.4 g).TUBB3+ axons were found adjacent to human and mice OS implants and upon TrkA disruption nerve density reduced by 88%. Overall, OS size (51%), Ki67 proliferative index (80%), vasculature (47%), and incidence of lung metastasis were significantly reduced upon denervation. Consistent with these phenotypic changes, scRNA-seq of denervated OS tumors suggested a decrease in Notch signaling and reduced oxidative-phosphorylation. Ligand-receptor interactome between mouse dorsal root ganglia (DRG) neurons and OS-associated endothelial cells identified putative growth factors that may play a role in neural regulation of OS growth and angiogenesis. In a translational effort, intratumoral injection of B-LNP demonstrated a 60% decrease in OS size with concomitant decreases in Ki67 proliferative index (25%), TUBB3+ axons (16.4%) and EMCN+ vessels (31%). Besides, von Frey test showed a 30% decrease in paw-withdrawal rate in B-LNP-treated mice, suggesting an alleviation of mechanical pain hypersensitivity. TrkA-expressing primary sensory neurons promoted OS progression. Importantly, neural inhibition attenuated OS-associated pathological nerve sprouting, secondarily leading to reduced OS-associated vasculature, disease progression, metastasis and overall survival. The FDA-approved B-LNP may have a dual therapeutic use in patients with OS, both as a local analgesic and a negative regulator of OS growth.

Comparative Effectiveness of Denosumab versus Zoledronic Acid among Postmenopausal Women with Osteoporosis in the U.S. Medicare Program *Jeffrey Curtis[1], Tarun Arora[2], Ye Liu[3], Tzu-Chieh Lin[6], Leslie Spangler[6], Vanessa Brunetti[6], Robert Stad[6], MICHELE MCDERMOTT[7], Brian Bradbury[6], Min Kim[8]. [1]University of Alabama at Birmingham, United States. [2]Foundation for Advancing Science, Technology, Education and Research, United States. [3]Univesity of Alabama at Birmingham, United States. [6]Amgen Inc., United States. [6]Amgen Inc., United Kingdom. [6]Amgen Inc., Switzerland. [7]Amgen, United States. [8], United States

ObjectivesAlthough clinical trials have shown that denosumab (Dmab) significantly increases bone mineral density at key skeletal sites more than zoledronic acid (ZA), evidence from randomized trials evaluating fracture outcomes is lacking. This retrospective cohort study evaluated the comparative effectiveness of Dmab versus ZA in reducing fracture risk among women with postmenopausal osteoporosis (PMO) in the U.S.MethodsFemale Medicare fee-for-service beneficiaries >= 66 years of age who newly initiated Dmab (n=89,990) or ZA (n=36,861) between Jan 1, 2012 to Dec 31, 2018 with no prior history of osteoporosis treatment were followed from treatment initiation (index date) until the first instance of a given fracture outcome, treatment discontinuation (defined as the end of exposure according to usual dosing intervals + 60-day gap) or switch, Medicare disenrollment, death, end of available data (Dec 31, 2019), or 5 years post-index date. A doubly robust inverse-probability of treatment (weights estimated from multivariate logistic regression models) and censoring (weights estimated from multivariate Cox Proportional Hazards regression models) weighted function was used to estimate the relative risk (RR) associated with the use of Dmab compared with ZA for major osteoporotic (MOP; nonvertebral and hospitalized vertebral), hip, nonvertebral (NV; includes hip, humerus, pelvis, radius/ulna, other femur), non-hip, nonvertebral (NHNV), and hospitalized vertebral (HV) fractures for the overall study period and by year of follow-up.ResultsOver a maximum of 5 years of follow-up, Dmab reduced the risk of MOP by 26% (RR=0.74; 95% CI: 0.59-0.89), hip by 34% (0.66; 0.43-0.90), NV by 33% (0.67; 0.52-0.82), and NHNV by 31% (0.69; 0.50-0.88), and HV fractures by 10% (0.90; 0.56-1.24) compared with ZA (Figure). Over time, Dmab reduced the risk of MOP fractures by 9% (0.91; 0.83-0.99) at year 1, 12% (0.88; 0.80-0.96) at year 2, and 12% (0.88; 0.78-0.98) at year 3. An increase in the magnitude of fracture risk reduction with increasing duration of exposure was also observed for other NV outcomes. ConclusionIn a cohort of over 125,000 treatment-naive women with PMO, we observed robust, clinically meaningful reductions in the risk of MOP, hip, NV, and NHNV fractures for patients on Dmab compared to ZA, with greater reductions in fracture risk with longer duration of exposure.

Different effects of daily teriparatide and weekly high-dose teriparatide on cortical and trabecular BMD of vertebra and proximal femur: Sub-analysis by QCT from the TERABIT study *Ko Chiba[1], Ryosuke Takahashi[1], Makoto Osaki[1]. [1]Nagasaki University Graduate School of Biomedical Sciences, Japan

Purpose:The effects of daily teriparatide (D-PTH) (20 μg) or weekly high-dose teriparatide (W-PTH) (56.5 μg) on the vertebra and proximal femur were investigated in post-

menopausal women with osteoporosis using quantitative computed tomography (QCT). Methods:A total of 131 postmenopausal osteoporosis patients with a history of fragility fractures were randomized to receive D-PTH, W-PTH, or a bisphosphonate (BP) (oral alendronate or risedronate). The efficacy of these drugs was investigated by comparing bone turnover markers (BTMs), dual-energy X-ray absorptiometry (DXA), and QCT at baseline and after 18 months of treatment.Results:BTMs showed that, in the D-PTH group, P1NP increased (+52.9%), whereas TRACP-5b remained high; in the W-PTH group, P1NP was maintained at the baseline level, whereas TRACP-5b decreased (-26.7%); and in the BP group, both TRACP-5b (-54.1%) and P1NP (-69.8%) decreased.In terms of DXA, D-PTH, W-PTH, and BP all increased lumbar spine areal bone mineral density (aBMD) (median +11.1%, +7.9%, +6.7%, respectively) and total hip aBMD (+2.6%, +2.1%, +3.0%) after 18 months.QCT of the vertebral bodies (T12 and L1) showed that D-PTH, W-PTH, and BP increased total volumetric BMD (Tot.vBMD) (+34.8%, +18.2%, +11.1%), trabecular volumetric BMD (Tb.vBMD) (+50.8%, +20.8%, +12.2%), and cortical volumetric BMD (Ct.vBMD) (+20.0%, +14.0%, +11.5%). The increases in Tb.vBMD was greater in the D-PTH group than in the W-PTH and BP groups.QCT of the proximal femur showed that D-PTH, W-PTH, and BP all increased Tot.vBMD (+2.8%, +3.6%, +3.2%) and Tb.vBMD (+7.7%, +5.1%, +3.4%). Although there was no significant increase in Ct.vBMD in the D-PTH group (-0.1%, +1.5%, +1.6%), cortical bone volume increased in all three treatment groups (+2.1%, +3.6%, +3.1%). The increase in Ct.vBMD was greater in the W-PTH and BP groups than in the D-PTH group.Conclusions:D-PTH had a strong effect on trabecular bone of vertebra. Although D-PTH did not increase cortical BMD of proximal femur, it increased trabecular BMD and cortical bone volume. W-PTH had a moderate effect on trabecular bone of vertebra, while improving both cortical and trabecular BMD of proximal femur.

Assessment of Romosozumab Treatment on Spine Bone Strength Using Biomechanical Computed Tomography Virtual Stress Tests *Tony Keaveny[1], Mary Oates[2], Donald Betah[2], Yifei Shi[2], Jen Timoshanko[3], Corinna Zygourakis[4], Mohamad Bydon[5], Kelly Krohn[6], Koji Ishikawa[7]. [1]University of California, Berkeley, United States. [2]Amgen Inc., United States. [3], United Kingdom. [4]Stanford University School Medicine, United States. [5]Mayo Clinic, United States. [6]U of AZ College of Medicine Phoenix, United States. [7]Showa University School of Medicine, Japan

BackgroundOsteoporosis (OP) is characterized by decreased bone density and strength, which increase the risk of fractures. OP is common in older patients undergoing spinal fusion and is a significant risk factor for post-surgical complications. Romosozumab (Romo), a sclerostin inhibitor, has been shown to increase bone mineral density (BMD) and vertebral strength and reduce fracture risk. Using a novel Finite Element Analysis we studied the pedicle screw-bone connection in pullout test and physiological spinal loads with different OP treatments, including Romo.MethodsThis retrospective secondary analysis used lumbar spine computed tomography (CT) data from postmenopausal women with low BMD or OP in the imaging substudies of the Phase 2 (NCT00896532) and Phase 3 ARCH (NCT01631214) trials. For the Phase 2 study, treatment groups were: Romo 210 mg QM, placebo [Pbo], or teriparatide [Tptd] for 12 months. In ARCH, treatment groups were: Romo or alendronate [Aln] for 12 months, then Aln for all for a second 12 months. For each patient, CT scans at baseline (BL) and follow-up (6, 12, and/or 24 months), were used to create a finite element model at each timepoint for the patient's L1 vertebra, virtually implanted with a pedicle screw, in a "shear pullout" configuration. Percent changes from BL in shear bone strength (N), volume of failed tissue (cm3) associated with shear bone loading related to weak bone, and periprosthetic BMD (mg/cm3) were compared by analysis of covariance models adjusting for baseline covariates.ResultsData were analyzed for 79 patients from each study (Phase 2: Romo, 24; Pbo, 27; Tptd, 28; ARCH: Romo/Aln, 44; Aln/Aln, 35). BL characteristics were similar across treatment groups within each study. In the Phase 2 study, at M12 compared to BL, Romo significantly increased shear bone strength, decreased volume of failed tissue, and increased periprosthetic BMD, compared to both Pbo and Tptd (Table 1A). In ARCH, at M6 and M12 compared to BL, Romo significantly increased shear bone strength, decreased volume of failed tissue, and increased periprosthetic BMD compared to Aln, and these changes were maintained at M24 after switching from Romo to Aln (Table 1B).ConclusionFor both studies, compared to its respective comparators, Romo significantly increased shear bone strength by finite element analysis and periprosthetic BMD and lowered the amount of failed tissue. These data demonstrate Romo's efficacy vs Tptd or Aln for improving lumbar spine bone density and strength associated with pedicle screw fixation.

Can We Treat Osteoporosis, Obesity And Neurodegeneration With A Single FSH-blocking Drug? *Judit Gimenez Roig[1], Anusha Rani Pallapati[1], Satish Rojekar[1], Funda Korkmaz[1], Damini Sant[2], Orly Barak[1], Farhath Sultana[1], Ofer Moldavski[1], Anisa Azatovna Gumerova[1], Hasni Kannangara[1], Uliana Cheliadinova[1], Clifford J. Rosen[3], John N. Caminis[4], Marcia Meseck[1], Victoria Elise DeMambro[3], Darya Vasilyeva[1], Steven Sims[1], Sakshi Gera[1], Ronit Witztum[1], Sari Miyashita[1], Vitaly Ryu[1], Mansi Saxena[1], Tal Frolinger[1], Anne Macdonald[1], Se-Min Kim[1], Georgii Pevnev[1], Daria Lizneva[1], Tony Yuen[1], Mone Zaidi[1]. [1]Icahn School of Medicine at Mount Sinai, United States, [2]Max Planck Institute for Biology of Ageing, Germany, [3]Maine Medical Center Research Institute, United States, [4]Shire, United States

Pharmacological and genetic studies suggest that FSH is an actionable target for diseases affecting millions, notably osteoporosis, obesity and Alzheimer's disease (AD). Blocking FSH action prevents bone loss (1, 2), fat accrual (3) and AD-like features in mice (4). We recently developed a first-in-class, humanized, epitope-specific FSH blocking antibody that binds to a 13-amino-acid-long sequence of FSH?-MS-Hu6-with a KD of 7.52 nM (5). We showed that MS-Hu6 binds specifically to FSH?, without binding to LH and TSH. For efficacy studies, we have blocked FSH action using either MS-Hu6 or the parent murine antibody, Hf2, targeted to the same epitope. Using our Good Laboratory Practice platform (Code of Federal Regulations, Title 21, Part 58), we report that FSH blockade prevents obesity, osteoporosis and AD in mice. We injected 20-week-old C57BL/6 male mice on a high-fat diet with a range of doses of Hf2 or vehicle s.c. five-days-a-week for 8 weeks. Hf2 (100 µg/mouse/day) reduced the increase in fat mass by 33% starting week 3, with a 7% reduction in body weight. In separate studies, MS-Hu6 not only caused beiging of white adipose tissue in UCP1-reporter ThermoMice (IVIS imaging), but also improved bone density and microstructure (micro-CT) by elevating bone formation (dynamic histomorphometry). The increase in bone mass and improved microstructure were replicated in Cliff Rosen's lab using C57BL6 mice 24 weeks post-ovariectomy. Novel Object Recognition testing of AD-prone, ovariectomized 3xTg mice showed a deficit in recognition memory, which was reversed after 8 weeks of Hf2 (100 µg/mouse/day for 5-days-a-week) exposure. Biodistribution studies using 89Zr-labelled, biotinylated or unconjugated MS-Hu6 in mice and monkeys showed localization to bone, bone marrow, fat depots and brain tissue. MS-Hu6 displayed a ? phase t½ of 7.8 days in humanized Tg32 mice. In monkeys, an acute single injection of MS-Hu6 did not affect vitals, and biochemical parameters remained within the normative range. We tested 215 variations of excipients using a range of physicochemical techniques, including protein thermal shift, size exclusion chromatography, dynamic light scattering, Fourier-transform infrared spectroscopy, circular dichroism spectroscopy, and differential scanning calorimetry, to yield a formulation with thermal, colloidal, monomeric and structural stability at an ultra-high concentration (100 mg/mL) with acceptable viscosity, clarity and turbidity parameters. MS-Hu6 showed the same "humanness" as human IgG1 in silico and was non-immunogenic in ELISPOT assays for IL-2 and IFN? in human PBMC cultures. In conclusion, MS-Hu6 is efficacious, durable and manufacturable, and is therefore poised for human testing as a multipurpose therapeutic for obesity, osteoporosis, and perhaps for AD. 1Cell, 2006; 2PNAS, 2018,; 3Nature, 2017; 4Nature, 2022; 5. Bisphosphonates Maintain BMD after Sequential Teriparatide and Denosumab in Premenopausal Women with Idiopathic Osteoporosis (PremenIOP) *Mafo Kamanda-Kosseh[1], Stephanie Shiau[2], Sanchita Agarwal[1], Ananya Kondapalli[1], Ivelisse Colon[1], Nayoung Kil[1], Mariana Bucovsky[1], Robert Recker[3], Joan Lappe[3], Julie Stubby[3], Elizabeth Shane[4], Adi Cohen[5]. [1]Columbia University Irving Medical Center, United States, [2]Rutgers University School of Public Health, United States, [3]Creighton University, United States, [4]Columbia University College of Physicians and Surgeons, , [5]Columbia University Medical Center, United States

We previously reported that teriparatide (TPTD) for 2 yrs followed by denosumab (Dmab) for 2-3 yrs leads to substantial increases in spine (LS) and hip BMD in PremenIOP. After completing sequential TPTD-Dmab, 24 PremenIOP (aged 43+/-8 yrs) enrolled in an open label Bisphosphonate Extension Study in which either (patient-centered choice) alendronate (ALN) 70mg po weekly or zoledronic acid (ZOL) 5mg IV was initiated 7M after the last Dmab dose. All were severely affected with low trauma adult fractures (range 0-12; 9 with vertebral fractures) and/or very low BMD. BMD by DXA and serum C-telopeptide (CTX) were measured every 6M; vertebral fracture assessment (VFA) was performed annually.On sequential TPTD-Dmab, the participants had large increases in BMD: 25+/-9% at LS, 11+/-6% at the total hip (TH), and 14+/-7% at the femoral neck (FN). Pretreatment baseline LS BMD Z score was -2.0+/-0.9, increasing to -0.1+/-1.0 after completing TPTD-Dmab. Mean CTX was 342+/-166 pg/mL at baseline and 173+/-203 pg/mL at end of Dmab.During the Bisphosphonate Extension Study, mean BMD and CTX changes in the entire group were small and not statistically significant at 6 or 12M (Figure). The 6 women who selected ZOL and the 18 who chose ALN did not differ at baseline by age, BMI, fractures, BMD, calciotropic hormones or CTX. In the ZOL group, there were small declines in BMD and increases in CTX, particularly between 6M and 12M, while greater stability was observed in the ALN group. The ZOL group had significantly greater increases in CTX and decreases in TH BMD than the ALN group (Fig B & D).Changes in BMD and CTX did not differ by duration of Dmab (36M vs <36M) and did not differ between 20 women who remained premenopausal and 4 who transitioned into menopause. Pre-TPTD CTX, likely reflecting baseline remodeling status, was inversely related to 12M BMD %change on bisphosphonate at the LS (r=-0.6; p=0.005) and FN (r=-0.5; p=0.04). No new vertebral (clinical or VFA-based) or non-vertebral fractures occurred.In summary, the large increases in BMD achieved after sequential TPTD-Dmab therapy in PremenIOP were maintained during a bisphosphonate transition year. Our data also suggest that weekly ALN may provide greater suppression of CTX and more stable BMD than ZOL, particularly at the hip and between 6 and 12M. Higher baseline CTX predicted more bone loss after Dmab cessation. We conclude that bisphosphonate therapy prevents significant bone loss after sequential TPTD-Dmab in PremenIOP.

Figure: Change in BMD and CTX on 12M of Bisphosphonate after Denosumab Withdrawal

Phlpp2 Limits the Protective Effects of Estrogen on Cortical Bone *ISMAEL KARKACHE[3], Elizabeth Vu[2], David Molstad[3], Kim Mansky[3], Elizabeth Bradley[4]. [3]University of Minnesota, , [2]University of Minnesota Twin Cities, United States, [3]University of Minnesota, United States, [4]University of Minnesota , United States

Pleckstrin Homology Domain and Leucine Rich Repeat Protein Phosphatases (Phlpp) are metal-dependent protein phosphatases solely comprised of isozymes Phlpp1/2 that dampen anabolic kinase activity. In women, age and estrogen status modulate Phlpp1 levels. Prior research demonstrated that osteoclast-directed deletion of Phlpp1 enhanced trabecular bone in females, but that Phlpp1 ablation did not protect against ovariectomy (Ovx) induced bone loss. Estradiol (E2) reduces osteoclast number by decreasing osteoclast progenitor (OCP) cellular respiration and enhancing apoptosis. These data suggest that Phlpp isoforms facilitate E2 actions on the skeleton, but the role of Phlpp2 is not known. We generated Phlpp2 deficient mice via conditional deletion in LysM-Cre expressing cells (Phlpp2 cKO). We first confirmed deletion of Phlpp2 within osteoclasts in vivo via IHC and within in vitro generated osteoclasts. In contrast to Phlpp1, 12-week-old Phlpp2 cKO female mice exhibited an 11% greater femoral midshaft cortical thickness than controls as revealed by micro-CT, but no changes in trabecular bone (n=8-10/group). Importantly, no differences were observed of Phlpp2 ablated males. We next performed Ovx or sham surgeries on 12-week-old female Phlpp2 ablated mice and their control littermates (n=7 per group). We confirmed enhanced endosteal midshaft femoral cortical thickness of Sham Phlpp2 cKO females. Ovariectomy reduced cortical thickness of littermate controls by 10% and Phlpp2 deficiency did not protect against this loss (Fig.1A). To discern the mechanisms for these effects, we next surveyed expression of estrogen receptor gene expression, Esr1/2, within Phlpp1/2 ablated osteoclasts. qPCR analysis revealed that Phlpp2 ablation enhanced Esr1 expression, whereas Esr2 expression increased with Phlpp1 deletion (Fig. 1B). These data mirror the compartment-specific localization of Esr2/1 and the effects of Phlpp1/2 ablation to trabecular and cortical bone, respectively. We further show that Phlpp2 ablation increases OCP responses to E2 via enhanced TUNEL-positive OCPs (Fig 1C, D), leading to decreased osteoclast numbers. Our data asserts that an intact estrogen status facilitates the effects of Phlpp2 to maintain cortical bone and that Phlpp2 ablated OCPs have increased sensitivity to estradiol, driving apoptosis. Overall, our findings demonstrate that Phlpp1/2 distinctly orchestrate maintenance of trabecular and cortical bone in an estrogen dependent-fashion.

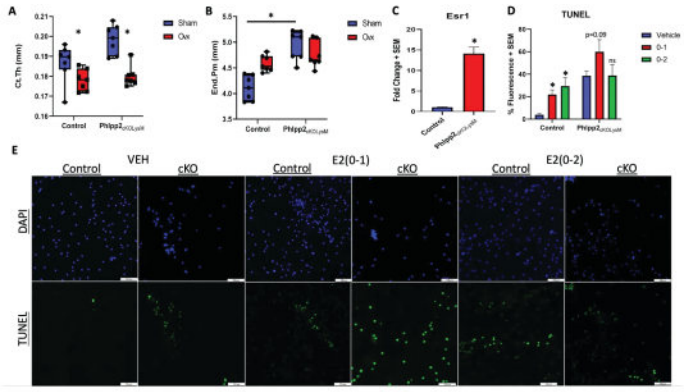

Figure 1: Enhanced Estrogen Sensitivity in Phlpp2 Ablated Osteoclast Progenitors Following, Despite Ovariectomy. Asterisks indicate statistical significance (*p <0.05). A-B) Female Phlpp2 cKO_{LysM} mice and their control littermates (n=7) were aged to 12-weeks at which ovariectomy or sham surgeries were performed. Micro-CT was performed at 8 weeks post-surgery and mid-shaft cortical thickness and endosteal/periosteal perimeter was measured. C-E) BMMs were harvested from 6-8-week-old female Phlpp2 cKO_{LysM} mice and their control littermates and cultured in osteoclastogenic conditions (50ng/ml MCSF, 90ng/ml RANKL) for three days. C) RNA was isolated from day 3 pre-osteoclast cultures and qPCR was performed to assess differential expression of Esr1. D-E) Cultures were treated with E2 in a time window from days 0-1, 0-2, or in vehicle for days 0-2. On day 3, cultures were fixed and TUNEL/DAPI stained. Images taken under a fluorescent microscope (10x) were merged and percentage TUNEL-positive/DAPI-positive cells were quantified. Scale bar is 100 microns.

GIRK3 deletion increases bone mass but does not prevent ovariectomy-induced bone loss *SAMANTHA WEAVER[2,] Jennifer Westendorf[2,] [2]Mayo Clinic, United States[,] [2]Mayo Clinic,

GIRK3 is one of four subunits of GIRK channels. GIRK channels are activated when GPCR ligands stimulate pertussis toxin-sensitive Gi/o-G proteins and the liberated G?? subunit binds to GIRK channels and increases gating, resulting in K+ efflux. Deletion of Girk3 increased femoral bone mineral density (BMD), bone volume fraction, and trabecular number in six-month-old male and female mice. In female mice, cortical bone thickness and tissue mineral density were also increased. Three-point bend tests of the femurs of female Girk3-/- mice revealed increased energy to failure and maximum load. No changes in cortical microarchitecture or strength were detected in males. Static histomorphometry revealed moderately reduced osteoclast activity (osteoclast surface / bone surface), mineral apposition rate, and bone formation rate in Girk3-/- mice, suggesting that osteoblast and osteoclast activity was coupled, but suppressed. Calvarial osteoblasts from Girk3-/- mice differentiated faster in vitro and expressed reduced levels of Wnt pathway inhibitors Sost and Sfrp4, and increased expression of pro-osteogenic Sfrp3 on day 14 of culture. Dkk1 prevented increased mineralization in Girk3-/- osteoblasts. These data demonstrate that Girk3 deletion increases in vitro mineralization in part through a WNT-dependent mechanism. To determine whether Girk3 deletion in osteoblasts was sufficient to recapitulate the high bone mass phenotype in Girk3-/- mice, we generated mice with a deletion of Girk3 in osteoblasts using the 2.3kb-Col1a1 promoter (Girk3-CKO). Male Girk3-CKO had increased trabecular and cortical bone mass, as well as increased energy to failure and maximum load, compared to Cre- controls. There was no phenotype in females. These data suggest that deletion of Girk3 in osteoblasts is sufficient to induce high bone mass in a sexually dimorphic manner. Finally, ovariectomy (OVX) was performed to determine if Girk3 deletion was sufficient to prevent bone loss caused by sex hormone withdrawal. Both sham-operated and OVX Girk3-/- mice had increased bone mass compared to WT mice at 24-weeks-old. WT-OVX mice had 16% lower BMD than WT-SHAM mice, while Girk3-/--OVX mice had 13% lower BMD than Girk3-/--SHAM mice. Girk3 deletion was therefore unable to completely prevent OVX-induced bone loss. Taken together, these data indicate that Girk3 deletion increases bone mass in adult mice through an osteoblastic, partially WNT-dependent mechanism.

Hdac1 and Hdac2 positively regulate N1ICD pathogenic signaling in committed osteoblasts *Haydee Torres[1,] Leetoria Hinojosa[2,] Ashley VanCleave[2,] Tania Rodezno[2,] Danielle May[3,] Kyle Roux[3,] Jennifer J. Westendorf[4,] Jianning Tao[5,] [1]Cancer Biology & Immunotherapies Group at Sanford Research; Department of Chemistry and Biochemistry, South Dakota State University; Department of Orthopedic Surgery, Mayo Clinic , United States[,] [2]Cancer Biology & Immunotherapies Group at Sanford Research, United States[,] [3]The Biochemistry Core at Sanford Research, United States[,] [4]Department of Orthopedic Surgery, Mayo Clinic; Department of Biochemistry & Molecular Biology, Mayo Clinic, United States[,] [5]Cancer Biology & Immunotherapies Group at Sanford Research; Department of Chemistry and Biochemistry, South Dakota State University; Department of Biomedical Engineering, University of South Dakota , United States

Notch receptors belong to a core evolutionarily conserved short-range cell communication signaling pathway that determine cell fate in developmental processes. Regulated successive intramembranous proteolytic-cleavages of the Notch receptor leads to nuclear translocation of the Notch intracellular domain (NICD), where it forms a Notch transcription complex with DNA-binding factors and co-regulators to induce target genes. We utilized a proximity-dependent biotin identification (BioID) method that revealed core Notch circuitry and identified N1ICD associating with chromatin co-regulators, including the NuRD complex (the nucleosome remodeling and deacetylase), SWI/SNF complex (SWItch/Sucrose Non-Fermentable), methyltransferases, and SUMO proteins (Small Ubiquitin-like Modifiers). Our protein-protein interaction network analysis predicted Histone deacetylase 1 (HDAC1) to be the top critical node in an activated Notch state. While an HDAC1-NICD interaction has been studied in vitro and in Drosophila melanogaster wing development, its role in vertebrate skeletal development and homeostasis is unclear. Here, we tested our hypothesis that HDAC1 plays a critical role in the pathogenesis of N1ICD-induced osteosclerosis. Conditional knockout of Hdac1 and Hdac2 in osteoblasts expressing N1ICD mutations had sexually dysmorphic effects on osteosclerosis. Male N1ICD mutant mice with homozygous deletions of Hdac1/2 (Col2.3kb-Cre;TGRosaN1ICD/+;Hdac1f/f;Hdac2f/f) had a 40% decrease in BV/TV and a 22% decrease in trabecular thickness at 4 weeks old when compared to mice with heterozygous deletions of Hdac1/2 (Col2.3kb-Cre;TGRosaN-1ICD/+;Hdac1f/+;Hdac2f/+). Female N1ICD mutant mice with a homozygous deletions of Hdac1/2 exhibited a 38% decrease in BV/TV, 15% decrease in trabecular thickness, and a 25% decrease in trabecular number when compared to mice with heterozygous deletions of Hdac1 (Col2.3kb-Cre;TGRosaN1ICD/+;Hdac1f/+;Hdac2f/f), implicating that HDAC1 deficiency mitigates N1ICD-induced osteosclerosis. Moreover, we found that mice with only deletion of Hdac1/2 and normal NICD (Col2.3kb-Cre;Hdac1f/f;Hdac2f/f) did not exhibit significant changes in skeletal microarchitecture at 4 weeks old. Ongoing studies of transcriptome changes in these mutant bones of mice may provide the molecular basis for these phenotypes. Thus, our studies may provide an insight how HDAC1 may positively regulate N1ICD pathogenic signaling in vivo.

Cellular and molecular mechanisms underlying regulation of bone homeostasis by the zinc receptor GPR39 *Noam Levaot[1,] Biplab Chaterjee[1,] Gal Gozlan[1,] Chen Abramovitch-Dahan[1,] Katharina Jähn-Rickert[2,] Björn Busse[2,] [1]Department of Physiology and Cell Biology, Ben-Gurion University of the Negev, Israel[,] [2]Department of Osteology and Biomechanics, University Medical Center Hamburg- Eppendorf, Hamburg, Germany., Germany

Zinc is a trace element that is crucial for cellular function and is regulated by various transporters and metallothioneins. G Coupled protein receptor 39 (GPR39) is a specialized zinc receptor which signals through Gq and Gs pathways. We previously showed that GPR39 is important for bone homeostasis and bone collagen content in male mice. In this study, we investigated the role of GPR39 in regulating bone homeostasis in females and found that GPR39 deficiency has a more severe impact on bone health in females than males. Structural and histological analyses revealed lower bone mass and abnormal mineralization in GPR39-deficient mice, with abnormal osteoclast distribution contributing to the reduction in bone volume in females. GPR39-deficient females also exhibited higher osteoporotic bone loss compared to normal female mice when challenged with ovariectomy. We also investigated the cellular basis for the impact of GPR39 deficiency on the skeleton using mice with a conditional deletion in the osteoblast lineage. Our results showed that osteoblast-specific deletion of GPR39 recapitulates the bone phenotype of mice with the germline deletion, indicating that the impact of GPR39 deficiency on the skeleton likely derives from its activity in the osteoblast lineage.Finally, we demonstrated that zinc signaling through GPR39 regulates the expression of collagen alpha 2 chain, providing a possible explanation for the abnormal collagen levels observed after GPR39 deletion in vivo and in vitro. Additionally, we found that GPR39 activity is essential for the regulation of collagen expression by TGF?, a central factor known to regulate collagen expression in normal and clinical conditions.In conclusion, this study provides insights into the cellular and molecular

mechanisms involved in sex-specific bone health and highlights the potential of GPR39 as a therapeutic target for bone-related disorders.

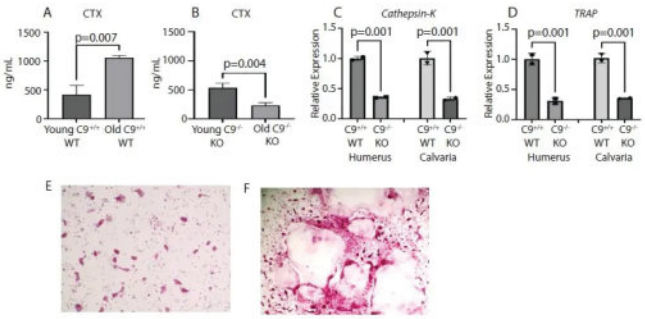
A Novel Role of TRAPPC9 in Bone Remodeling and Osteoclast Differentiation
*Gabrielle Robinson[2], Alexander Powell[2], Hope Ball[2], Fayez Safadi[2]. [2]Northeast Ohio Medical University, United States. [2]Northeast Ohio Medical University,

Intellectual disability (ID) affects about 4.92 million Americans, which accounts for approximately 17% of the American population. Skeletal abnormalities have been described in patients with ID. X-linked forms of ID have been investigated, while the autosomal-recessive forms of ID have yet to be studied. Specifically Non-syndromic autosomal-recessive intellectual disability (NSARID) develops as a result of mutations in the trafficking protein particle complex subunit 9 (TRAPPC9) gene. Patients possessing this mutation exhibit obesity, develop microcephaly, and skeletal abnormalities inclusive of an increase in bone mass, resulting in a denser cranium, limb deformities, and the loss of teeth. The direct linkage by which TRAPPC9 mutations contribute to skeletogenic homeostasis has yet to be characterized and explained. To definitively understand the impact of TRAPPC9 on skeletogenesis, we investigated the physiological role of TRAPPC9 in bone homeostasis. We characterized the skeletal phenotype of TRAPPC9 global knockout (KO) mice. When analyzing the bone weight across both the TRAPPC9 WT and KO mice, at ages 8 weeks and 8 months. At 8 weeks of age, TRAPPC9 KO mice showed no significant differences from the WT mice, while at 8 months the KO mice had an increased body weight by 1.3-fold when compared to WT animals. We then performed dual X-ray absorptiometry (DEXA) to analyze the bone mineral density (BMD). DEXA analysis showed TRAPPC9 KOs increased in BMD as they aged, while WT's BMD decreased with age. Suggesting that TRAPPC9 deficiency protects against age-related bone loss. Next, we analyzed the serum biomarker of CTX and found that the TRAPPC9 KOs exhibited significantly lower serum CTX levels at 8 months compared to 8 weeks of age. As expected, TRAPPC9 WT's exhibited increased serum levels of CTX at 8 months than at 8 weeks. qPCR analysis performed on calvaria, and humeri of 8-week-old mice showed that the TRAPPC9 KO mice exhibited lower expression levels of osteoclast markers (Cathepsin-K, TRAP). Taken together, these data show that TRAPPC9 deficiency contributes to skeletogenic homeostasis via the dysregulation of osteoclast differentiation and function, resulting in increased bone mass. These findings correlate with findings observed in TRAPPC9 mutation in patients. The data generated in this study is the first to characterize the skeletal phenotype of this TRAPPC9 null mice, aiding in the development of therapeutic approaches for NSARID.



A. The CTX Serum levels in young and old TRAPPC9 WT mice, the old WT mice had increased serum levels of CTX. **B. The CTX Serum levels** in young and old TRAPPC9 KO mice, the young WT mice had increased serum levels of CTX. **C. Cathepsin-K** mRNA expression levels in the calvaria and humeri were decreased in TRAPPC9 KO mice compared to TRAPPC9 WT. **D. TRAP** mRNA expression levels in the calvaria and humeri were decreased in TRAPPC9 KO mice than the TRAPPC9 WT. **E &F.** Osteoclast differentiation derived from the TRAPPC9 WT **(E)** and TRAPPC9 KO mice **(F)**, stained for TRAP and imaged at 10x magnification. TRAPPC9 Kos have increased osteoclast differentiation compared to WT mice.

The HIF-1?/PLOD2 axis regulates collagen cross-linking and mesenchymal progenitor cell fate responsible for traumatic heterotopic ossification
*Heeseog Kang[1], Amy L. Strong[2], Yuxiao Sun[1], Alec C. Bancroft[1], Ji Hye Choi[1], Conan Juan[1], Lei Guo[3], Juhoon Lee[4], Robert N Kent III[5], David Hudson[6], Brendon M. Baker[5], Kevin Dalby[4], Lin Xu[3], Benjamin Levi[1]. [1]Center for Organogenesis and Trauma, Department of Surgery, University of Texas Southwestern, United States. [2]Section of Plastic Surgery, Department of Surgery, University of Michigan, United States. [3]Quantitative Biomedical Research Center, Department of Population and Data Sciences, University of Texas Southwestern, United States. [6]Department of Orthopaedics and Sports Medicine, University of Washington, United States

Heterotopic ossification (HO) is a debilitating condition, where ectopic bone formation occurs within extra-skeletal soft tissues. The inflammatory response to tissue damage activates hypoxic signaling that modulates cell proliferation, survival, metabolism, and aberrant differentiation leading to HO and progression. Previously, we reported that activation of hypoxia-inducible factor 1? (HIF-1?) promoted ectopic bone formation in traumatic HO, however, the underlying mechanisms by which hypoxia and the HIF-1? pathway contribute to the aberrant bone formation have yet to be elucidated. Using a well-established burn/tenotomy (BT) HO mouse model, we performed scRNA-seq, immunofluorescent histology, and primary cultures of HO-forming mesenchymal progenitor cells (MPCs) to better define the role of HIF-1? in traumatic HO. Zeugopod-specific mesenchymal cell deletion of Hif1a (Hoxa11-CreERT2;Hif1afl/fl) significantly mitigated HO volume in the BT injury mouse model. ScRNA-seq analysis revealed that Hoxa11(+) lineage specific KO of Hif1a significantly decreased expression of genes associated with glycolysis and collagen cross-linking associated enzymes, many of which were upregulated during HO formation. Consistently, in vitro studies using cultured MPCs isolated from the HO site of Hoxa11-CreERT2;Hif1afl/fl mice demonstrated decreased lactate production and down-regulated expression of collagen cross-linking associated enzymes, including lysyl oxidases (LOX) and procollagen-lysine,2-oxoglutarate 5-dioxygenase 2 (PLOD2). Immunofluorescent staining and second harmonic generation imaging of Hoxa11-CreERT2;Hif1afl/fl demonstrated decreased expression of the collagen cross-linking associated enzymes and impaired collagen cross-linking at the injury site. Treatment of mice post-BT with ?-aminopropionitrile (BAPN), a LOX inhibitor, dramatically and significantly diminished HO volume even with a brief treatment period. Furthermore, in vitro studies using MPCs treated with newly screened PLOD2 inhibitor compounds revealed that inhibition of PLOD2 activity significantly decreased collagen cross-linking, alignment of collagen fibers, MPCs migration and osteogenic differentiation, supporting the central role of the HIF-1?/PLOD2 axis in MPCs metabolic reprogramming, collagen cross-linking, and MPC fate. These results suggest targeting the molecular components in the HIF-1?/PLOD2 pathway to be a promising therapeutic strategy to mitigate HO formation and progression.

Loss of TFAM in PRX1 lineage cells causes an Osteogenesis Imperfecta-like phenotype and increased HIF1a activity prevents it
*Mohd Parvez Khan[1], Giulia Lanzolla[1], Elena Sabini[1], Brittany M Laslow[1], Dian Wang[1], Fanxin Long[2], Ernestina Schipani[1]. [1]University of Pennsylvania, United States. [2]CHOP, Philadelphia, Pennsylvania, United States

Once thought to be a consequence of the state of the cell, glycolytic metabolism is now known to control cell differentiation. Both glycolysis and oxidative phosphorylation (OXPhos) are required for osteoblastogenesis. To gain insights into the role of OXPhos in bone mass accrual, we generated a mutant mouse lacking Mitochondrial Transcription Factor A (TFAM) in mesenchymal progenitors of the limb bud and their descendants by using the PRX1-Cre driver (TFAM mice). TFAM regulates transcription of the mitochondrial genes that encode thirteen subunits of the electron transport chain and thus controls OXPhos. TFAM mice display a significant shortening of the long bones, which is already detectable at birth, worsens postnatally, and is associated with growth plate abnormalities and deformities. More importantly, spontaneous mid-shaft fractures are present in mutant long bones by three weeks of age. MicroCT and histomorphometry analysis showed a severe thinning of cortical bone in mutants compared to controls. This was secondary to a dramatic impairment of osteoid accumulation and bone formation rates in the diaphyseal periosteum. Osteoclast number was also significantly increased at that site, implying that augmented resorption may contribute to the phenotype. The long bone phenotype of TFAM mutants, namely shortening, increased fragility, and spontaneous fractures, is reminiscent of Osteogenesis Imperfecta (OI). Single-cell RNA sequencing of periosteal cells revealed that the pool of osteoblastic cells was reduced in mutants, whereas the number of mesenchymal progenitors identified by concomitant expression of markers such as Sca1, PRX1, PDGFRa, and CD90 was increased. Moreover, expression of genes encoding collagens, enzymes involved in posttranslational modifications of collagens, and endoplasmic reticulum chaperons, including serpinH, was downregulated in mutant osteoblastic cells. Levels of osteocalcin mRNA were also significantly lower in the same cells. Conversely, mRNAs encoding downstream targets of TgFbeta signaling such as p21 and serpine1, were upregulated. To establish wheth-

er this phenotype could be corrected by augmenting glycolysis, we bred TFAM mice with mice expressing a mutant Hypoxia Inducible Factor 1alpha (HIF1a), which is constitutively active independently of oxygen levels (HIF1dPA) in PRX1 lineage cells (TFAM/HIF1dPA mice). TFAM/HIF1dPA mice did not develop spontaneous fractures; moreover, thickness of cortical bone and the ability of periosteal cells to accumulate osteoid were fully restored in double mutant mice. HIF1a promotes glycolysis and posttranslational modifications of collagens; we are now investigating whether both events contribute to "rescuing" the bone phenotype of TFAM mice. In conclusion, loss of TFAM in PRX1 lineage cells causes an OI-like phenotype that is prevented by increased HIF1a activity in the same cells.

Glucocorticoid-induced Reduction in Osteogenesis and Angiogenesis is Coupled through Altered Skeletal Stem Cell Lineage Dynamics *Thomas Ambrosi[1], Yuting Wang[2], Matthew Murphy[2], Charles Chan[2], Nancy Lane[3]. [1]UC Davis, United States, [2]Stanford University, United States, [3]University of California, Davis Medical Center, United States

Glucocorticoids (GCs) are potent anti-inflammatory compounds, however, continued exposure results in bone loss and osteonecrosis. Skeletal stem cells (SSCs) are crucial for osteogenesis; it is tempting to speculate that GCs might affect their function. Detrimental changes to angiogenesis have been implicated in GC-induced bone loss. The mechanism by which GCs alter vascularity remains unknown. Our study aimed to evaluate GC-effects on both osteogenesis and angiogenesis, as well as if treatment with PTH modifies the effects in a mouse model of GC bone loss. BALB/cj male mice, age 9wks were randomized to placebo (PLB) for 28 or 56 days (d) or GC (MP pellets of 2.5mg) for 28d, then recovery (29-56d) or 56d, or GC for 28d followed by hPTH (29-56d). Outcome measures included bone mass, histology, flow cytometry for SSCs and multipotent progenitors (BCSPs), vascular progenitors (CD31, Tie2), in vitro SSC cultures for osteogenesis, chondrogenesis, and single cell RNA sequencing (scRNAseq). Flow cytometry-purified SSCs were lentivirally barcoded and transplanted into the renal capsule for 28d during GC and hPTH treatments to investigate clonal lineage dynamics and signaling using scRNAseq. GC exposure led to trabecular, but not cortical, bone loss and reduced mechanical strength in 28- and 56d exposure regimens. Similarly, we observed reduced surface-based bone formation rate and increased osteoclast activity by TRAP staining and BM cultures. SSCs and BCSPs of GC mice were reduced in frequency and showed impaired osteogenic and chondrogenic differentiation capacity in vitro compared to controls. In contrast, CD31+ endothelial cells were increased but displayed distorted phenotypical features in immunohistological staining. Interestingly, removal of GC pellets after 28d did not improve any of these parameters with or without PTH treatment. However, GCs + hPTH treatment reversed all GC-induced changes back to control levels. Bone tissue scRNAseq confirmed these findings, as GC reduced osteochondrogenic and increased CAR and Smooth muscle cells. This was accompanied by increased pro-endothelial and pro-inflammatory signaling. Altered clonal SSC differentiation dynamics in vivo perpetuated the reduction in bone formation driving altered endothelial morphogenesis that could only be reversed by PTH treatment with concurrent GC exposure. These findings help to explain the cellular basis of how PTH treatment can mitigate GC induced bone loss and possibly osteonecrosis.

CAR/LepR+ Cells Express BMP Inhibitors Negatively Regulating Bone Formation in Vivo *Wei Zou[1], Nidhi Rohatgi[1], Aersilan Alimasi[1], Steven Teitelbaum[1]. [1]Washington University in St. Louis School of Medicine, United States

C-X-C motif chemokine 12 (CXCL12)-abundant reticular (CAR) cells, which are LepR+, are marrow residing stromal cells believed to be osteoblast progenitors. The mechanism by which CAR/LepR+ cells differentiate into osteoblast is not well known. Our lab has generated an inducible fat deletion mouse model by mating mice expressing an inducible DTR to those bearing adiponectin (ADQ)-Cre. Within 4 days of DTR activation, the systemic bone mass of DTRADQ mice begins to increase due to stimulated osteogenesis, with a 1,000% enhancement by 10-14 days. This adipocyte ablation-mediated enhancement of skeletal mass reflects bone morphogenetic protein (BMP) receptor activation following the elimination of its inhibitors, Gremlin1 and Chrdl1 by depletion of marrow residing adiponectin-expressing cells. In our recent work, we found virtually all CAR/LepR+ cells are derived from adiponectin positive lineage cells and DTR activation completely depletes marrow of CAR cells. By sorting CAR cells from Cxcl12-GFP reporter mice, we found they are the principal source of the BMP inhibitors. To further explore the effect of CAR/LepR+ cells on bone, we mated floxed DTR mice with LepR Cre (DTRLepR). Depletion of CAR/LepR+ cells by DTR activation decreases BMPR inhibitors expression in marrow, and induces 5-6 fold increase of bone mass in diaphysis of DTRLepR mice in 10 days compared with WT control, while marrow adipose cells were not significantly affected in DTRLepR mice. Similar to DTRADQ mice, administration of BMP inhibitors completely blocks the bone mass enhancement, indicating that BMPR activation mediates new bone formation in DTRLepR. BMP targeted cells in DTRADQ mice are early committed osteoblast lineage cells driven by the 3.6Col1a1 promoter likely differentiating into mature osteoblasts characterized by activated 2.3Col1a1 promoter. Taken together, our data show CAR/LepR+ cells are not only osteoblast progenitors differentiating into osteoblasts, but are also the principal source of BMP inhibitors in marrow negatively regulating bone formation in vivo. Thus, unexpectedly, elimination of CAR/LepR+ cells, which are osteoblast progenitors, rapidly increases bone mass due to BMP activation of more committed osteoblast lineage cells.

ERK Suppresses the Plasticity of Periosteal Skeletal Stem Cells *Alisha Yallowitz[1], Shawon Debnath[2], Hwanhee Ho[3], Michelle Cung[3], Yeon-Suk Yang[4], Jae Hyuck Shim[4], Matthew Greenblatt[5]. [1]Weill Cornell Medicine, United States, [2]Weill Cornell Medicine, Cornell University, , [3]Department of Pathology and Laboratory Medicine, Weill Cornell Medicine, United States, [4]UMASS Medical School, United States, [5]Weill Cornell Medical College, United States

We previously reported a periosteal stem cell (CTSK+ skeletal stem cells, CTSK+ SSCs) that mediates intramembranous ossification under baseline conditions (Debnath et al. Nature 2018). However, these cells undergo a plasticity event after skeletal fracture whereby they acquire the gene expression profile and endochondral bone formation capacity of endosteal stem cells. The molecular pathways by which these normally intramembranous-specialized CTSK+SSCs interconvert into cells with the properties of endosteal stem cells and mediate endochondral fracture repair is unknown. Here, we have identified that the ERK signaling pathway acts as a molecular regulator of fracture induced plasticity in CTSK+SSCs. The ERK pathway is constitutively active in CTSK+SSCs and suppresses their plasticity under basal conditions. When the ERK pathway is disrupted in CTSK+SSCs, as in Mek1flox/flox; Mek2-/- CTSK-cre mice (Mek1CTSKMek2-/-), CTSK+SSCs expand and display a cell intrinsic gain in the capacity to mediate endochondral ossification. In contrast, enforced activation of the ERK pathway in CTSK+SSCs via a conditional constitutively active Mek1 allele (Mek1DDCTSK mice) prevents CTSK+SSC plasticity and inhibits the formation of the cartilaginous callus during fracture healing, resulting in nonunion. Thus, ERK-regulated CTSK+SSC plasticity is critical for fracture repair. Additionally, Mek1CTSKMek2-/- mice develop spontaneous osteochondroma formation in the periosteum, a phenotype that is similar to human multiple exostoses/osteochondroma. Thus, osteochondromas represent induction of the fracture induced CTSK+SSC plasticity pathway in the absence of fracture. Altogether, these findings confer a surprising link between osteochondroma formation and fracture repair and identifies the first molecular regulator of plasticity among SSC types.

Examining the Role of Zinc Fingers and Homeoboxes 2 (Zhx2) in Chronic Kidney Disease-related Bone & Cardiovascular Health *Jordan Matz[1], Corinne Metzger[3], Huda Mahmood[3], Christopher Miller[3], Arelis Quintana-Martinez[3], Gagandeep Sooch[4], Matthew Allen[3], Erica Clinkenbeard[3]. [1]IU School of Medicine, , [3]Indiana University School of Medicine, , [3]Indiana University School of Medicine, United States, [4]Marian University College of Osteopathic Medicine, United States

Chronic Kidney Disease (CKD) is estimated to affect more than 1 in 7 US adults. CKD-mineral and bone disorder (CKD-MBD), a common sequela, independently leads to vascular calcification, increased fracture risk, and mortality. Mice placed on CKD-inducing 0.2% adenine diet (AD) for 8 weeks show increased cortical bone porosity, osteoclast activity, and marrow adiposity, mirroring human patients. The differentiation skewing between osteoblast and adipocyte in CKD however remains unclear. Zinc finger and homeobox 2 (Zxh2), a transcriptional repressor, was previously shown to be critical for odontoblast differentiation. Further, lack of Zhx2 promotes hepatic steatosis with high fat diet. We hypothesize Zhx2 potentiates osteoblast commitment by inhibiting adipocyte gene expression. We utilized BALB/cJ (/cJ) mice which harbor a hypomorphic mutation in the Zhx2 locus,

drastically decreasing Zhx2 mRNA compared to normal BALB/c (/c) mice. AD feeding in both sexes significantly increased serum Blood Urea Nitrogen vs casein control consistent with CKD; however, /cJ mice had significantly lower values than /c mice. On casein, /cJ females exhibited lower trabecular bone volume (Tb.BV/TV; p<0.01), reduced Bglap mRNA (p<0.01), and increased adipogenic Lpl mRNA (p<0.05) vs /c. AD-fed /c females lost Tb.BV/TV and reduced Bglap mRNA comparable to /cJ levels which correlated with reduced bone Zhx2 mRNA vs /c casein. Male /cJ mice exhibited reductions in Bglap (5-fold, p<0.01), Alpl (2.5-fold; p<0.01), and Dmp1 (2.5-fold, p<0.01) mRNA compared to /c on casein, with no differences in Lpl mRNA or trabecular bone parameters. In contrast to females, AD-fed /c males had modestly increased Tb.BV/TV whereas Tb.BV/TV decreased in AD-fed /cJ males. Consistent with CKD, AD-fed /cJ mice exhibited modestly elevated serum phosphate and fibroblast growth factor 23 (FGF23) vs /c mice. Thus, we assessed tissues for downstream calcifications via X-ray. Analysis of isolated hearts showed AD-fed /c mice incurred heart calcifications (2/7 females; 4/6 males), whereas BALB/cJ mice appeared protected (0/8 male and female). In conclusion, Zhx2 is a transcription factor that exhibits influence on outcomes related to CKD and mineral metabolism. Most notably, /cJ mice lacking Zhx2 were protected from cardiac calcification incidence. These results have important implications for patients with CKD-MBD and downstream outcomes related to disrupted mineral metabolism.

Bariatric Surgery is Associated with Increased Fracture Risk Among Veterans *Eileen H. Koh[1], Tiffany Y. Kim[2], Hui Shen[2], Mary A. Whooley[2], Matthew L. Maciejewski[3], Theodore S. Z. Berkowitz[4], Valerie Smith[3], Lygia Stewart[2], Anne L. Schafer[2]. [1]University of California, San Francisco, United States. [2]University of California, San Francisco and San Francisco Veterans Affairs Health Care System, United States. [3]Durham Veterans Affairs Health Services Research and Development and Duke University, United States. [4]Durham Veterans Affairs Health Services Research and Development, United States

Despite its metabolic and mortality benefits, bariatric surgery has negative skeletal effects. The Roux-en-Y gastric bypass (RYGB) procedure is associated with increased fracture risk in the general bariatric surgery population, who are predominantly premenopausal women. It is unclear whether postoperative fracture risk is increased in men, and whether patients with obesity who undergo sleeve gastrectomy (SG), now the most commonly performed procedure, are more likely to fracture than nonsurgical patients. We compared fracture risk among US Veterans who underwent bariatric surgery from 2000-2020 at a Veterans Affairs (VA) facility or paid for by VA and matched Veterans with obesity who did not have surgery. Surgical patients were matched 1:3 to nonsurgical patients by age, sex, year, and pre-op BMI. We used ICD codes to capture incident fracture from VA electronic health records, VA purchased care claims, and Medicare claims. Cox proportional hazards models were used to determine the relationship between bariatric surgery and subsequent fracture risk. Our surgical cohort, comprised of 8357 patients [3182 RYGB, 4168 SG, 291 adjustable gastric banding (AGB)], was 70% men with mean age 52+/-10 years and BMI 45+/-7 kg/m2. Compared to 25,057 matched Veterans who did not have surgery, surgical patients had higher baseline rates of obesity-related comorbidities including diabetes (48% vs 36%). During an average 7 years follow-up, surgical patients had higher rates of incident fracture (25.1 vs 13.9 per 1000 person-years). Bariatric surgery was associated with a 67% increased risk of incident fracture (HR 1.67, 95% CI 1.56-1.79, p<0.001) after adjustment for race/ethnicity, geographic location, and comorbidities. Bariatric surgery was also associated with incident hip fracture (HR 2.42, 95% CI 1.97-2.96, p <0.001), spine fracture (HR 1.81, 95% CI 1.60-2.05, p<0.001), and radius fracture (HR 2.36, 95% CI 2.03-2.75, p< 0.001). Compared to matched controls, RYGB was associated with increased risk of fracture (HR 1.91, 95% CI 1.73-2.11, p<0.001), as was SG (HR 1.48, 95% CI 1.31-1.67, p<0.001), but there was no difference in fracture rates between RYGB and SG (p=0.18). There was no evidence for an association between AGB and fracture risk (HR 0.97, 95% CI 0.68-1.40, p=0.88). Our findings show that RYGB and SG are associated with increased risk of fracture in this Veteran population of predominantly older men, including at major osteoporotic fracture sites.

Osteocytes Induce Drug Resistance via the NOTCH3-CXCL12 Signaling Axis in Multiple Myeloma *Hayley Sabol[1], Cody Ashby[1], Manish Adhikari[1], Japneet Kaur[1], Aric Anloague[1], Sharmin Khan[1], Samrat Roy Chodhury[1], Michela Palmieri[1], Lawry Barnes[1], Elena Ambrogini[1], Carolina Schinke[1], Intawat Nookaew[1], Jesus Delgado-Calle[1]. [1]University of Arkansas for Medical Sciences, United States

Multiple myeloma (MM) remains incurable due to disease relapse and drug resistance. Notch signals between MM cells and cells of the tumor niche (TME) confer drug resistance, but the cellular/molecular mechanisms are not entirely known. Using in silico analysis of clinical and transcriptomic public and internal databases, we found that 1) NOTCH3 is upregulated in MM cells from newly diagnosed MM patients (NDMM) vs. healthy donors, 2) increases in relapsed/refractory MM (RRMM) vs. NDMM patients, and 3) NDMM patients with high NOTCH3 expression have worse responses to Bortezomib (BOR)-based therapies. Because NOTCH3 mRNA levels did not correlate with somatic mutations in NOTCH3, we tested if NOTCH3 is regulated by TME cells and its role in responses to chemotherapy. Osteocytes (Ots), recently defined as key cells in the TME, increased NOTCH3 in MM cells and protected them from apoptosis induced by BOR or VRd (BOR+Lenalidomide+Dexamethasone) in vitro. This protection was lost by NOTCH3 knockdown (NOTCH3KD) and enhanced by NOTCH3 activation (NOTCH3OE) in MM cells. Next, we compared BOR (0.1 mg/kg, 5x/wk) responses in control (C) vs NOTCH3OE MM cells in vivo. All untreated mice bearing C or NOTCH3OE cells died at 4 wks. In mice injected with C MM cells, BOR reduced tumors by 65%, improved survival (7/10 alive), and had 38% more bone mass, 25% more P1NP, and 29% less CTX than untreated mice. In contrast, in NOTCH3OE-bearing mice, BOR only reduced tumors by 23% and did not improve survival (1/10 alive), bone mass, or serum markers, supporting NOTCH3 confers BOR resistance. We then compared the MM cell transcriptome of NDMM patients with high vs. low NOTCH3 expression to find the mechanism for BOR resistance. We found that high NOTCH3 NDMM and RRMM patients had enrichment in chemokine and cell adhesion pathways and CXCL12 upregulation. Ots upregulated CXCL12 and activated the CXCR4/ERK pathway in MM cells in vitro. These effects were blunted in NOTCH3KD and enhanced in NOTCH3OE MM cells. Genetic inhibition of CXCL12 in NOTCH3OE cells prevented Ot's protection and restored BOR/VRd sensitivity, supporting CXCL12 works in an autocrine fashion. Lastly, Plerixafor, a CXCR4/CXCL12 inhibitor, restored NOTCH3OE MM cells sensitivity to BOR/VRd in vitro and in human bones bearing NOTCH3OE tumors cultured ex vivo. Our clinical and experimental data show Ots transmit drug resistance signals and unravel a novel targetable NOTCH3-CXCL12 pro-survival signaling axis in the MM TME.

Osteoblasts are a source of bone metastases-associated fibroblasts (BMAFs) *Jennifer Zarrer[1], Marie-Therese Haider[2], Nicole Ridlmaier[2], Rafael Preuer[2], Daniel J. Smit[3], Hiroaki Saito[1], Eric Hesse[1], Hanna Taipaleenmäki[1]. [1]Institute of Musculoskeletal Medicine, University Hospital, LMU Munich, Munich, Germany, Germany. [2]Molecular Skeletal Biology Laboratory, Department of Trauma, Hand and Reconstructive Surgery, University Medical Center Hamburg-Eppendorf, Hamburg, Germany, Germany. [3]Institute of Biochemistry and Signal Transduction, University Medical Center Hamburg-Eppendorf, Hamburg, Germany, Germany

In breast cancer bone metastases the abundance of adjacent osteoblasts (OBs) is diminished. To determine the fate of OBs, we combined a lineage-tracing model (Osx-cre-ERt+;Ai9) with intracardiac injection of 4T1 breast cancer cells and performed single cell RNA sequencing (scRNAseq) of tdTomato-positive (tdTom+) OBs in metastases-bearing and healthy control animals. Bioinformatic analysis revealed a distinct cluster of tdTom+ OBs in metastases-bearing mice that express genes related to tumor microenvironment, fibrosis and cancer-associated fibroblast (CAF) proliferation (e.g. Cxcl12, Tnc, Mmps, Pdgfr-?, Pdgfr-?). CAFs reside inside tumors providing a micro-milieu that supports tumor growth. However, little is known about metastasis-associated fibroblasts (MAFs), in particular in bone metastases. Based on our findings, we hypothesized that OBs might abandon the bone surface and become MAFs. Supporting our hypothesis, histological analysis demonstrated elongated tdTom+ OBs within metastases, which we termed bone metastases-associated fibroblasts (BMAFs), while only a few OBs were present on nearby bone surfaces. Consistently, MC3T3-E1- and primary OBs acquired a spindle shape morphology upon stimulation with medium conditioned by 4T1 or MDA-MB-231 breast cancer cells (CCM), which also increased OB migration and OB-induced collagen remodeling. Furthermore, in an ex vivo co-culture model, OBs in the vicinity of cancer cells became elongated and migrated in-between tumor cells. Immunoblot, qRT-PCR, scRNAseq and histological analyses revealed a reduction of OB markers (Runx2, Osx) and an increase of BMAF-associated genes (e.g. Pdgfr-?, Pdgfr-?) in CCM-stimulated OBs and cancer-associated tdTom+ OBs. To elucidate the mechanisms transitioning OBs to BMAFs, we performed RNA sequencing and identified an activated IL-17A signaling pathway in CCM-stimulated OBs compared to controls, which was confirmed by immunoblot and qRT-PCR analyses of downstream targets (C/ebp, Ccl2). Furthermore, recombinant IL-17A promoted OB migration and acquisition of a BMAF phenotype while inhibition of IL-17A signaling using an anti-IL-17 antibody restored the CCM-induced morphological changes and OB migration. In vivo, anti-IL-17A reduced the number and growth of bone metastases determined by bioluminescence imaging and histology. Together, these results demonstrate that OBs give rise to BMAFs at least in part through IL-17A, which might contribute to metastatic growth.

Bone fracture causes long-term impairment of the bone marrow niche for hematopoietic stem cells *Elise Jeffery[1], Sean Ahler[1], Bethany Davis[1], Sean Morrison[1]. [1]UT Southwestern Medical Center, United States

Bone fracture is estimated to occur in 2.3% of people every year (GBD Fracture Collaborators, The Lancet, 2021). In addition to damaging bone, fracture also significantly damages the bone marrow (BM), which is the primary site of hematopoiesis in healthy adults. Hematopoietic stem cells (HSCs) in the BM reside adjacent to sinusoidal blood vessels and

perivascular stromal cells, which secrete chemokines essential for HSC maintenance and survival (Crane et al, Nat Rev Immun, 2017). During fracture repair, the BM stroma is regenerated in part by periosteal cells that contribute to the formation of the fracture callus (Jeffery et al, Cell Stem Cell, 2022). However, it's unclear to what extent the regenerated BM stroma supports hematopoiesis. To investigate this, we analyzed the frequency of HSCs, restricted progenitors, and mature lineages in mice five weeks after tibial fracture, a time point when the bone cortex has fully re-formed and the marrow has regenerated (Jeffery et al, Cell Stem Cell, 2022). We found a striking three-fold reduction in the frequency of HSCs in post-fracture BM compared to that of the contralateral uninjured tibia. In contrast, there was no difference in the frequencies of lineage restricted progenitors or of mature hematopoietic populations. These data suggest that post-fracture BM is specifically toxic to HSCs. The degree of fracture stabilization did not affect the phenotype, as we observed a similar reduction in HSC frequency after non-stabilized fracture and pin-stabilized fracture. Surprisingly, the reduction in HSC frequency was maintained for at least six months post-fracture, suggesting that fracture has a long-term effect on the hematopoietic microenvironment. We hypothesized that this reduction in HSC frequency was due to impaired niche cell function in the regenerated BM. However, we found no significant changes in stromal cell number, morphology, or niche factor expression in stromal cells from regenerated BM compared to stromal cells from normal BM. In contrast, when we analyzed the morphology of endothelial cells following fracture, we found a significant increase in the number of arterioles, as well as irregular organization of sinusoids with high variability in sinusoid width. These data suggest that the sinusoidal niche for HSCs may be compromised in regenerated BM, and that the regrowth and remodeling of blood vessels in the BM is a limiting factor for the proper resumption of hematopoiesis following fracture.

PTH Stimulates Osteoblast Secretion of Slit3 to Repel Aberrant Vertebral Innervation and Relieve Low Back Pain Associated with Spinal Degeneration
*Weixin Zhang[1], Arryn Otte[2], Sisir Kumar Barik[3], Mei Wan[2], Xu Cao[2], Janet Crane[2]. [1]Johns Hopkins university, , [2]Johns Hopkins University, United States, [3],

Low back pain (LBP) is the leading cause of disability globally, affecting one out of every four people. Nonspecific LBP is associated with spinal degeneration, particularly with vertebral endplate bone expansion and sclerosis. We have analyzed two mouse models with spinal degeneration, aging mice and lumbar spine instability (LSI) and found that parathyroid hormone (PTH) treatment reduced vertebral endplate sclerosis and improved pain behaviors. Most notably, porosity of the vertebral endplate significantly decreased while the tolerance of mechanical pressure significantly increased in PTH treated (40 μg/kg/day) groups relative to the vehicle groups in both aging mice and wild type (WT) LSI mice. Aberrant innervation noted in the vertebral body and endplate during spinal degeneration was reduced with PTH treatment as quantified by PGP9.5+ nerve fibers. Beta-3tubulin+ and CGRP+ neurons also significantly decreased in dorsal root ganglion within PTH treatment relative to vehicle control in both mice models. To explore the mechanism of PTH-reduction of innervation, we screened multiple axon guidance cues. The neuronal repulsion factor Slit3 significantly increased in the endplate after PTH treatment in WT LSI model. E47 and Foxa2, two transcription factors of Slit3, were significantly increased after PTH treatment (100 nmol for 3 days) in MC3T3 cells with osteoblast differentiation inducible culture medium. CHIP assay further indicated that the expression of Slit3 was significantly increased by Foxa2 with PTH stimulation in vitro. In vivo models deleting PTH type 1 receptor (PPR) in osteoblasts (OsteocalcinCrePPRf/f LSI mice) prevented PTH-reduction of endplate porosity and improvement in pressure tests, whereas PPR deletion in chondrocytes (Col2aCreERt2P-PRf/f LSI mice) continued to improve to PTH in regard to porosity and pressure tests. Furthermore, deletion of Slit3 in osteoblasts (OsteocalcinCreSlit3f/f LSI mice) did not differ between PTH and vehicle treatment in regard to total endplate porosity nor pressure test. Altogether, PTH stimulates Slit3 to repel sensory nerve innervation and provides symptomatic relief of LBP associated with spinal degeneration.

In vivo stimulation of Tfeb, a master regulator of autophagy and lysosomal biogenesis, via in vivo CRISPR activation increases bone mass and strength
*Alicen James[2], James Hendrixson[2], Ilham Kadhim[2], Jacob Laster[2], AMY SATO[3], Stuart Berryhill[2], Julie Crawford[2], Melda Onal[2]. [2]University of Arkansas for Medical Sciences, , [2]University of Arkansas for Medical Sciences, United States, [3]UAMS, United States

Autophagy is a recycling pathway in which cellular components, including damaged or dysfunctional proteins, protein aggregates, and organelles are delivered to lysosomes for degradation. Reduction or insufficiency of autophagy is thought to contribute to a number of skeletal diseases such as skeletal aging. Accordingly, elimination of autophagy from the entire osteoblast lineage or only from osteocytes reduces osteoblast number, decreases bone formation, and causes low bone mass. However, whether increasing autophagy in osteoblast lineage cells is beneficial for bone health under physiological or pathological conditions is unknown. To address this, we generated a novel model to increase endogenous Tfeb expression in the osteoblast lineage. Transcription factor EB (Tfeb) is a master transcriptional regulator of autophagy and lysosomal biogenesis. Consistent with this, Tfeb overexpression (OE) induces autophagy in cultured osteoblasts. We stimulated expression of the endogenous Tfeb gene in osteoblast lineage cells of mice via in vivo CRISPR activation. Specifically, we expressed a sgRNA targeting the Tfeb transcription start site from the Rosa26 locus and activated a dCas9::SPH transgene using the Osx1-Cre transgene. This maneuver increased Tfeb expression 2.5-fold in RNA isolated from whole bones. At 8 weeks of age, the skeletal phenotype of mice overexpressing Tfeb was similar to littermate controls. However, at 4 months of age, Tfeb overexpressing male mice displayed increased femoral and vertebral cortical thickness. Histological analysis revealed that the increase in femoral cortical thickness was due to increased bone formation. Tfeb OE was also anabolic for femoral and vertebral cancellous bone. Analysis of osteoblast and osteoclast marker gene expression in lumbar vertebrae revealed that the anabolic impact of Tfeb OE was associated with high bone turnover. Moreover, the anabolic actions of Tfeb OE were sufficient to elevate bone strength as determined by femoral three-point bending analysis. Similar to males, serial BMD measurements of female mice showed that Tfeb OE in the osteoblast lineage also increases bone mass of female mice. Moreover, the high bone mass of female mice became more pronounced between 3 to 8 months of age. In conclusion, Tfeb overexpression in osteoblast lineage cells is anabolic and results in mechanically stronger bones and may represent an effective approach to combat age-associated bone loss.

Osteoclast-specific Deletion of ?2-Adrenergic Receptor Limits Trabecular Bone Acquisition in Male, but not Female Mice
*Rebecca Peters[3], Ryan Neilson[2], Hannah Feliciano[3], Katherine Motyl[4]. [3]MaineHealth Institute for Research, , [2]MMCRI, United States, [3]MaineHealth Institute for Research, United States, [4]MaineHealth, United States

The sympathetic nervous system (SNS) is important for maintenance of bone homeostasis through ?-adrenergic signaling. Our lab and others found that osteoclasts are direct targets of the SNS, and that ?-blockers limit osteoclast differentiation. Osteoclasts express both ?1- and ?2-adrenergic receptor (?2AR), but ?2AR is more highly expressed. To directly examine the effects of ?2AR on osteoclasts, we developed an osteoclast-specific ?2AR knockout mouse model. Adrb2fl/fl mice were crossed with the myeloid lineage specific Lyz2Cre/Cre (a.k.a. LysM-Cre) mice. We tested the efficiency of deletion with Adrb2fl/fl-Lyz2Cre/+ (Cre/+) and Adrb2fl/flLyz2Cre/Cre (Cre/Cre) mice and found deletion of Adrb2 was comparable in both using gene expression and in situ hybridization in the distal femur. Using μCT, we measured the bone microarchitecture of wildtype (+/+) and Cre/+ male and female mice at 8 and 26 weeks of age (N=7-10). In male mice with the deletion, L5 vertebrae trabecular bone parameters (BV/TV, BMD, Tb.Th) were significantly lower. Distal femur trabecular BMD was reduced by 10% and SMI was elevated by 35% in Cre/+ compared to +/+ ($p<0.05$). Cortical bone (Ct.Ar/Tt.Ar, Ct.TMD) tended to be lower in Cre/+ mice ($p<0.09$). Both osteoclast and osteoblast marker genes were reduced in tibia, including Acp5, Alpl, Col1a1 and Tnfsf11 (Rankl). Although no changes in serum CTX-1 or P1NP were observed in untreated mice, ?2AR deletion in osteoclasts attenuated the elevated CTX-1 caused by the ?2AR agonist salbutamol (N=3, $p=0.031$). The low bone mass phenotype subsided by 26 weeks, suggesting age-related bone loss is unaffected by Adrb2 deletion in osteoclasts in male mice. Female mice had no significant changes in bone microarchitecture or serum bone remodeling markers at 8 or 26 weeks of age. Although global deletion of Adrb2 has been reported to cause a high bone mass phenotype, our work indicates that ?2AR function in bone is sex, age, cell-type, and stress dependent. We have also found that ?2AR deletion in osteoclasts may have indirect effects on osteoblast function, indicated by lower osteoblast marker gene expression. Future studies will examine this using osteoblast culture and co-culture studies with osteoclasts. These studies will aid in our understanding of mechanisms through which stress and ?-blockers influence bone density, which may inform osteoporosis prevention and treatment strategies.

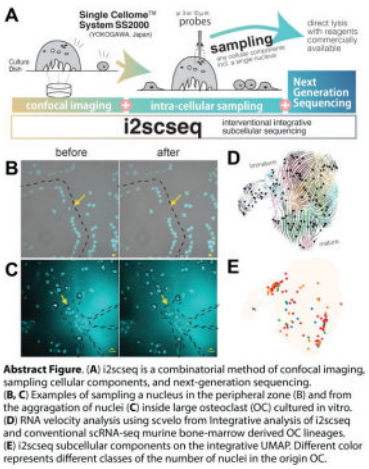
The transcriptome at single-cell resolution clarifies the diversity of cell populations. Single-cell RNA-seq (scRNA-seq) has already been adopted for giant cells such as osteoclasts (OCs) (Omata, Okada, JBMR plus 2022). Although large OCs could not pass through a fluid-based cell dissociation device because of their diameter, acid-producing mature OCs were captured using conventional scRNA-seq.At ASBMR 2022, we presented intra-single cell sequencing (iSCseq) (Okada, bioRxiv 2022). iSCseq is a combinatorial method of high-resolution confocal imaging, picking of intracellular components, including a single nucleus, using the Single CellomeTM System SS2000 (Yokogawa, Japan), and next-generation sequencing at high resolution for mRNA. Our previous results showed that individual nuclei within the same cell are heterogeneous in terms of gene expression.The next version of iSCseq called i2scseq (interventional and integrative subcellular sequencing) can also collect cytoplasm in a small ordinary cell with a 3um probe and capture the living subcellular transcriptome. The average number of genes per cell detected by a 10um probe is much higher, and one by a 3um is equivalent to traditional fluid-based sequencing.i2scseq was used for the in vitro lineage of cells differentiating into OCs. i2scseq clarified that some small cells, which were not morphologically regarded as OCs, were classified into the final cluster of lineages, and vice versa, that giant OC contain immature nuclei in terms of gene expression. With integrative analysis of i2scseq and fluid-based sequencing datasets using a deep machine learning method, large OCs have embedded components at many stages of differentiation.i2scseq clarified the subcellular heterogeneity of mature OCs at a higher resolution than previous iSCseq. We partially solved the question of why conventional scRNA-seq has captured so-called mature OCs. i2scseq is expected to be a core method in cell biology.



Abstract Figure. (**A**) i2scseq is a combinatorial method of confocal imaging, sampling cellular components, and next-generation sequencing. Estimating 'Skeletal Age' by Bone Loss in Elderly Men and Women *Ngoc Huynh[1], Krisel De Dios[1], Thach Tran[1], Tuan Nguyen[2]. [1]University of Technology Sydney, Australia. [2]University of Technology Sydney , Australia

Background and Aim: Skeletal Age is defined as the age of the skeleton as a result of a fracture or exposure to risk factors that elevate the risk of fracture. Higher rates of bone loss are associated with an elevated risk of both fracture and mortality. In this study, we aimed to assess the impact of bone loss on bone fragility by estimating skeletal age using bone loss in elderly men and women. Methods: We analyzed the data from the Study of Osteoporosis Fracture (SOF) and Osteoporotic Fractures in Men (MrOS) that included 9704 women and 5994 men aged 64 years and above. Bone mineral density (BMD) at the femoral neck was measured at baseline and subsequent visits. Mortality was ascertained from death certificates and hospital records. We limited the analysis to those with at least 3 BMD measurements (3848 women and 2925 men). The linear regression model was used to estimate the rate of change in BMD for each individual. The multivariable Cox's proportional hazard model was used to quantify the contribution of the rate of BMD change to mortality, adjusted for age, body mass index, smoking status, alcohol consumption, dietary calcium intake, estrogen and bisphosphonate treatment. The magnitude of the association between bone loss and mortality was then transformed into the number of years of life lost using Gompertz's law of mortality and the US life table. Skeletal age is then determined by the sum of chronological age and years of life lost. Results: In women, the average rate of change in femoral neck bone mineral density (BMD) was found to be -0.61 +/- 1.2% [mean+/-SD] per year, while in men, it was -0.16 +/- 0.9% per year. Throughout the study, 1942 women and 1949 men died. For women, each standard deviation [SD] increase in femoral neck BMD loss was linked to a 1.2-fold (95%CI, 1.1-1.3) increase in total mortality, while for men, the increase was 1.4-fold (95%CI, 1.35-1.5) after adjusting for age, baseline FNBMD, BMI, smoking and drinking status. Additionally, each SD increase in bone loss was associated with a loss of 1.9 years and 3.5 years of life in women and men, respectively. For the same rate of bone loss, men experienced a more substantial loss of years of life than women. Moreover, a 60-year-old woman with a femoral neck BMD loss of more than 2% is estimated to have a skeletal age of 63.5 years. Conclusion: In elderly men and women, excess bone loss is associated with an increased loss of years of life and accelerated bone fragility.

PurposeAntiosteoporosis medications are given to individuals of various ages, but we do not know whether the effect is similar in different age groups. The aim of this study was to use data from key trials of antiosteoporosis medications to determine whether the anti-fracture efficacy or BMD changes associated with treatment differ in people above and below 70 years. The threshold was set at this age as it gave similar numbers of subjects in the studies with vertebral fracture as the endpoint.MethodsWe used individual patient data from 23 randomised placebo-controlled clinical trials of antiosteoporosis medications. Data were stratified by age (<70 and >=70 years old), and the treatment-related fracture risk reduction was estimated in each subgroup, using logistic regression for morphometric vertebral fractures and Cox regression for all clinical, non-vertebral, hip and "all" (combination of non-vertebral and clinical or morphometric vertebral fractures) fractures. The treatment effect on 24-month change in BMD was estimated in each subgroup using linear regression. We performed analyses on all trials, and again separately on trials of bisphosphonates only. We tested the interaction between age subgroup and treatment in all analyses.ResultsThese analyses included 123,164 participants; 57% 0.05) (Figure). The use of antiosteoporotic drugs in people aged 70 and older resulted in significantly greater absolute and percent increases in BMD at 24 months at the total hip (3.8% [3.7, 3.9] vs. 3.1% [3.0, 3.2]), femoral neck (3.4% [3.3, 3.5] vs. 3.0% [2.9, 3.1]) and lumbar spine ((4.4% [4.2, 4.5] vs. 3.9% [3.8, 4.0]) (all p<0.0001).ConclusionsIn summary, antiosteoporotic medications reduced the risk of fractures similarly among those above and below 70 years of age but were more effective at increasing BMD among those at least 70 years.

Type 2 Diabetes is Associated with Better Bone Microarchitecture, higher BMD, but Impaired Physical Function and Increased Risk of Incident Fracture in Older Swedish Women from the SUPERB study. *Lisa Johansson[1], Kristian Axelsson[2], Mattias Lorentzon[3], Henrik Litsne[4], Michail Zoulakis[5]. [1]Institute of medicine, , [2]Institute of Medicine, Sahlgrenska Academy, Gothenburg University, , [3]Sahlgrenska Academy, University of Gothenburg, Sweden, [4]Sahlgrenska Osteoporosis Centre,University of Gothenburg, , Sweden, [5]Sahlgrenska Osteoporosis Centre, Institute of Medicine,University of Gothenburg, Sweden

Several studies have shown that type 2 diabetes mellitus (T2DM) is associated with incident fracture, but it is not clear if the risk increase is due to impaired bone microarchitecture, low bone material strength index (BMSi) or poor physical function. The aim of this study was to determine if T2DM is associated with bone microarchitecture, BMSi, physical function, and risk of incident fracture in older Swedish women.In total, 3028 Swedish women, 75-80 years old were included in the prospective SUPERB study. At baseline, information on clinical risk factors (CRFs) was collected using questionnaires. Bone mineral density (BMD) was measured with dual-energy X-ray absorptiometry, bone microarchitecture with HR-pQCT (XtremeCT), and BMSi obtained using the Osteoprobe device (n=630). Physical function was assessed using timed up and go (TUG), one leg standing (OLS), grip strength, chair stand test and by measurements of gait speed. Data on incident fractures were retrieved from a regional x-ray archive.At baseline, the 294 women with T2DM were compared to women (n=2714) without diabetes. Women with T2DM had higher BMD at all sites (total hip 4.7%, femoral neck (FN) 3.9% and lumbar spine L1-L4 5.4%, all p<0.01) than women without. At the ultradistal tibia, T2DM women had a greater cortical area (7.3%, p<0.01) and density (1.2%, p=0.03), as well as higher trabecular bone volume fraction (8.6%, p<0.01). There was no difference in BMSi between groups (n=630; T2DM 77.8+/-8.1 vs. controls 78.1+/-7.3, p=0.81). Women with T2DM performed significantly worse on all physical function tests than their non-diabetic controls. For example, grips strength was 10.1% lower, gait speed 10.2% slower, and TUG time 13.1% (p<0.001 for all comparisons) slower in women with T2DM than in those without.During 7.3 (4.4, 8,4) years (median (IQR) of follow-up there were 1071 incident any fractures, 797 major osteoporotic fractures (MOF), and 232 hip fractures. In adjusted (for age, BMI, FRAX CRFs and FN BMD) Cox regression models T2DM was associated with an increased risk of any fracture (HR 95% CI 1.26 [1.04-1.53], but the associations with MOF (HR 1.16 [0.92-1.46]) or hip fracture (HR 1.31 [0.85-2.00]) did not reach statistical significance.In conclusion, older women with T2DM have considerably better bone microarchitecture, and no different BMSi, but substantially poorer physical function than nondiabetic women, which could be the principal reason for the increased fracture risk observed in T2DM women.

FRI-001

Automated immunohistochemistry for TRAcP facilitates osteoclast detection and counting for bone histomorphometry: A validation study *Marie-Josée Bégin[1], Natalie Dion[2], Louis-Georges Ste-Marie[1]. [1]Division of Endocrinology, Department of Medicine, Centre hospitalier de l'Université de Montréal, Université de Montréal, Canada, [2]Department of Pathology, Centre hospitalier de l'Université de Montréal, Université de Montréal, Canada

Histomorphometric analysis of undecalcified bone specimens is the gold standard for diagnosis of complex bone disorders. This analysis requires the measurement of many variables, including osteoclasts (Oc) count per bone perimeter (N.Oc/B.Pm). Oc are identified by their morphology and multinuclearity on Goldner's trichrome stained (GTS) sections. To facilitate Oc count, histological sections are stained by an enzymatic histochemical reaction (EHR) of Tartrate Resistant Acid Phosphatase (TRAcP), an Oc biomarker. This technique has certain limitations including the possible alteration of enzymatic activity by bone tissue preparation with ethanol fixation and methyl methacrylate embedding (EFMMAE). In pathology laboratories, biomarkers such as TRAcP are routinely detected by automated immunohistochemistry technique (AIHC) performed on sections of formalin-fixed and paraffin-embedded (FFPE) of decalcified bone biopsies. We aim to validate the use TRAcP detection by AIHC on sections of undecalcified bone tissue EFMMAE in order to improve Oc identification and counting. To this end, transiliac bone biopsies from 20 adult patients (68.7 +/- 8.7 yo) affected by various metabolic bone diseases were studied. AIHC was performed with a Ventana BenchMark ULTRA system (Roche-Diagnosis) using mouse monoclonal antibody for TRAcP (clone 9C5) on deplastified sections with a protocol usually used for FFPE tissue. Osteoclastic detection by AIHC was confirmed by GTS on consecutive sections (Figure 1), as well as with EHR TRAcP and with AIHC Cathepsin K. The AIHC TRAcP showed a strong positive correlation with N.Oc/B.Pm measurements on GTS (r=0.90), as well as with bone formation rate per bone surface (BFR/BS) (r=0.84). Interestingly, there was a significantly greater detection of Oc with AIHC than with GTS (p<0.001). Furthermore, the difference in Oc counts between the two methods was significantly higher in high turnover states compared to low turnover (p=0.021). Taken together, this study validates the use of AIHC TRAcP on undecalcified bone tissue EFMMAE as an effective technique for Oc detection and outperformed Oc count by standard GTS method, especially in the high turnover states. AIHC should be considered as an alternative and easier method to EHR TRAcP. To our knowledge, this is the first time that AIHC has been successfully performed on undecalcified bone tissue EFMMAE, paving the way for the detection of other cellular biomarkers for clinical purposes.

Effectiveness of Asfotase Alfa for Treatment of Adults With Hypophosphatasia: Results from a Global Registry *Priya S. Kishnani[1], Gabriel Ángel Martos-Moreno[2], Agnès Linglart[3], Anna Petryk[4], Andrew Messali[4], Shona Fang[4], Cheryl Rockman-Greenberg[5], Keiichi Ozono[6], Wolfgang Högler[7], Lothar Seefried[8], Kathryn M. Dahir[9]. [1]Duke University Medical Center, United States, [2]Hospital Infantil Universitario Niño Jesús, IIS La Princesa, Universidad Autónoma de Madrid, CIBERobn, ISCIII, Spain, [3]Paris-Saclay University, AP-HP and INSERM, France, [4]Alexion, AstraZeneca Rare Disease, United States, [5]University of Manitoba, Canada, [6]Osaka University, Japan, [7]Johannes Kepler University Linz, Austria, [8]University of Würzburg, Germany, [9]Vanderbilt University Medical Center, United States

Objectives: To assess asfotase alfa's effectiveness on mobility, functional status, quality of life (QOL), and pain in adults with hypophosphatasia (HPP).Methods: Patients enrolled in the Global HPP Registry (NCT02306720; EUPAS13514) who had an alkaline phosphatase below the LLN for age and sex and/or a documented ALPL gene variant, initiated asfotase alfa at age >=18 years, and been treated for >=6 months at last follow-up were included. Outcomes were evaluated as mean change from mean baseline (BL) value through 36 months; assessments were not performed at all timepoints for all patients.Results: Among included patients (N=190), median age at treatment start was 45.5 years; 91.1% were characterized as having pediatric-onset HPP. 6MWT distance walked was 404 m (n=31) at BL and improved over time vs BL (change: 93 m at 12 months [95%CI: 47, 138; n=18], 62 m at 24 months [95%CI: 0, 124; n=15], and 45 m at 36 months [95%CI: ?83, 172; n=7]). The SF36v2 Physical Component Summary score was 35.7 (n=48) at BL and improved over time (change: 4.68 at 6 months [95%CI: 0.16, 9.21; n=34], 4.61 at 12 months [95%CI: 1.02, 8.19; n=28], 4.94 at 24 months [95%CI: ?2.23, 12.11; n=22], and 5.13 at 36 months [95%CI: ?0.96, 11.21; n=21]). SF36v2 Mental Component Summary score improvements were not statistically significant at all timepoints. Health Assessment Questionnaire-Disability Index

scores were generally unchanged over time. Self-reported Brief Pain Inventory Short Form scores improved at all timepoints from a BL of 4.86 (change: ?0.72 at 6 months [95%CI: ?1.23, ?0.21; n=38], ?1.07 at 12 months [95%CI: ?1.62, ?0.52; n=31], ?1.13 at 24 months [95%CI: ?1.76, ?0.51; n=26], and ?0.97 at 36 months [95%CI: ?1.70, ?0.24; n=23]). The most common AEs were injection site reactions and injection-associated reactions, occurring in 29 (13.4%) and 13 (6.0%) patients, respectively. Eleven serious AEs related to asfotase alfa were reported in 7 patients.Conclusion: Adults with HPP who received asfotase alfa for >=6 months experienced improvements in mobility, physical function, QOL, and pain, which were maintained over 3 years of follow-up.

Mobility and Health-related Quality of Life in Adults with Pediatric-onset Hypophosphatasia Treated With Asfotase Alfa: Interim Analysis From the UK Managed Access Agreement *Katie E. Moss[1,] Richard Keen[2,] Shona Fang[4,] Alexandros Zygouras[4,] Muhammad Javaid[5,] Tarekegn Geberhiwot[6,] Kenneth Poole[7,] Peter Selby[8,] Jennifer S. Walsh[9,] Judith S. Bubbear[2,] [1]St. George's University Hospitals, United Kingdom, [2]Royal National Orthopaedic Hospital, United Kingdom, [4]Alexion, AstraZeneca Rare Disease, United States, [4]Alexion, AstraZeneca Rare Disease, United Kingdom, [5]Oxford University, United Kingdom, [6]Queen Elizabeth Hospital, United Kingdom, [7]Cambridge NIHR Biomedical Research Centre, Addenbrooke's Hospital; University of Cambridge, United Kingdom, [8]Manchester Royal Infirmary, United Kingdom, [9]University of Sheffield, United Kingdom

Background: Asfotase alfa is a tissue-nonspecific alkaline phosphatase enzyme replacement therapy used to treat hypophosphatasia (HPP). Data describing effects of asfotase alfa on mobility, pain, and health-related quality of life (HRQoL) in adults with HPP are limited. Methods: This analysis used data from the UK Managed Access Agreement to assess mobility and HRQoL in adults with pediatric-onset HPP treated with asfotase alfa. Data were collected at enrollment, 3 and 6 months after enrollment, and every 6 months thereafter. All adults initiated asfotase alfa treatment after enrollment. Interim results are presented as median (min, max; n); change from baseline to Month 24 is reported as median (95% confidence interval).Results: Of 25 adults enrolled, 17 with >6 months of exposure were included in the study population (12 women, 5 men); 21 who received >=1 dose of asfotase alfa were evaluated for safety. Age at enrollment was 44.0 (22.0, 60.0) years. Treatment duration was 1.5 (0.5, 3.2) years. Bleck score improved from a baseline of 6.0 (2.0, 9.0; n=17) by 2.0 (1.3, 2.7; n=8). The 6-Minute Walk Test distance walked improved from a baseline of 130.0 (28.0, 360.0; n=10) by 160.0 (2.5, 290.9; n=5) meters. Pain severity score improved from a baseline of 8.0 (4.3, 10.0; n=16) by ?3.2 (?5.6, 0.9; n=7). EQ-5D-3L utility score improved from a baseline of 0.1 (?0.3, 0.5; n=17) by 0.3 (0.1, 0.5; n=8). Of 13 adults prescribed opioids, 2 stopped and 5 reduced use after starting asfotase alfa. One vertebral (1 patient) and 2 metatarsal (1 patient) fractures occurred 1 week and 13.5 months, respectively, after initiating asfotase alfa. Serious adverse events were infrequent (n=3, 4 events), with 2 events related to asfotase alfa (injection site reaction, dysesthesia; Figure). No patients discontinued asfotase alfa.Conclusion: asfotase alfa improved mobility, pain, and HRQoL in adults with pediatric-onset HPP, with a favourable benefit/risk profile.

FRI-009

Abdominal aorta calcification detected on vertebral fracture assessment DXA scans and all-cause and cardiovascular mortality in adults. *Carlos Orces[1,] [1]Laredo Medical Center,

Objective: Abdominal aorta calcification (AAC) is a well known risk factor of cardiovascular events and mortality. Whether AAC detected on vertebral fracture assessment DXA scans is associated with all-cause and cardiovascular mortality has not been extensively studied. Methods: The present study was based on data from participants aged 50 years and older in the National Health and Nutrition Examination Survey cycle 2013-2014. Vertebral fracture assessment on lateral spine scans was conducted using Hologic Discovery model A densitometers (Hologic, Inc., Marlborough, Massachusetts), which also provided AAC measurement for L1-L4. The AAC8 score was used to estimate the total length of calcification of the anterior and posterior aortic walls in front of the spine L1-L4. The AAC8 scores were grouped into "0" if no calcification was seen; "1" if the calcification was equal to the height of one vertebra or less; "2" if the length of calcification was more than one but less than or equal to the height of two vertebrae; >= 3 if calcification occurred in more than two vertebrae. Mortality was examined using the NHANES 2019 public-use linked mortality files. Time to death was calculated in months. Results: A total of 2,243 participants with a mean age of 63.0 (SE 0.2) years comprised the study sample. During a median follow up of 71 months, a total of 256 (9.3%) participants died. Of those, 84 (32.8%) deaths occurred from cardiovascular diseases. As shown in Figure 1, the proportion of subjects with AAC8 >= 3 score had significantly lower survival than their counterparts with minor AAC8 scores. Moreover, survival across AAC8 scores diverged about 40 months into the study. Adjusted Cox proportional hazards regression demonstrated that participants with AAC8 >= 3 score had 1.8 times higher risk of all-cause mortality than those with AAC8 = 0 (HR 1.82; 95% CI, 1.15 to 2.89; p < .05). Similarly, the risk of cardiovascular mortality was 1.5-fold higher in participants with AAC8 score >= 3 thant those without calcification. However, this association did not reach statistical significance (HR 1.57; 95% CI, 0.80 to 3.10; p = .018).Conclusions: AAC severity detected on vertebral fracture assessment DXA scans was associated with increased risk of all-cause mortality in a nationally representative sample of U.S. adults.

FRI-011

A single infusion of Zoledronic acid suppressed bone turnover markers for up to seven years: Results from the Zoledronate in the Prevention of Paget's disease (ZiPP) study. *Jonathan Tang[1,] William Fraser[1,] Jonathan Phillips[2,] Isabelle Piec[1,] Rachel Dunn[1,] Catriona Keerie[2,] Steff Lewis[2,] Stuart Ralston[2,] ZiPP inverstigators[2,] [1]University of East Anglia, United Kingdom, [2]University of Edinburgh, United Kingdom

Background: Zoledronate in the Prevention of Paget's disease (ZiPP) trial (ClinicalTrials.gov ID: NCT03859895) is a multi-centre, double-blind, placebo-controlled, randomised trial of intravenous Zoledronic acid (ZA) in sequestosome 1 (SQSTM1) mutation carriers. SQSTM1 mutation has high penetrance and is associated with the early onset of Paget's disease of bone. Methods: Participants with the SQSTM1 genotype were randomised to receive either a single dose of 5mg zoledronic acid (Aclasta, Novartis); intervention group (n=111), age mean (range) 49.8 (32-74)yrs, or a placebo (n=111), 50.5 (32-75)yrs, by intravenous infusion. Serum samples collected were rapidly centrifuged and stored frozen for bone markers CTX (resorption), PINP (formation) and BSALP (osteoblasts activity) every 12 months from baseline for five years and at end-of-study (EoS) 2-yr follow-up. Urine bone resorption marker uNTX and radionuclide bone scans were performed at baseline/EoS).Results: In the Intervention group, CTX and PINP showed respective decreases in serum concentrations of average -44.8% and -29.2% across all time points; the greatest reductions were observed at 12 mths (CTX -57.6%, PINP -46.7%), and remained below baseline concentrations to EoS (CTX -15.2%, PINP -20%). Serum BSALP showed a -20.9% decrease at 12 mths, then returned to baseline concentration at 36 mths. uNTX showed a -36% decrease at EoS. Treatment effect (zoledronate vs placebo) was highly significant for CTX and PINP (ANCOVA p<0.0001) and significant for BSALP (p=0.0005). Bone scans revealed ZA treatment effect was associated with lower risks of developing new bone lesions (odds ratio, 95% CI: 0.406,

0.0-3.425, p=0.246) and further activities of existing lesions in patients (0.083, 0.0-0.424, p=0.003).Conclusion: Our findings showed in SQSTM1 mutation carriers, a single treatment of 5mg ZA can achieve long-term suppression of bone resorption and formation markers for up to 7 years. ZA treatment is beneficial against the formation of bone lesions and improves outcome in patients with existing lesions. The different rates of decrease in bone markers offer insights into the bone remodelling process post ZA administration.

FRI-012

Assessment of Pain, Stiffness, and Physical Functioning Pre and During Burosumab Among Adults With X-linked Hypophosphatemia: Results from a Multinational, Long-term, Prospective Outcomes Disease Monitoring Program *Erru Yang[1], Zunqiu Chen[1], Joel Hetzer[1], Alison Skrinar[1]. [1]Ultragenyx Pharmaceutical Inc., United States

Purpose: Loss-of-function mutations in PHEX gene lead to excess FGF23 that in turn results in hypophosphatemia, leading to chronic debilitating musculoskeletal impairments in patients with X-linked hypophosphatemia (XLH). Treatments include burosumab, a fully-human monoclonal antibody to FGF23, or the combination of oral phosphate and active vitamin D (Pi/D). XLH symptoms in adults include bone/joint pain, stiffness, and fatigue. Previous research validated the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) in adults with XLH. This study assesses burosumab impact on WOMAC among adults from an XLH Disease Monitoring Program (XLH-DMP; NCT03651505). Methods: The DMP is a 10-year study to collect real-world data on the safety and effectiveness of supportive care and burosumab for the treatment of XLH in adults and children. WOMAC has 24 items divided into three subscales: Pain (5 items), stiffness (2 items), and physical function (PF, 17 items). WOMAC scores collected from adults at enrollment were compared to scores obtained one year later for three cohorts: 1, burosumab-naïve at enrollment with burosumab dosed within 90 days post-enrollment; 2, burosumab-naïve at enrollment with burosumab dosed between 91-180 days post-enrollment; 3, no-burosumab at/before enrollment and during one year post enrollment.Results: As of February 2023, 30 and 14 burosumab-naïve and 55 no-burosumab patients from North America were selected into cohort 1, 2 and 3, respectively. Average WOMAC scores were 38, 52.1, 34 for pain, stiffness, and PF for cohort 1, and 40.7, 51.8, 37 for cohort 2, and 26.4, 36.6, 21.1 for cohort 3 at enrollment. At year 1, reduction of 11.8, 11.7 and 8 scores were observed in pain, stiffness, and PF for cohort 1; and reduction of 15.3, 13.4, and 9.1 were observed for cohort 2. No-burosumab cohort had minimal reduction of scores in pain (2.1) and PF (0.9), with 5-score reduction in stiffness.Conclusion: Adult patients with XLH who initiated burosumab within 180 days of DMP enrollment had worse pre-burosumab quality of life in terms of WOMAC scores in pain, stiffness and PF compared with patients without burosumab. Clinically meaningful improvement in pain (>9.7) and stiffness (>10) with burosumab were observed one year after DMP enrollment among adults with XLH and were consistent with results from a randomized, double-blind placebo-controlled registration study.

Experimental and Computational Mechanics of Bone Fragility in Type-2 Diabetes: A Longitudinal Investigation using Zucker Diabetic Fatty (ZDF) Rats *Genna Monahan[1], Marissa Britton[1], Jessica Schiavi-Tritz[2], Ted Vaughan[1]. [1]Biomechanics Research Centre (BioMEC), School of Engineering, University of Galway, Ireland. [2]Université de Lorraine, CNRS UMR 7274, Nancy, France, France

While Type-2 Diabetes (T2D) is associated with an increased bone fracture risk, the pathophysiological factors that contribute to impaired bone biomechanics remain poorly understood. The objective of this study was to investigate biological, biophysical and biomechanical factors that contribute to bone fragility in T2D using a Zucker Diabetic Fatty (ZDF) rat.Femora and blood serum were collected from male [ZDF: fa/fa (T2D) and Lean: fa/+ (Control)] rats, euthanized at 12-, 26- and 46-wk of age (n = 7-9, per age, per condition). Serum markers such as HbA1c/ HbA1 and interlukin-6 (IL-6) and bone turnover markers such as sclerostin (Sost) and C-telopeptide of collagen alpha-I (CTX-I) were measured using ELISA kits. Fluorometric assays and high performance liquid chromatography were used to measure bulk AGEs and adducts carboxylmethyl-lysine (CML), respectively. Cortical and trabecular regions of bone were scanned using micro-computed tomography (micro-CT). Pre- and post-fracture scans of the right proximal femurs were imaged, while a region of cortical and trabecular bone from the distal metaphysis were imaged. Biomechanical analysis was carried out on the femora using a fracture toughness test and sideways fall configuration using a custom-built rig. Finally, image-based finite element models were generated to simulate the sideways fall test and prediction tissue-level stress/strain.Firstly, serum markers showed that the diabetic state disrupted normal bone homeostasis in 46-wk diabetic rats versus controls (HbA1c/ HbA1, 2-fold ?, IL-6, 2.3-fold ?), with possibly impaired osteoblast activity (Sost, 3.7-fold ?). Along with altered cellular activity, changes to the organic component of the bone matrix were shown to be affected, whereby CML, a non-fluorescent AGE trended towards an increase in the 46-wk diabetic rats than controls ($p = 0.07$). Micro-computed tomography (micro-CT) showed that diabetic rats had higher cortical porosity than controls ($p < 0.001$). Biomechanical fracture toughness testing revealed that the sub-tissue alterations lead to significant reductions in tissue-level cracking toughness (Tcr, 45.5% ?) and work-to-fracture (Wf, 31.6% ?) in 46-wk diabetic rats versus controls, highlighting that diabetic tissue has significantly reduced energy dissipation capacity. Overall, this study provides a novel insight into the pathophysiological mechanisms and sequence of events that lead to bone fragility in severe T2D in this ZDF rat model.

Chromosomal sex (XX vs XY) contributes to bone and muscle mass independently of the gonadal sex (ovaries vs testis) in the 4 core genotype mouse model. *Lilian Plotkin[1], Matthew Arnett[2], Dyann Segvich[3], Padmini Deosthale[1], Chiebuka Okpara[4], JULIAN BALANTA-MELO[5], FABRIZIO PIN[6], Joseph Wallace[7]. [1]Indiana University School of Medicine, United States. [2]I, United States. [3]Indiana University-Purdue University Indianapolis, United States. [4]Lehigh University, United States. [5]Universidad del Valle, Colombia. [6], United States. [7]Indiana University Purdue University Indianapolis (IUPUI), United States

Vertebrate sexual dimorphism is ascribed to the presence of testis or ovaries, and, hence, to gonad-specific hormone production. Sex differences also stem from the presence of sex chromosomes (XX or XY). To tease out the contribution of chromosome (CS) from gonad (GS) sex, the Sry gene that dictates testis formation was either deleted in XY mice, resulting in XYF mice with ovaries or overexpressed in XX mice, resulting in XXM mice with testis. These mice, together with XY males (M) and XX females (F) form the 4core genotype (FCG) model. It has been shown that levels of estrogen in XXF/XYF and androgen in XXM/XYM are similar. We now show that the musculoskeletal phenotype of 2 and 4 month (m) FCG mice depends on both GS and CS. Mice were scanned for DXA, blood/tissues were collected, and bones were tested by µCT and 3-point bending. GS/CS effects were assessed by 2-way ANOVA (Tukey post-hoc test). GS influenced body weight (BW), and total/femur/spine BMD at 2m, and BW and total/femur BMD at 4m, all lower in gonadal females (Table1). A GS-CS interaction was found in 2m mouse spine BMD, which was lower in XYF than XYM, but similar in XXF and XXM mice. At 4m, XY mice show lower BW and BMD at the 3 sites than XX mice, whereas % lean mass was higher in XYM and XYF than the respective XX mice, and % fat mass was lower in XYM vs XXM, indicating CS effects (Table2). Skeletal muscle weights were lower in gonadal females (XXF/XYF) than in males (XXM/XYM) at 2m (Table3) whereas soleus muscle weight was higher in XYM than in XXM mice and no different in females. Fewer differences were found at 4m, with a CS-dependent effect in QC weight (higher in XXM than in XYM). µCT showed GS and CS contribution to structural parameters and TMD in femur mid-diaphysis -lower in XYF vs XXF, no different in males- whereas only GS affected marrow cavity and total tissue area and MOI at 4m (Table4). Bone mechanical properties were overall lower in gonadal females (Table5). CS only affected ultimate force - lower in XYF vs XXF, no different in males. GS affected all distal femur trabecular structural parameters, which were lower in gonadal females, but only partially L5 vertebrae (Table4). L5 tissue mineral density TMD depended on CS and was higher only in XXF vs XYF. Finally, GS and CS also affected serum chemokine levels, which might explain changes in bone and muscle cell function (Table6). Thus, while GS has a major role, CS is a so far unrecognized contributor to bone/muscle mass and bone strength.

Musculoskeletal phenotype of FCG mice at 2 and 4 months of age. Values indicate mean±sd, only parameters that are significantly different at least for one comparison are shown by 2-way ANOVA: @= gonadal sex effect; £= chromosome sex effect; &=G5xC5 interaction. Tukey post-hoc test: * p<0.05 vs corresponding gonadal sex, # p< 0.05 vs corresponding chromosome sex. Underlined bold corresponds to p<0.05 for gonadal female XX vs gonadal male XY.

Fracture Healing Leads to Localized Structural Bone Loss Quantified using Void Space Analysis *Danielle Whittier[1], Matthias Walle[2], Charles Ledoux[3], Penny Atkins[1], Caitlyn Collins[4], Julia Holtmann[5], Matthias Zumstein[6], Patrik Christen[7], Kurt Lippuner[8], Ralph Müller[3]. [1]Institute for Biomechanics, ETH Zurich; Department of Osteoporosis, University Hospital of Bern, Switzerland. [2]ETH Zurich, . [3]Institute for Biomechanics, ETH Zurich, Switzerland. [4]Virginia Tech, United States. [5]Department of Orthopaedic Surgery and Traumatology, University Hospital of Bern, Switzerland. [6]Department of Orthopaedic Surgery and Traumatology, University Hospital of Bern; Sonnenhof Orthopaedics, Bern, Switzerland, Switzerland. [7]Institute for Information Systems, FHNW, Switzerland. [8]Department of Osteoporosis, University Hospital of Bern, Switzerland

High-resolution peripheral quantitative computed tomography (HR-pQCT) has shown rapid changes in bone mineral density (BMD), morphology, and biomechanical properties at the distal radius during fracture healing. However, patient outcomes in terms of BMD are highly variable, suggesting that changes in bone microarchitecture may also play a role in patient-specific recovery and long-term bone strength. This study uses void space analysis to identify regions of adverse localized structural bone loss during fracture healing.Twenty-six patients (21 female, 5 male; aged 18-79 years) with conservatively-treated distal radius fractures were scanned using HR-pQCT (XtremeCT II, 61 µm) at 6 timepoints post-fracture (weeks 1, 3, 5, 12, 26, and 52). The common scan region across timepoints was determine using 3D rigid registration, and total BMD (TtBMD), bone volume fraction (BVTV), and void space volume faction (VSTV) were quantified at the first and last available timepoint for each participant. The cumulative formation of VSTV across sequential timepoints (termed void space expansion) was also quantified to capture structural voids that developed during fracture healing as opposed to those that arose due the fracture incident. Changes in BMD, BVTV, and VSTV between the first and last visit were compared using paired t-tests or Wilcoxon test, depending on data distribution.The median time of the first and last post-fracture visits were 1.1 weeks (IQR = 0.9-1.1) and 52.3 weeks (42.9-54.1), respectively. During this interval, VSTV increased five-fold in size from 1.0% (0.6-9.0%) to 5.5% (2.5-12.4%) (Figure 1A, p=0.01). Void space expansion occurred more rapidly in the first 26 weeks of fracture healing (Figure 1B) and did not necessarily occur in the immediate fracture region, but rather the surrounding area (Figure 1C). In contrast, TtBMD and BVTV did not significantly differ between the first and last study visits, where TtBMD was 283 +/- 55 mg HA/cm3 and 269 +/- 62 mg HA/cm3 (p=0.16) at the first and last visit, and BVTV was 42 +/- 2% and 41 +/- 2% (p=0.48) at the first and last visit, respectively.This study suggests that there may be adverse changes in bone microarchitecture during fracture healing, despite the potential preservation of overall TtBMD and BVTV in the fracture and surrounding region. The formation of void spaces may have long-term implications on patient bone strength and could provide insight into who is at risk of re-fracture.

FRI-043

Bone Microarchitecture and Bone Strength at the Distal Radius Related to the Pubertal Growth Spurt in Adolescence *Imanma Tiffany Egeonu[1], James Johnston[1], Saija Kontulainen[1]. [1]University of Saskatchewan, Canada

Increase incidence of forearm fractures at the time of the adolescent growth spurt is well documented but it is unclear if bone structure is weaker during this rapid period of growth. The purpose of this research was to compare bone strength and micro-architectural outcomes of the distal radius across the pubertal growth spurt. We categorized 143 typically developing children (60 females) into 3 groups, based on their estimated somatic maturity (years from the age at peak height velocity, APHV): Pre -0.5y prior to APHV; Peri +/-0.5y within APHV, and Post >0.5y post to APHV. We analyzed distal radius HR-pQCT images to obtain trabecular and cortical bone microstructure and finite element (FE) derived strength outcomes. We created an FE model with mechanical properties scaled in relation to image bone mineral density to estimate: stiffness, off-axis fracture load, and related factor-of-risk. We compared bone strength and microarchitecture across the groups using MANCOVA (age, height, and body mass as covariates), followed by pairwise comparisons. Age and body size adjusted distal radius strength and micro-architecture differed across the groups (Wilks' Lambda, p<0.05). Peri group had 20% lower bone stiffness than Pre (p=0.01), and 39% higher factor-of-risk than Post (p=0.01) groups. Peri had 12-19% lower trabecular thickness, bone volume, trabecular bone density and total bone density than Pre group. Peri group also had 5-19% lower cortical thickness, cortical bone mineral density and tissue mineral density, cortical total and bone volume, and cortical area than Post group (p<0.05). Findings indicate lower bone strength and maturity-specific deficits in trabecular and cortical bone micro-architecture and density at the distal radius around the age at peak height velocity. Prospective monitoring of bone strength development over the pubertal growth spurt is warranted. These findings support the hypothesis of transient weakness in bone development during the peak growth spurt in adolescence.

Splenectomy Specifically Ameliorated Osteosclerosis in Lumbar Vertebra of Female Mpig6b null (Mpig6b?/?) Mice *Sirion Aksornthong[1], Kerstin Tiedemann[2], Svetlana V. Komarova[2]. [1]Department of Experimental Surgery, McGill University; Shriners Hospital for Children, Canada, Canada. [2]Faculty of Dental Medicine and Oral Health Sciences, McGill University; Shriners Hospital for Children, Canada, Canada

Myeloproliferative neoplasms are a group of blood cancers, in which abnormalities in bone marrow are associated with abnormal bone gain and osteosclerosis. Bone marrow megakaryocytes (MKs) strongly implicated in osteosclerosis (OS), are maintained in a resting state with the help of the inhibitory receptor G6b-B. Null and loss-of-function mutations in the gene coding G6b-B, Mpig6b in mice and MPIG6B in humans lead to myelofibrosis associated with macrothrombocytopenia, splenomegaly and osteosclerosis. MKs can affect bone cells through cell-cell contact or soluble factors. In female Mpig6b?/? mice, megakaryopoiesis was shifting to the spleen, however, OS progression continued. The goal of this project was to assess the role of circulating factors in mediating osteosclerosis in Mpig6b?/?

mice using a clinically relevant procedure of splenectomy. At the age of 31-37 weeks, when long bone OS is established, but other skeletal sites are not yet affected, female Mpig6b?/? and littermate control (LC) mice were subjected to splenectomy or sham surgery, and 20 weeks later, the hematopoietic parameters, and bone structure by μCT at the femur and lumbar vertebra were analyzed. Macrothrombocytopenia with decreased counts ($p < 0.01$) of larger ($p < 0.05$) platelets persisted in splenectomized and sham-operated Mpig6b?/? mice. The analysis of the femur indicated increased BV/TV ($p < 0.01$) and trabecular thickness ($p < 0.05$) and the decreased medullary area ($p < 0.01$) in 52-week-old splenectomized and sham-operated Mpig6b?/? mice compared to LC, no change in microarchitectures and mechanical properties of the femur was found between splenectomized Mpig6b?/? mice and sham group. In contrast, in vertebra of sham-operated Mpig6b?/? mice, osteosclerosis continued to develop, while splenectomy led the decreased BV/TV ($p < 0.05$) and a tendency to decrease trabecular number with increased trabecular separation in lumbar vertebrae of Mpig6b?/? mice compared to both the sham-operated Mpig6b?/? and splenectomized LC. Using the quantitative plasma proteomics, we identified three proteins, the coagulation factor V, Ig kappa chain C region and intercellular adhesion molecule 2, which were significantly affected in Mpig6b?/? mice compared to LC, and reversed to normal levels after splenectomy. This study contributes to determining molecular interactions between bone and bone marrow in myelofibrosis and will enable the development of novel treatments for patients with this disorder.

Osteoblast-specific ablation of FGF23 attenuates obesity-induced bone loss in male mice *Napatsorn Imerb[1], MIN YOUNG PARK[2], Despina Sitara[3]. [1]Chiang Mai University, , [2], United States, [3]New York University College of Dentistry, United States

FGF23 is a phosphotropic hormone, mainly produced by osteoblasts/osteocytes, which regulates mineral homeostasis. Recent studies demonstrated that FGF23 is linked to chronic metabolic conditions, including cardiovascular disease, type II diabetes, obesity, and osteoporosis. High circulating levels of FGF23 are positively correlated with greater fat accumulation in obesity and low bone mass in menopausal women, implying a role of FGF23 in energy metabolism and the crosstalk between bone and fat. However, the action of FGF23 in osteoblasts and its role in bone metabolism in obesity have not been demonstrated. We generated osteoblast-specific Fgf23 null mice using Cre recombinase under the control of the mouse collagen type 2.3 (Col2.3) promoter. Male control (Fgf23flox/flox) and knockout (KO, Col2.3CreFgf23flox/flox) mice were fed high fat diet (HFD) (60 %kcal fat) for 24 weeks starting at 8 weeks of age. Body weight and body fat measurements were taken weekly during the 24 weeks of HFD intervention. Serum, femur, and tibiae were collected upon sacrifice. Micro-computed tomography was used to evaluate bone microarchitecture in left femur. Expression of bone- and adipocyte-specific genes in bone and bone marrow were assessed by qRT-PCR. Our data show that bone Fgf23 expression was almost completely abolished (85-90% reduction) in the KO mice. After 24 weeks of HFD, control and KO mice had comparable gain in body weight and percentage of body fat. However, KO mice fed HFD exhibited a higher BV/TV fraction and reduced trabecular separation compared to control mice, and these were associated with a significant decrease in bone and bone marrow mRNA levels of osteoclastic genes such as RANKL and TRAP5. Moreover, osteoblast-specific genes such as Runx2 and osteocalcin were also decreased in the bone and bone marrow of KO mice compared to control mice. Interestingly, expression of PPAR, and TNF-? in bone and bone marrow were significantly decreased in KO mice compared to controls. Together, our data suggest that osteoblastic Fgf23 modulates bone marrow adiposity, inflammation, and bone resorption. In summary, our findings demonstrate for the first time that osteoblast-specific ablation of Fgf23 improves bone mass and alleviates obesity-induced bone loss by regulating bone marrow adiposity and attenuating bone resorption in male mice. Targeting osteoblastic Fgf23 may be a potential strategy for treating metabolic bone disease in obesity.

miR122 regulates FGF23 cleavage in iron deficiency *Jane Joy Thomas[1], JOHN VON DRASEK[2], GUILLAUME COURBON[3], JADAEH SPINDLER[2], Aline Martin[2], Valentin David[1]. [1]Northwestern University, Feinberg School of Medicine, United States, [2]Northwestern University, United States, [3]Center for Translational Metabolism and Health, France

Proteolytic cleavage of intact fibroblast growth factor 23 (iFGF23) yields C-terminal FGF23 peptides (Cter-FGF23) that play a protective role in iron metabolism during acute inflammation. Increased circulating Cter-FGF23 levels are also observed in iron deficiency anemia (IDA) due to simultaneous increase in production and cleavage of intact iFGF23. O-glycosylation of iFGF23 176-RXXR-179 cleavage site by GALNT3 protects iFGF23 from cleavage, but the regulation of GALNT3 in IDA is unknown.We found that IDA increases the expression of miR-122-5p (miR122), which is a predicted inhibitor of Galnt3 expression. We hypothesized that inhibition of GALNT3 by miR122 results in increased iFGF23 cleavage in IDA.Since miR122 is mainly produced by the liver, we generated mice harboring a conditional deletion of miR122 in hepatocytes (miR122cKO) by crossing miR122 floxed mice with mice expressing a Cre recombinase driven by the Albumin promoter. We induced IDA by feeding 3-week-old wild-type (WT) and miR122cKO mice either a control diet (Ctr) or a low iron diet (IDA) for 3 weeks. At 6 weeks of age, we analyzed serum biochemical and hematological parameters as well as bone Galnt3 expression in all mice.Compared to WT-Ctr, miR122cKO-Ctr mice exhibited reduced miR-122 levels, increased bone Galnt3 expression and iFGF23 levels, despite normal total cFGF23. These mice also showed reduced iron levels and transferrin saturation, but normal hemoglobin levels and red blood cells counts. As expected, WT-IDA mice were anemic and showed higher levels of miR122, reduced Galnt3 expression along with a 3.6-fold increase in total cFGF23 compared to WT-Ctr, and a slight but significant increase in iFGF23. Compared to WT-IDA, miR122cKO-IDA mice showed increased Galnt3 expression, total cFGF23 levels and higher iFGF23, resulting in an increased i/cFGF23 ratio, a surrogate marker of FGF23 cleavage. miR122cKO-IDA mice also exhibited further reduced levels of iron and transferrin saturation, but this did not aggravate the severity of anemia in these mice.Our results demonstrate that iron deficiency increases miR122, which inhibits Galnt3 osseous expression and results in increased FGF23 cleavage, elevated Cter-FGF23 but reduced iFGF23. miR122 could be a potential therapeutic target to reduce iFGF23 and thus improve adverse outcomes in diseases associated with iFGF23 excess.

Examining the Role of Zinc Fingers and Homeoboxes 2 (Zhx2) in Chronic Kidney Disease-related Bone & Cardiovascular Health *Jordan Matz[1], Corinne Metzger[3], Huda Mahmood[3], Christopher Miller[3], Arelis Quintana-Martinez[3], Gagandeep Sooch[4], Matthew Allen[3], Erica Clinkenbeard[3]. [1]IU School of Medicine, , [3]Indiana University School of Medicine, , [3]Indiana University School of Medicine, United States, [4]Marian University College of Osteopathic Medicine, United States

Chronic Kidney Disease (CKD) is estimated to affect more than 1 in 7 US adults. CKD-mineral and bone disorder (CKD-MBD), a common sequela, independently leads to vascular calcification, increased fracture risk, and mortality. Mice placed on CKD-inducing 0.2% adenine diet (AD) for 8 weeks show increased cortical bone porosity, osteoclast activity, and marrow adiposity, mirroring human patients. The differentiation skewing between osteoblast and adipocyte in CKD however remains unclear. Zinc finger and homeobox 2 (Zxh2), a transcriptional repressor, was previously shown to be critical for odontoblast differentiation. Further, lack of Zhx2 promotes hepatic steatosis with high fat diet. We hypothesize Zhx2 potentiates osteoblast commitment by inhibiting adipocyte gene expression. We utilized BALB/cJ (/cJ) mice which harbor a hypomorphic mutation in the Zhx2 locus, drastically decreasing Zhx2 mRNA compared to normal BALB/c (/c) mice. AD feeding in both sexes significantly increased serum Blood Urea Nitrogen vs casein control consistent with CKD; however, /cJ mice had significantly lower values than /c mice. On casein, /cJ females exhibited lower trabecular bone volume (Tb.BV/TV; $p<0.01$), reduced Bglap mRNA ($p<0.01$), and increased adipogenic Lpl mRNA ($p<0.05$) vs /c. AD-fed /c females lost Tb.BV/TV and reduced Bglap mRNA comparable to /cJ levels which correlated with reduced bone Zhx2 mRNA vs /c casein. Male /cJ mice exhibited reductions in Bglap (5-fold, $p<0.01$), Alpl (2.5-fold; $p<0.01$), and Dmp1 (2.5-fold, $p<0.01$) mRNA compared to /c on casein, with no differences in Lpl mRNA or trabecular bone parameters. In contrast to females, AD-fed /c males had modestly increased Tb.BV/TV whereas Tb.BV/TV decreased in AD-fed /cJ males. Consistent with CKD, AD-fed /cJ mice exhibited modestly elevated serum phosphate and fibroblast growth factor 23 (FGF23) vs /c mice. Thus, we assessed tissues for downstream calcifications via X-ray. Analysis of isolated hearts showed AD-fed /c mice incurred heart calcifications (2/7 females; 4/6 males), whereas BALB/cJ mice appeared protected (0/8 male and female). In conclusion, Zhx2 is a transcription factor that exhibits influence on outcomes related to CKD and mineral metabolism. Most notably, /cJ mice lacking Zhx2 were protected from cardiac calcification incidence. These results have important implications for patients with CKD-MBD and downstream outcomes related to disrupted mineral metabolism.

Membrane Estrogen Receptor-? Signaling in POMC Neurons is Crucial for Normal Bone Metabolism in Female Mice *Yiwen Jiang[1], Karin Horkeby[1], Jianyao Wu[1], Karin Nilsson[2], PETRA HENNING[3], Sofia Movérare-Skrtic[4], Claes Ohlsson[5], Marie Lagerquist[4]. [1]Sahlgrenska Osteoporosis Centre, Centre for Bone and Arthritis Research at Institute of Medicine, Sahlgrenska Academy at University of Gothenburg, Sweden, Sweden, [2], Sweden, [3]UNIVERSITY OF GOTHENBURG, Sweden, [4]Medicine, Sweden, [5]Center for Bone and Arthritis Research at the Sahlgrenska Academy, Sweden

Estrogen receptor-? (ER?) signaling in the central nervous system is involved in the regulation of bone metabolism1,2. We have previously shown that deletion of ER?, specifically in proopiomelanocortin (POMC) neurons, increases bone mass and mechanical strength3. We and others have also revealed that membrane-initiated estrogen receptor-? (mER?) signaling plays an important role in regulating estrogenic effects in bone. However, it remains unknown whether mER? signaling in POMC neurons is involved in mediating estrogenic effects in bone.For this purpose, we have generated a novel ER?-C451Aflox/flox mouse

model (C451Af/f) in which the C451A mutation disables the membrane localization of ER?. C451Af/f mice were mated with POMC-Cre mice to breed POMC-C451A mice, lacking mER? signaling in POMC-expressing neurons, and homozygous C451Af/f littermate controls.Phenotyping at 16 weeks of age showed multiple changes between POMC-C451A mice (n=8) and C451Af/f littermate controls (n=9). Areal bone mineral density (BMD), measured by DEXA, was significantly increased in POMC-C451A mice (total body, +5%, p<0.001; lumbar spine, +16%, p<0.001). Cortical thickness and trabecular BMD, measured by pQCT, were increased in long bones (cortical thickness: femur, +13%, p<0.001, tibia, +13%, p<0.001; trabecular BMD: femur, +32%, p<0.05, tibia, +29%, p<0.001). In addition, cortical bone in vertebrae L5 and bone volume fraction (BV/TV), measured by ?CT, were also increased in POMC-C451A mice compared with controls (BV/TV: +37%, p<0.001; cortical thickness: +18%, p<0.01). Uterus weight was unaffected in POMC-C451A mice, suggesting normal sex steroid feedback regulation.In conclusion, our study emphasizes the inhibitory effect of neuronal ER? signaling on bone mass, in contrast to the stimulatory bone effects by peripheral ER? signaling. This demonstrates that mER? signaling in POMC neurons plays an important role in this negative regulation of bone mass.Reference1. Herber CB, et al. Nat Commun, 2019.2. Ohlsson C, et al. FRI-058

L- ?-aminoisobutyric Acid (L-BAIBA) Treatment Enhances Musculoskeletal Properties in Combination with Voluntary Wheel Running Exercise in Male Mice *Julian Vallejo[1], Yukiko Kitase[2], Thiagarajan Ganesh[3], Mark Dallas[4], Yixia Xie[4], Mark Johnson[5], Lynda Bonewald[6], Michael Wacker[7]. [1]University of Missouri-Kansas City, School of Medicine, United States. [2]Indiana University, School of Medicine, United States. [3]University of Missouri-Kansas City, School of Science and Engineering, United States. [4]University of Missouri-Kansas City, School of Dentistry, United States. [5]University of Missouri, Kansas City Dental School, United States. [6]Indiana University School of Medicine, United States. [7]University of Missouri-Kansas City School of Medicine, United States

L-BAIBA is a metabolite secreted from contracting skeletal muscle. Exercise is commonly known to produce system-wide benefits and L-BAIBA appears to play a role in this process. In addition to metabolic homeostasis, recent studies suggest that L-BAIBA may also promote cardiac health and maintenance of bone. We have shown that L-BAIBA treatment in mice prevents musculoskeletal decline during chronic disuse. However, the effects of L-BAIBA on musculoskeletal and cardiac tissue in exercising mice are unknown. Therefore, we hypothesized that the combination of exercise with L-BAIBA treatment would promote greater benefits than exercise alone. Male 12 month old C57BL6 mice performed voluntary wheel running (VWR) with L-BAIBA treatment (VWR+L-BAIBA; n=7), VWR only (n=9), L-BAIBA only (n=8), or none (control; n=8) for three months. L-BAIBA was supplied in the drinking water (100 mg/kg/day). At the end of the study, hearts had no significant differences in conscious electrocardiogram parameters or size between groups. In bone, VWR had no significant effect alone, however VWR+L-BAIBA maintained higher trabecular thickness (VWR+L-BAIBA: 0.043+/-0.01 vs Control: 0.035+/-0.00mm, p<0.05) and connectivity (VWR+L-BAIBA: -3.7+/-1.4 vs Control: -1.3+/-1.5mm-1, p<0.05). Although VWR+L-BAIBA showed smaller bone diameter (VWR+L-BAIBA: 2.2+/-0.1 vs VWR: 2.5+/-0.2mm, p<0.05) thereby lower Moment of Inertia (VWR+L-BAIBA: 0.20+/-0.02 vs VWR: 0.24+/-0.02mm4, p<0.05), tibia mechanical testing revealed higher Modulus of Elasticity (VWR+L-BAIBA: 4.77+/-0.36 and L-BAIBA: 4.78+/-0.36 vs VWR: 4.13+/-0.43GPa, p<0.05), suggesting L-BAIBA retains better bone material properties. Therefore, the VWR+L-BAIBA required less compensatory periosteal expansion, which resulted in no differences in biomechanical properties of Elastic Stiffness among groups. VWR+L-BAIBA showed lower femoral bone marrow adipose compared to control (VWR+L-BAIBA: 0.03+/-0.03 vs Control: 0.08+/-0.03mm2, p<0.05). Soleus skeletal muscles from VWR+L-BAIBA mice were significantly larger (VWR+L-BAIBA: 10.4+/-1.0 vs Control: 12.3+/-0.7mg, p<0.05) and contracted with more force (VWR+L-BAIBA: 301.2+/-37.6 vs Control: 263.6+/-19.1mN, p<0.05). In EDL muscle VWR improved fatigue resistance and recovery from fatigue (p<0.01) while VWR+L-BAIBA did not. These findings suggest a physiological interaction between exercise and L-BAIBA to enhance bone structural and material qualities, prevent an increase in bone marrow adipose, and improve muscle mass and strength.

Fluid Flow Shear Stress Bone Conditioned Media Increases Intracellular Cardiomyocyte Calcium *Anuhya Dayal[1], Julian Vallejo[2], Nuria Lara-Castillo[3], Mark Johnson[3], Michael Wacker[2]. [1]University of Missouri - Kansas City, School of Medicine , United States. [2]University of Missouri - Kansas City, School of Medicine , United States. [3]University of Missouri - Kansas City, School of Dentistry, United States

Bone is a dynamic organ, serving countless endocrine functions in the body. As fluid flows through bone, via the lacunar-canalicular system and interstitially, it generates fluid flow shear stress (FFSS). FFSS variably stresses osteocytes, impacting the subsequent cytokines and endocrine factors released.We previously demonstrated that administration of FFSS osteocyte conditioned media (CM) to murine whole hearts increased both peak force and area under contractile waveforms by approximately 25% (p<0.01, n=6-7). Here, we aim to elucidate the cellular signaling for this response. Cardiomyocyte calcium (Ca2+) release is widely established as one of the primary mechanisms for increasing cardiac contractility. Thus, we hypothesized that FFSS CM administration to cardiomyocytes will increase intracellular Ca2+ levels. Cultured H9C2 cardiomyocytes were differentiated for 7 days at 37oC then stained with fluo-8 AM (Ca2+ indicator dye). Blank (control) and FFSS conditioned media obtained from osteocyte-like MLOY4 cultured cells were perfused over the H9C2 cells both with and without electrical pacing (1 Hz). Intracellular fluorescence was monitored for 20 min, with perfusion in this order: 5 min Ringer's solution (baseline), 7 min 7.5% FFSS media or 7.5% blank media, 7 min 2.5 mM KCl (positive control). For analysis, fluorescence was reported as a percentage of KCl response.We observed an increase in intracellular Ca2+ with FFSS CM perfusion of cardiomyocytes compared to control; average cell Ca2+ levels after FFSS CM were 72 +/-21% of its max response (KCl) and blank was 28 +/- 11% (p=0.01; n=4 series; 20-30 cells/series). Not only did the magnitude of intracellular Ca2+ increase with FFSS osteocyte CM, but the number of cells demonstrating elevated Ca2+ also increased 1.4-fold (p<0.0001). Interestingly, these increases were absent in experiments without pacing (p=0.001, n=16 series, 20-30 cells/series).Our findings strongly indicate a connection between osteocyte FFSS CM increasing cardiomyocyte Ca2+ as a mechanism to increase cardiac contractility. These effects were only observed with electrical pacing; thus, it is likely that bone factors in FFSS CM sensitize or activate targets such as voltage-gated Ca2+ channels. These conclusions further elucidate bone-heart crosstalk and provide significant, exciting data supporting our hypothesis that bone release factors that impact the heart, indicating implications for cardiovascular health in exercise and aging.

FRI-061

Deletion of Fra1 in osteoblasts by Runx2-Cre causes a reduced adipose tissue mass *Julia Luther[1], Mona Neven[1], Olga Winter[1], Lana Rosenthal[1], Michael Amling[1], Jean-Pierre David[1], Thorsten Schinke[1]. [1]Institute for Osteology and Biomechanics (IOBM), University Medical Center Hamburg-Eppendorf, Hamburg, Germany, Germany

The activator protein-1 (AP-1) transcription factor family member Fra1 has been described to cause increased bone mass and decreased adipose tissue mass when ubiquitously overexpressed in mice. Epiblast-specific deletion of Fra1 by More-Cre, conversely, caused osteopenia due to a decreased bone formation rate. In vitro experiments with primary calvarial osteoblasts showed a reduced mineralizing activity. Osteoclast number and activity was not affected in vivo, however, osteoclasts showed a differentiation defect in vitro.To analyse the cell autonomous phenotype in vivo, we generated mice with an osteoclast- or an osteoblast-specific deletion of Fra1 (Fosl1) using LysM-Cre and Runx2-Cre, respectively. Deletion of Fra1 specifically in osteoclasts did not lead to a change in trabecular bone mass in 12-week- or in 1-year-old LysM-Cre;Fra1fl/fl mice compared to control animals (14.23+/-3.49% (control) versus 12.85+/-2.733% (LysM-Cre;Fra1fl/fl) at the age of 1 year). In addition, osteoclast number per bone perimeter was not affected in young mice (N.Oc/B.Pm: 4,307+/-1,86mm-1 (control) versus 4,928+/-1,42mm-1 (LysM-Cre;Fra1fl/fl)), confirming that Fra1 is not necessary for osteoclast differentiation in vivo. When deleting Fra1 in osteoblasts no significant change in bone mass was observed in 12-week as well as 1-year-old Runx2-Cre;Fra1fl/fl compared to control mice (15.53+/-2.243% (control) versus 13.36+/-0.7766% (Runx2-Cre;Fra1fl/fl) at the age of 1 year). Furthermore, the number of osteoblasts was unchanged in 12-week-old mice (N.Ob/B.Pm: 32,24+/-6,54mm-1 (control) versus 39,38+/-9,66mm-1 (Runx2-Cre;Fra1fl/fl)). However, we could observe a significantly reduced adipose tissue mass accrual in mice with an osteoblast-specific deletion of Fra1, accompanied by a lack of increase in adipocyte cell diameter in 1-year-old Runx2-Cre;Fra1fl/fl mice. Thus, Fra1 expression in Runx2-Cre positive pre-osteoblasts regulates adipose tissue metabolism. In contrast, the bone-anabolic function might be driven by Fra1 expression in early mesenchymal osteoblast progenitors rather than in committed pre-osteoblasts.

Spatial histomorphometry reveals that local peripheral nerves modulate but are not required for skeletal adaptation to applied load *ALEC BEEVE[1], Anna Li[2], MOHAMED HASSAN[1], Matthew Silva[3], Erica Scheller[2]. [1], . [2]Washington University, United States. [3]Washington University in St. Louis School of Medicine, United States

Mechanical loading is required for bone health and results in skeletal adaptation to optimize strength. Local nerve axons, particularly within the periosteum, may respond to load-induced biomechanical and biochemical cues. However, their role in the bone anabolic response remains controversial. We hypothesized that spatial alignment of periosteal nerves with sites of load-induced bone formation in both intact and denervated conditions would clarify this relationship. To achieve this, we developed RadialQuant, a new custom tool for spatial histomorphometry. Tibiae of control and neurectomized (sciatic/femoral nerve cut) pan-neuronal Baf53b-tdTomato reporter mice were loaded with a 5-day regimen to induce lamellar bone formation prior to analysis after 6-days. Mineralizing surface (MS), mineral apposition rate (MAR), bone formation rate (BFR), bone area, cortical thickness, and periosteal nerve axon density were quantified simultaneously in non-decalcified sections of the

mid-diaphysis using RadialQuant. In control animals, anabolic loading induced maximal periosteal bone formation at the site of peak compression, as has been reported previously. Loading did not significantly change overall periosteal nerve density. However, a trending 28% increase in periosteal axons in loaded limbs was noted at the site of peak compression, possibly indicating subtle, local nerve sprouting after applied load. Neurectomy depleted 88% of all periosteal axons, with near-total depletion on load-responsive surfaces. Neurectomy alone also caused de novo bone formation on the lateral aspect of the mid-diaphysis. However, neurectomy did not inhibit load-induced increases in periosteal bone area, MS/BS, MAR, or BFR. Rather, neurectomy spatially redistributed load-induced bone formation towards the lateral tibial surface. This spatial shift resulted from reduction in periosteal bone formation indices at the site of peak compression (-38-63%) and enhancement of indices of skeletal adaptation at the lateral surface (+70-1300%), altogether contributing to comparable load-induced changes in total bone area (+5.5% with load in control mice; +8.9% with load in neurectomized animals). Our results show that local skeletal innervation modulates but is not required for skeletal adaptation to applied load. This supports the continued use of loading and weight-bearing exercise as an effective strategy to increase bone mass, even in patients with peripheral nerve damage or dysfunction.

IL-34 mediated osteolysis exacerbates pathogenic features of Alzheimer's disease *Anny Ho[4], CHIAKI YAMADA[2], Bidii Ngala[3], Amilia Nusbaum[3], Carolina Duarte[4], Juliet Akkaoui[5], Christopher Michael Garcia[6], William Kochen[4], Alexandru Movila[3]. [4]Nova Southeastern University, United States. [2], . [3]Indiana University School of Dentistry, United States. [4]Nova Southeastern University, . [5]Florida International University, United States. [6]Indiana University School of Medicine, United States

Alzheimer's disease (AD) is characterized by progressive neurodegeneration and a gradual decline in memory and cognitive functions. The hallmark features of AD are associated with elevated accumulation of aggravated amyloid beta (A?) peptides, hyperphosphorylated Tau (p-Tau), and neuroinflammation. Emerging evidence indicated that inflammatory osteolysis exacerbates AD neurodegeneration and neuroinflammation via unknown molecular mechanisms. Signaling through the colony-stimulating factor-1 receptor (CSF-1r) is critical for maintaining the physiological and pathological signaling of blood myeloid cells and microglia. CSF-1r is activated by macrophage colony-stimulating factor-1 (M-CSF) and interleukin-34 (IL-34). While the impact of M-CSF in bone physiology and pathology is well addressed, it remains controversial whether IL-34-mediated bone osteolysis promotes AD neuroinflammation and neurodegeneration. Surprisingly, we observed that IL-34 plays a critical role in inflammatory osteolysis in wild-type mice. To evaluate the effects of IL-34 on AD cognitive behavioral phenotype and neuroinflammation, female and male triple transgenic 3x-Tg AD mice and corresponding control were randomly divided into two experimental groups (10 mice/sex/group). Mice were subcutaneously injected with 100 µl of mouse recombinant IL-34 protein solution in PBS or PBS alone over the calvaria bone every other day for 42 days. In addition, we compared the effects of IL-34 and M-CSF on macrophages, microglia, and RANKL-mediated osteoclastogensis in relation to AD pathology. This study demonstrated that local calvaria injection of recombinant IL-34 protein dramatically elevated AD-like memory loss, pathogenic amyloidogenesis, p-Tau, and neuroinflammation-associated RAGE expression in female 3x-Tg mice. Furthermore, IL-34 promoted calvaria inflammatory osteolysis compared to the sham control injected group of female and male mice. Our data also indicated that IL-34-microglia and bone-marrow-derived macrophages isolated from 3x-Tg mice released significantly higher amounts of pro-inflammatory cytokines, TNF-?, IL-1?, and IL-6, compared to M-CSF-proliferated cells in vitro. In addition, IL-34 elevates RANKL-primed osteoclastogenesis in the presence of key AD-associated A?40 and A?42 peptides. Therefore, our data indicated that a novel therapeutic regimen targeting IL-34 could suppress neuroinflammation, neurodegeneration, and elevated bone loss observed in patients with AD.

Crohn's and Bones: Examining Bone Quality using HR-pQCT *Rachel E. Klassen[1], Aysha J. Macci[2], Cathy Lu[3], Lauren A. Burt[1], Steven K. Boyd[1]. [1]McCaig Institute for Bone and Joint Health , Canada. [2]Division of Gastroenterology and Heptaology, Canada. [3]Division of Gastroenterology and Hepatology, Canada

Introduction: Crohn's Disease (CD) negatively affects bone density through factors including diet and physical activity changes, steroid use, bowel resections, and disease mediated inflammatory pathways. Two problems prevent the optimization of skeletal health in individuals with CD: 1) inadequate knowledge of the mechanisms underpinning skeletal fragility associated with CD, and 2) the failure to identify individuals with CD who are at risk for low bone mineral density (BMD). Using high resolution peripheral quantitative computed tomography (HR-pQCT) and dual X-ray absorptiometry (DXA), the aims of this study were to determine differences in bone quality, quantity, and strength between controls and individuals with CD, and within the CD group between inflammatory and fibrostenotic CD phenotypes. Methods: Male and female participants aged 55 years and over were recruited. HR-pQCT scans at the radius and tibia were obtained in addition to standard DXA analysis of the hip and spine. Controls were age, sex, and body mass index matched at a 1:1 ratio. Blood work, health history questionaires, and medical chart review captured various health history and disease severity data. An estimate of strength was determined using finite element analysis. A measure of the void spaces from HR-pQCT was conducted and statistical analyses compared group differences. Results: A total of 45 CD and 45 controls were recruited. Significant differences in density, microarchitecture, and geometry parameters were found between controls and the CD group. A sub-analysis found additional differences between inflammatory versus fibrostenotic CD phenotypes. Overall, the CD and fibrostenotic groups had weaker, less dense, and poorer bone microarchitecture than the control and inflammatory groups. Void spaces were more prevalent, appearing 48% of the time at the radius and 39% of the time at the tibia in the CD group (Figure 1). Conclusions: Pathological endosteal resorption may explain the bone microarchitecture observed in the CD group; this is enhanced in the fibrostenotic group. Our future work will examine lifestyle factors, disease severity, CD treatment type, and time since diagnosis. Earlier identification and diagnostic evaluation from HR-pQCT data combined with known risk factors for low BMD may allow for more timely preventative medical therapy.

Bariatric Surgery is Associated with Increased Fracture Risk Among Veterans *Eileen H. Koh[1], Tiffany Y. Kim[2], Hui Shen[2], Mary A. Whooley[2], Matthew L. Maciejewski[3], Theodore S. Z. Berkowitz[4], Valerie Smith[3], Lygia Stewart[2], Anne L. Schafer[2]. [1]University of California, San Francisco, United States. [2]University of California, San Francisco and San Francisco Veterans Affairs Health Care System, United States. [3]Durham Veterans Affairs Health Services Research and Development and Duke University, United States. [4]Durham Veterans Affairs Health Services Research and Development, United States

Despite its metabolic and mortality benefits, bariatric surgery has negative skeletal effects. The Roux-en-Y gastric bypass (RYGB) procedure is associated with increased fracture risk in the general bariatric surgery population, who are predominantly premenopausal women. It is unclear whether postoperative fracture risk is increased in men, and whether patients with obesity who undergo sleeve gastrectomy (SG), now the most commonly performed procedure, are more likely to fracture than nonsurgical patients. We compared fracture risk among US Veterans who underwent bariatric surgery from 2000-2020 at a Veterans Affairs (VA) facility or paid for by VA and matched Veterans with obesity who did not have surgery. Surgical patients were matched 1:3 to nonsurgical patients by age, sex, year, and pre-op BMI. We used ICD codes to capture incident fracture from VA electronic health records, VA purchased care claims, and Medicare claims. Cox proportional hazards models were used to determine the relationship between bariatric surgery and subsequent fracture risk. Our surgical cohort, comprised of 8357 patients [3182 RYGB, 4168 SG, 291 adjustable gastric banding (AGB)], was 70% men with mean age 52+/-10 years and BMI 45+/-7 kg/m2. Compared to 25,057 matched Veterans who did not have surgery, surgical patients had higher baseline rates of obesity-related comorbidities including diabetes (48% vs 36%). During an average 7 years follow-up, surgical patients had higher rates of incident fracture (25.1 vs 13.9 per 1000 person-years). Bariatric surgery was associated with a 67% increased risk of incident fracture (HR 1.67, 95% CI 1.56-1.79, p<0.001) after adjustment for race/ethnicity, geographic location, and comorbidities. Bariatric surgery was also associated with incident hip fracture (HR 2.42, 95% CI 1.97-2.96, p <0.001), spine fracture (HR 1.81, 95% CI 1.60-2.05, p<0.001), and radius fracture (HR 2.36, 95% CI 2.03-2.75, p< 0.001). Compared to matched controls, RYGB was associated with increased risk of fracture (HR 1.91, 95% CI 1.73-2.11, p<0.001), as was SG (HR 1.48, 95% CI 1.31-1.67, p<0.001), but there was no difference in fracture rates between RYGB and SG (p=0.18). There was no evidence for an association between AGB and fracture risk (HR 0.97, 95% CI 0.68-1.40, p=0.88). Our findings show that RYGB and SG are associated with increased risk of fracture in this Veteran population of predominantly older men, including at major osteoporotic fracture sites.

Impact of Osteoporosis Pharmacotherapy on Functional Outcomes after Ischemic Stroke *So Young Park[1], Sang-Hwa Lee[2]. [1]Division of Endocrinology and Metabolism Department of Internal Medicine, Kyung Hee University College of Medicine, , Republic of Korea. [2]Department of Neurology, Chuncheon Sacred Heart Hospital, Hallym University College of Medicine, Republic of Korea

Purpose: This study evaluated whether osteoporosis pharmacotherapy (OPT) affects functional outcome in acute ischemic stroke patients with osteoporosis.Methods: Using a single-center registry database, we consecutively registered acute ischemic stroke patients between May 2016 and December 2020. All patients older than 55 years underwent routine bone densitometry within 7 days of stroke onset. OPT prescription was confirmed by reviewing medical records. We classified the patients into OPT and no OPT groups. We performed propensity score matching (PSM) to overcome the imbalance in multiple covariates between the two groups. We investigated whether OPT affects 1-year functional outcomes by multivariate analysis using PSM cohort.Results: Among 1,307 consecutively registered acute ischemic stroke patients, 381 patients were enrolled in this study, of whom 134 (35.2%) were prescribed OPT at discharge, which was maintained for 1 year. In multivariate analysis using PSM cohort. the OPT group had a lower risk of dependency (odds ratio [OR], 0.52; 95% confidence interval [CI], 0.27-0.996) and poor functional outcome at 1 year (OR, 0.24; 95% CI, 0.10-0.57). The OPT group also had increased chance of late functional improvement (OR, 6.16; 95% CI, 1.12-33.79).Conclusion: This study showed that OPT could reduce dependency and poor functional outcome and increase the chance of improving functional outcome at 3 months and 1 year after ischemic stroke onset, and these findings could be helpful for improving functional outcomes and bone health after ischemic stroke.?

Fractures and JAK-inhibitors: Evidence of a Safety Signal from the WHO Global Pharmacovigilance VigiBase Data *Andreas Clausen[1], Adrian Martinez-De la Torre[1], Andrea Burden[2], Stefan Weiler[1]. [1]Swiss Federal Institute of Technology (ETH) Zurich, Institute of Pharmaceutical Sciences, Switzerland. [2]Swiss Federal Institute of Technology (ETH) Zurich, Switzerland

Background: The Janus Kinase (JAK) inhibitors are promising new treatments for inflammatory rheumatic diseases. However, numerous safety concerns have been raised. Most recently, the European Medicines Agency (EMA) updated the warning to include an elevated risk of fractures for tofacitinib, but not upadacitinib or baricitinib.Objective: We conducted a global pharmacovigilance analysis of tofacitinib, upadacitinib, and baricitinib to describe and evaluate the safety signal for fractures.Methods: Individual case safety reports (ICSRs) for tofacitinib, upadacitinib, and baricitinib were identified from the World Health Organization (WHO) global pharmacovigilance database, VigiBase on March 14 2023. The primary outcome of interest was a bone fracture (excluding tooth and avulsion fractures). ICSR demographics were summarized overall and among those with a fracture. A disproportionality analysis using reporting odds ratios (RORs) and 95% confidence intervals (CIs) evaluated the reporting of a bone fracture with one of the JAK-inhibitors compared to all other drugs in the VigiBase, during the same period.Results: We identified 122,037 ICSRs for tofacitinib, 27,786 ICSRs for upadacitinib, and 14,616 ICSRs for baricitinib between 2011 and 2023. Among the ICSRs, we identified 2,202 (1.8%), 634 (2.3%), and 144 (1.0%) reports where a bone fracture was reported for tofacitinib, upadacitinib, and baricitinib, respectively. ICSR characteristics are provided in Table 1. Those with a bone fracture, were more often female, older, and had a higher number of co-reported medications (Table 1). ICSRs with a fracture had a higher reported prevalence of glucocorticoids, opioids, and bisphosphonates. All JAK-inhibitors were associated with increased reporting for fracture (Table 1): tofacitinib (ROR 3.39, 95% CI 3.25 - 3.53), upadacitinib (ROR 4.28, 95% CI 3.95 - 4.63), baricitinib (ROR 1.82, 95% CI 1.54 - 2.14).Conclusion: While a warning for fractures is only included for tofacitinib, the results from this global pharmacovigilance analysis identified elevated reporting of fractures with tofacitinib, upadacitinib, and baricitinib. However, ICSRs with fractures were older and more likely to have other drugs that may indicate a baseline fracture risk reported. Therefore, further causality assessment is required.

Comparative effects of antihypertensive medications on fracture risk in elderly patients with hypertension *Seung Shin Park[3], Hanna Jang[2], Sung Hye Kong[3], Hyunmook Jeong[3], Siyeon Yi[3], Seung Hun Lee[4], Jeonghoon Ha[5], Kwangsoo Kim[3], Jung Hee Kim[3], SANG WAN KIM[6], Chan Soo Shin[7]. [3]Seoul National University Hospital, Korea, Democratic People's Republic of. [2]Seoul National University Bundang Hospital, Korea, Democratic People's Republic of. [3]Seoul National University Hospital, Republic of Korea. [4]Asan Medical Center, Korea, Democratic People's Republic of. [5], Republic of Korea. [6]Seoul National University College of Medicine, Boramae Medical Center, Republic of Korea. [7]Seoul National University College of Medicine, Republic of Korea

Background:Hypertension and osteoporosis commonly coexist in the elderly, and some antihypertensive medications have been reported to potentially lower the risk of fractures. However, there is limited data comparing the effects of different antihypertensive agents and their combinations on fracture risk. We aimed to investigate the individual and combined effects of antihypertensive drugs on fracture risk in this study.Methods:A total of 28,247 patients who received antihypertensive medications for at least one year between 2008 and 2012 at Seoul National University Hospital were retrospectively reviewed using common data model. Patients were categorized into groups based on their antihypertensive medication use: antiotensin receptor blocker (ARB), calcium channel blocker (CCB), beta blocker (BB), ARB with CCB, ARB with BB, ARB with thiazide, CCB with BB, and ARB with BB and thiazide, for the purpose of analysis. Fracture risks, defined as major osteoporotic fractures (MOFs), vertebral fractures (VFs), and hip fractures (HFs), were analyzed using the Cox proportional hazard model with adjustments made for age, sex, body mass index, previous history of fractures, secondary osteoporosis-related conditions, diabetes mellitus, drug use, and the use of osteoporosis medications.Results:The number of patients using ARB, CCB, BB, ARB with CCB, ARB with BB, ARB with thiazide, CCB with BB, and ARB with BB and thiazide were 5,515, 7,514, 4,940, 5,022, 1,055, 1,965, 1,874, and 362, respectively. Among the total patient population, females accounted for 50.6%, and the average age and BMI were 65.8 years and 24.5 kg/m2, respectively. Compared to the CCB group, the BB group showed a significantly increased risk of osteoporotic fractures (MOFs) and vertebral fractures (VFs) (Hazard ratio (HR) 1.24, 95% confidence interval (CI) [1.01, 1.52] for MOFs; HR 1.40, 95% CI [1.08, 1.91] for VFs). In contrast to the BB group, the ARB with BB group and ARB with BB and thiazide groups demonstrated decreased HRs for VFs of 0.51 and 0.29, respectively (95% CI [0.28, 0.94] and [0.09, 0.93]). No significant differences in fracture risk were observed between the ARB monotherapy group and the ARB with BB, ARB with CCB, or ARB with thiazide groups (HR 1.07, 1.03, and 0.87 respectively). Conclusion:In hypertensive patients with concomitant osteoporosis, prioritizing the use of ARB and thiazide over BB when selecting medications may help reduce the risk of fractures.

Associations Between the Changes in Gut Microbiota and Bone and Muscle Outcomes After Sleeve Gastrectomy *Angela Yang[1], Julie-Catherine Coll[2], Thibault Varin[3], Serge Simard[3], Suzanne Morin[4], Fabrice Mac-Way[5], André Tchernof[6], Bettina Willie[4], Stéfane Lebel[7], André Marette[3], Claudia Gagnon[8]. [1]Universite Laval, , [2]CHU de Québec Research Centre, Quebec Heart and Lung Institute Research Centre, Canada. [3]Quebec Heart and Lung Institute Research Centre, Canada. [4]McGill University, Canada. [5]CHU de Québec Research Centre, Department of Medicine, Laval University, Canada. [6]Quebec Heart and Lung Institute Research Centre, Department of Medicine, Laval University, Canada. [7]Quebec Heart and Lung Institute Research Centre, Department of Surgery, Laval University, Canada. [8]CHU de Quebec, Universite Laval, Canada

The mechanisms leading to bone and muscle loss after sleeve gastrectomy (SG) remain unclear. We aimed to determine whether changes in the gut microbiota following SG are associated with this bone and muscle loss.This is an exploratory analysis of a multicentre prospective cohort study, in which 70 participants with severe obesity had the following parameters measured before and one year after SG: lumbar spine, total hip, and femoral neck areal bone mineral density (aBMD) and whole-body lean mass by dual-energy X-ray absorptiometry; lumbar spine, total hip, femoral neck, tibia, and radius volumetric BMD (vBMD), bone strength (maximum cross-sectional moment of inertia [CSMI] and maximum section modulus [Z]), and mid-femur muscle cross-sectional area by quantitative computed tomography; serum bone turnover markers (C-terminal crossed-linked telopeptide of type 1 collagen [CTX], procollagen type 1 N-terminal propeptide [P1NP], osteocalcin); lower limb absolute and relative muscle strength by isometric dynamometry. Gut microbiota from stool samples was analyzed by 16S rRNA gene sequencing at baseline and one year after SG. Results are presented as percentage or mean+/-SD. Linear regression analyses adjusted for age and sex were used to assess the associations between microbial, bone, and muscle parameters.A preliminary sample of 19 participants (79.0% women [26.7% postmenopausal], 57.9% with type 2 diabetes, mean age 45.3+/-9.5 years, mean BMI 40.1+/-0.6 kg/m2 at baseline) was analyzed. One year after SG, weight (-26.3+/-6.1%), aBMD (-6.4 to -8.5% depending on skeletal sites), vBMD (-1.0 to -7.4% depending on skeletal sites), whole-body lean mass and mid-femur muscle cross-sectional area as well as lower limb absolute muscle strength all decreased significantly (Table). Bone strength parameters did not change. All serum bone turnover markers increased significantly. Alpha diversity, represented by Shannon (p=0.04) and Simpson (p=0.02) indices, increased significantly while beta microbial diversity did not change (p=0.60).In this preliminary sample, significant associations were identified between bacteria genera and some bone parameters, but not between microbial and muscle parameters. Further analysis of the additional participants is ongoing to confirm that associations observed between gut microbiota composition and bone outcomes after SG persist in the larger cohort.

Treatment With Monthly Romosozumab Injections Increases Areal Bone Mineral Density at the Lumbar Spine and Hip in Women With Chronic Spinal Cord Injury *W. Brent Edwards[1], Laura E. Crack[1], Tudor Muresan[1], Narina Simonian[2], Thomas J. Schnitzer[2]. [1]University of Calgary, Canada. [2]Northwestern University Feinberg School of Medicine, United States

Sublesional bone loss is a known complication of spinal cord injury (SCI) with low bone mineral density (BMD) and increased fracture risk persisting into the chronic phase of injury. While existing literature focuses on pharmaceutical treatment options to prevent bone loss in acute SCI, limited investigations have examined potential therapies to increase BMD in chronic SCI. Romosozumab, a monoclonal antibody that inhibits sclerostin, has illustrated significant bone growth in pre-clinical models and among able-bodied post-menopausal clinical populations. The purpose of this study was to examine the efficacy of romosozumab to increase BMD in women with chronic SCI and an inability to ambulate. Twelve women with a mean (SD) age of 45.4 (9.1) years and injury duration of 15.1 (11.2) years, were administered monthly subcutaneous injections of romosozumab (210 mg) for one year. Areal BMD of the lumbar spine and hip (total hip and femoral neck) were measured at baseline and after 6 and 12 months using dual energy x-ray absorptiometry (DXA). The study is on-going and currently nine of the 12 participants have completed all aforementioned data collection. A preliminary analysis was conducted using longitudinal mixed-effects models to examine the effect of one year of romosozumab treatment on DXA-derived areal BMD measures. Areal BMD at the lumbar spine significantly increased ($p<0.001$) by an average of 6.1 (3.6)% and 9.3 (3.1)% after 6- and 12-months, respectively (Fig. 1). DXA-derived BMD at the total hip increased ($p<0.001$) with average gains of 2.2 (2.6)% and 4.1 (3.1)% after 6- and 12-months, respectively. Results were similar when isolating the femoral neck ($p=0.014$), which increased by an average of 1.8 (6.9)% at 6-months and 4.6 (4.9)% at 12-months. These results are comparable to the treatment efficacy of romosozumab for post-menopausal osteoporosis, which induced an annual increase in areal BMD of approximately 17% at the lumbar spine and 5% at the hip1. These preliminary findings demonstrate that treatment with romosozumab in women with chronic SCI increases areal BMD at the lumbar spine and hip, similar to effects in post-menopausal osteoporosis in able-bodied women. On-going data collection in this clinical trial will lead to further analysis with a larger sample size, and evaluation of bone mineral at the knee and hip using computed tomography.[1] Ishibashi H et al. (2017). Bone. 103:209-215

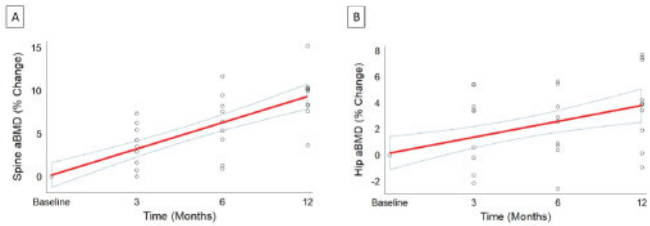

Figure 1. Individual (n=9) and average (95% CI) percentage change in lumbar spine (A) and total hip (B) areal bone mineral density (aBMD) throughout 12 months of treatment with subcutaneous injections of romosozumab (210 mg)

IL-4 Protects the Male Mouse from Age-Associated Trabecular Bone Decline, While IL-4 Deficiency May Contribute to Bone Loss and Fracture in People Living With HIV. *Sadaf Dabeer[1], Daiana Weiss[1], Tatyana Vikulina[1], Ashish Tripathi[1], Ajay Chawla[2], Ighovwerha Ofotokun[3], M. Neale Weitzmann[4]. [1]Emory University, United States. [2]University of California, United States. [3]The Grady Healthcare System, United States. [4]Emory University School of Medicine, United States

HIV infection leads to bone loss in People living with HIV (PLH). This is aggravated by antiretroviral therapy (ART), resulting in high rates of fractures in PLH. The mechanisms driving HIV-induced bone loss prior to ART are multifactorial, and incompletely delineated. IL-4, a potent inhibitor of osteoclastogenesis and bone resorption, is secreted by CD4+ Th2 cells. As CD4 T cells are depleted in HIV infection, we hypothesized that an ensuing decline in IL-4 levels in PLH, may contribute to bone loss. We thus quantified IL-4 in PLH prior to ART and in uninfected controls and found a significant decline in serum levels of IL-4. Furthermore, serum levels of IL-4 were significantly, inversely associated with serum CTX, a marker of bone resorption. To further investigate the effect of IL-4 deficiency on bone, we used prospective in vivo μCT to phenotype the skeletons of male and female WT control and IL-4 knockout (KO) mice, from 2 to 20 months of age. The data revealed a significant decrease in BV/TV and bone structure indices, in both male and female IL-4 KO mice at 10 months of age. Between 6 and 20 months of age, female WT and IL-4 KO mice underwent age associated bone loss that was exacerbated in female mice between 6 and 10 months but resolved at later timepoints. By contrast, BV/TV was stable in WT male mice between 6 and 20 months, while IL-4 KO male mice underwent significant progressive bone loss. The data highlight an important sex difference and suggest that IL-4 may protect the male skeleton from age-related declines in trabecular bone. To further explore the mechanisms of

IL-4 action in vivo, mice with a conditional deletion of the IL-4 receptor alpha (IL-4R?) in the monocyte/osteoclast lineage, were generated by crossing IL-4R? floxed mice with LysM-Cre mice. The conditional deletion of IL-4 signaling in the monocyte/osteoclast lineage resulted in a significant decline in BV/TV and in structural indices in both male and female mice at 10 months of age, implicating the monocyte/osteoclast-cell lineage as major target cells of IL-4 in vivo. Overall, the data suggest that IL-4 may play a crucial role in protecting the male skeleton from age-related trabecular bone loss. The data further support the hypothesis that a decline in IL-4 due to HIV infection, may contribute to increased bone loss and fracture risk in PLH. Therefore, IL-4 could be a novel potential biomarker and therapeutic target for reversing HIV and age-related bone loss.

Mechanisms of the Anti-Anabolic Action of Progranulin from Transcriptional Profiling *Robert Nissenson[1.] [1]VA Medical Center and University of California, San Francisco, United States

Deficient bone formation is a prominent feature of bone loss associated with inflammation and aging. Progranulin (PGRN) is a protein that is implicated in the immune response in disorders that affect bone health such as rheumatoid arthritis. We have shown that global deletion of the Grn gene that encodes PGRN results in protection of female mice from bone loss that occurs between 3 and 12 months of age. Similar protection was seen with targeted deletion of Grn in Cx3cr1-cre positive myeloid cells. These results suggest that the negative effect of PGRN on bone formation results from an interaction between bone marrow macrophages (BMMs) and osteoblasts (OBs). To gain insight into the mechanism behind this, we have compared the BMM populations in WT vs Grn KO female mice. FACS analysis identified a discrete population of BMMs in WT mice that displayed low level expression of the marker Mac2 (galectin-3). This Mac2 Lo population was almost completely absent in Grn KO mice. Transcriptome analysis demonstrated that Mac2 Lo BMMs were enriched (> 5-fold) in the expression of several genes involved in inflammatory responses (Nlrp3, Il1b, Ptgs2, Ccr1, Cxcl2, Selplg, Clec7a, Trem1, Csf1, Il17ra, Tlr6, Ccl3). To explore how expression of PGRN by BMMs influences osteogenesis, we carried out transcriptomic studies of WT vs. Grn KO bone marrow stromal cells (BMSCs). BMSCs were isolated from adult female WT and Grn KO mice and were induced to undergo osteogenesis. At cell culture day 21, genome wide transcriptome analysis was carried out by RNAseq. 160 genes were up-regulated >2-fold in Grn KO cultures in three paired data sets. Bioinformatic analysis of these genes identified “mitosis” and “cell cycle regulation” as highly enriched pathways. 77 genes were down-regulated > 2-fold in Grn KO cultures in these three paired data sets. Bioinformatic analysis of these genes identified “signaling by G protein-coupled receptors” and “Gi signaling events” as the most enriched pathways. These findings indicate that PGRN expression maintains a distinct pro-inflammatory population of BMMs in adult female mice. PGRN may act to suppress proliferation while promoting Gi signaling in OBs. Our previous results demonstrate that blockade of Gi signaling in OBs in vivo has effects on bone that phenocopy the effects seen in Grn KO mice. Taken together, these findings suggest that BMM-derived PGRN may function upstream of OB Gi signaling to suppress bone formation in adult female mice.

Inflammasome activation is an important mechanism in chemotherapy-induced bone loss *Chun Wang[1.] Gabriel Mbalaviele[2.] [1]Division of Bone and Mineral Diseases, Washington University School of Medicine, United States. [2]Washington University in St. Louis School of Medicine, United States

Doxorubicin is a widely used chemotherapy drug for the treatment of a variety of tumors including breast cancer. Despite its success in improving survival rates of cancer patients, it causes deleterious side effects, including bone marrow toxicity, neutropenia, irreversible heart muscle damage, osteoporosis, and fracture risk, but the underlying mechanisms remain unknown. We hypothesized that doxorubicin causes DNA damage, which leaks to the cytoplasm, and cell death, which releases DNA to the extracellular environment. We further hypothesized that mislocalized DNA is sensed by inflammasomes, intracellular protein complexes that propagate inflammation through various mechanisms, including the maturation and secretion of IL-1?. To test these ideas, we used a non-tumor-bearing mouse model, which allowed the assessment of direct tissue off-target effects of this drug in the absence of tumor confounding outcomes. A single injection of 5 mg/kg doxorubicin to wild-type (WT) mice caused NETosis, a form of neutrophil cell death that follows the release to the extracellular space of genomic DNA and granular contents known as neutrophil extracellular traps (NETs). Specifically, doxorubicin administration increased serum levels of NETosis markers such as citrullinated histone 3 and myeloperoxidase. This response correlated with cytopenia, elevated IL-1? serum levels, increased osteoclast number (N.Oc/BS: vehicle = 4.84+/-0.43; doxorubicin = 12.53+/-1.56), and bone loss (BV/TV: vehicle = 29.21+/-3.93%; doxorubicin = 12.29+/-1.82%). Since damaged or mislocalized DNA is mainly detected by inflammasomes assembled by AIM2 or NLRP3 sensors, we determined their role in doxorubicin actions. Consistent with our hypothesis, doxorubicin osteopenic effects were attenuated in animals lacking AIM2 inflammasome or NLRP3 inflammasome, to some extent (BV/TV: WT = 12.29+/-1.82%; Aim2-/- = 23.33+/-4.05%; Nlrp3-/- = 16.68+/-2.05%). Thus, off-target actions of doxorubicin cause inflammasome activation, a response that ultimately, leads to bone loss.

Hematopoietic and stromal Dmp1-Cre labeled cells form a unique niche in the bone marrow *Sierra Root[1.] Brya Matthews[2.] Elena Torreggiani[1.] IVO KALAJZIC[3.] [1]Center for Regenerative Medicine and Skeletal Development, UConn Health, United States. [2]University of Auckland, New Zealand. [3]University of Connecticut Health Center, United States

Skeletogenesis and hematopoiesis are interdependent. Niches are formed between cells of both lineages and support specific lineage commitment. Because of the complex topography of the bone marrow (BM) space, the identity and function of cells within specialized niches has not been fully elucidated. DMP1-Cre animals have been utilized in bone biology studies as mature osteoblasts and osteocytes highly express DMP1. However, DMP1 has been identified in nonmineralized tissue including CXCL12+ BM cells and an undefined CD45+ hematopoietic population. We aimed to investigate the role of this unconsidered BM population. We crossed DMP1-Cre with Ai9 reporter mice and analyzed the tdTomato+ (tdT+) population and niche. By flow cytometry and Image Stream, 1% of cells are CD45+tdT+ and express myeloid markers including CD11b. By histology, tdT+CXCL12+ stromal cells are in direct contact with F4/80+ macrophages. CD45+tdT+ cells are established early in ontogeny by E15.5. CD45+tdT+ cells phagocytose latex beads, respond to LPS, and are radioresistant. Furthermore, depletion of macrophages with clodronate liposomes and 5-FU treatment caused a significant decrease in the tdT+CD11b+ gated F4/80+Ly6G+ population. Characterization of resident macrophage populations identified CD45+tdT+ cells to be erythroid island macrophages (EIM). Flow cytometric analysis of intact erythroid blood islands (EBI) demonstrated enrichment of tdT+ cells that were Ly6G+CD51+VCAM1+CD169+ER-HR3+. Upon treatment with GCSF, CD45+tdT+ EBIs and EIM significantly decrease. By histology, endogenous DMP1 protein was evaluated with tdT reporter. Extracellular DMP1 protein was located next to or on the processes of tdT+ stromal cells and in direct contact with tdT+ macrophages expressing cytoplasmic and nuclear DMP1. Using tamoxifen inducible DMP1-CreER, a myeloid CD45+tdT+ population expands in adult mice. By histology tdT+ stromal cells express RANKL, stromal processes are seen in direct contact with B cells and tdT+ sorted cells express a key niche factor for B cells, IL7. Secondary hematopoietic organs were also analyzed and a similar tdT+ population that express RANKL found to reside in thymus. In conclusion, DMP1-Cre labels a unique macrophage/stromal niche expressing key microenvironmental factors RANKL and IL7.In memory of Dr. Hector Leonardo Aguila †

Quantitative Lightsheet microscopy of human bones reveals a highly vascularized but degenerated sinusoidal environment for skeletal stem cells with aging *tszlong chu[1.] EMIL KRIUKOV[1.] DANA TROMPET[1.] Misty Shuo Zhang[2.] Ostap Dregval[3.] Björn Barenius[4.] Lars Sa?vendahl[5.] Andrei Chagin[3.] [1], . [2]First Affliated Zhejiang Univeristy Hospital, China. [3]Gothenburg University, Sweden. [4]Södersjukhuset, Karolinska Institutet, Sweden. [5]Karolinska Institutet and Karolinska University Hospital, Sweden

The current understanding of human bone and its marrow spatial organization is largely limited to 2D analysis of tissue sections. Here we developed a tissue-clearing approach coupled with multiplexed detection of mRNAs and proteins, which allows 3D visualization, reconstruction, and quantification of various structures and markers in large samples of aged human bone. As a proof-of-principle, quantitative automated 3D profiling of 380,000 osteocytes embedded within the bone matrix revealed a drastic loss of SOST-expressing (mRNA) osteocytes, i.e., Romosozumab targeted cells, the relocation of the remaining SOST+ cells toward the bone surface, and increased spatial dispersion with age. Multiplex RNA probing of DMP1+FGF23+SOST+ cells revealed that the lineage continuum of osteocytes was relatively sustained thereby indicating the reduction of SOST+ cells with age was not primarily caused by upstream reduction of immature osteocyte supply. By combining 3D mRNA and protein detection, we further characterized CXCL12-expressing stromal cells (CAR cells) in the human bone marrow in relation to arteriolar and sinusoidal vasculature, adipocytes, and bone matrix. The density of CAR cells did not change significantly with age, but their surrounding did. In young bones, CAR cells were found in close proximity to both the bone surface and sinusoids (Endoglin+ vessels), whereas with age these cells were found mostly near arteriolar bed with about 25% of cells trapped within adipocytes. Quantification of CD271+ and CD146+ subsets of CXCL12+ stroma revealed that these two populations of skeletal stem and progenitor cells occupy distinct trabecular and arteriolar niches while sharing a sinusoidal environment that degenerates with age. Therefore our work provides the first comprehensive spatial characterization of changing bone microenvironment in relation to human aging.

Osteoblast-triggered downregulation of Nucleoporins transforms myelodysplastic cells to induce development of acute myeloid leukemia *Alvaro Cuesta-Dominguez[1], Ioanna Mosialou[1], Brygida Bisikirska[1], Marta Galan-Diez[1], Abdullah Ali[2], Diana Kotini[3], Malgorzata Olszewska[3], Manon Jaud[3], Stephanie Braunstein[4], Aaron Viny[4], Junfei Zhao[5], Raul Rabadan[5], Eirini Papapetrou[3], Azra Raza[2], Stavroula Kousteni[1]. [1]Department of Physiology and Cellular Biophysics, Columbia University Irving Medical Center, United States. [2]Center for Myelodysplastic syndromes, Columbia University Irving Medical Center, United States. [3]Department of Oncological Sciences, Icahn School of Medicine at Mount Sinai, United States. [4]Department of Genetics and Development, Columbia University Irving Medical Center, United States. [5]Department of Systems Biology, Columbia University Irving Medical Center, United States

Acute myeloid leukemia (AML) often transforms from pre-AML states such as myelodysplastic syndromes (MDS). To gain mechanistic insight into the transformation of MDS to AML we compared the transcriptional profile of hematopoietic stem and progenitor cells (HSPCs) from mouse models of osteoblast-induced MDS and AML mice as well as of bone marrow mononuclear cells from patients at their MDS and AML transformed stages. We found a decrease in the expression of Nucleoporin (NUP) family members with transformation to AML that was confirmed in two additional MDS to AML mouse models and following analysis of publicly available human data. Notably, low NUPs expression associates with poor prognosis in AML. shRNA knockdown of NUPs in HSPCs from MDS mice and transplantation to wild type recipients led to fully penetrant AML with blast infiltration in blood, bone marrow and spleen. To examine the relevance of NUPs in human disease we downregulated NUPs expression in a model of induced Pluripotent Stem Cell (iPSC)-derived HSPCs harboring the MDS-relevant SRSF2P95L and ASXL1646fs*12 mutations (SA). shNUPS-SA overcame exhaustion and loss of CD34 expression that is typical of MDS cells. Surviving cells maintained growth for as long as 10 months, acquired phenotypic characteristics of AML blasts and presented a 2.5-fold upregulation of the leukemic biomarker CD123. Unlike MDS cells, shNUPS-SA HSPCs engrafted in NSG mice, establishing the transformative potential of NUP downregulation in a humanized in vivo model. Transcriptional changes caused by NUPs downregulation in MDS-SA HSPCs captured transformation by comparison to gene expression datasets of iPSC-HSPC models of MDS and AML. GSEA analysis revealed upregulation of a signature that is highly expressed in pediatric AML and encompasses genes involved in mitochondrial biogenesis and neutrophil activation. Chromatin accessibility analysis by ATACseq in the human MDS-L cell line showed increased accessibility in genes involved in proliferation (MAPK10, RAB36, RAB7A), apoptosis (PIM3), cell cycle (CDK7) and ribosomal biogenesis (RPS12, RPL19, RPL18A, RPS19). Thus, low NUPs expression drives transformation of MDS to AML by activating a multi-pronged network of AML-favoring biological outcomes that involve rescuing MDS cells from apoptosis and promoting their entry to cell cycle and proliferation, while at the same time enhancing their metabolic activity to fuel blast expansion and activation of the immature myeloid lineage.

An IAP antagonist combined with a novel adoptive dendritic cell targeting delivery of TNF to treat breast cancer *Rong Duan[1], Philip Milton[1], Jun Wu[1], Md. Mahmudul Hasan Akash[1], Xin Liu[1], Brendan Boyce[1], Zhenqiang Yao[2]. [1]University of Rochester Medical Center, United States. [2]University of Rochester, United States

Inhibitor of apoptosis proteins (IAPs) restrain caspase-mediated apoptosis. The IAP antagonist, SM-164, which efficiently degrades IAPs, does not kill cancer cells, but we found that it enabled TNF? to strongly induce breast cancer (BC) cell apoptosis in vitro, and combined with TNF? it significantly reduced the % of leg bones with metastases from heart-injected MDA-MB-231 BC cells in a mouse model (40% vs 88% in vehicle, p<0.01). SM-164 alone or a standard chemotherapy (SCT) regimen reduced tumor burden in bone, but not the % of bones with metastases. However, SM-164+TNF? more effectively reduced tumor burden in bone than SM-164 or SCT. Treatment of mice inoculated with MDA-MB-231 cells with a TNF antibody or with clodronate, which depletes macrophages, reduced the inhibitory effect of SM-164 on tumor growth in bone, and clodronate inhibited osteolysis. These findings suggest that TNF?+SM-164 could be an effective therapy to reduce BC bone metastasis. However, systemically administrated TNF? can have serious side effects and is not a practical therapy. Thus, we examined the effects of targeted delivery of TNF?+SM-164 on BC. Overexpression of Mucin1, a surface glycoprotein on epithelial cells, is associated with tumorigenesis and metastases. We induced and expanded dendritic cells (DCs) from human peripheral blood using M-CSF and GM-CSF and engineered them to express TNF? and chimeric CD66b-Mucin1 scFv, which was constructed by linking Mucin1 monoclonal Ab scFv to the extracellular domain of a truncated portion of myeloid cell receptor, CD66b, to target BC. We called these novel engineered DCs Mucin1-directed DCs producing TNF? (M-DCsTNF). Conditioned medium from M-DCsTNF (contains 300 pg/ml TNF?) strongly induced MDA-MB-231 cell death in the presence of SM-164 in vitro; this was blocked by a TNF Ab. Specific binding of M-DCsTNF to MDA-MB-231 cells was confirmed in bones in NSG mice. Importantly, SM-164 given with a one-time injection of M-DCsTNF significantly reduced the growth of human BC from orthotopically-injected Her2+ BT474 BC cells (median tumor weight 6.25 vs. 98.4 mg in vehicle, p<0.01) and patient-derived xenograft (PDX) of triple-negative BC (tumor wt. 0.78+/-0.42 vs. 1.56+/-0.82 g in vehicle, p<0.05) in NSG mice. In contrast, SM164 alone did not inhibit BC growth in the PDX model. Our findings suggest that an adoptive cell targeted delivery of TNF? to BC deposits combined with SM-164 may be a novel effective approach to treat breast cancer.

Prostate Cancer Bone Metastasis Alters Gut Microbiota Composition by Enhancing Gut Leakiness *Kelly Contino[1], Jenna Ollodart[1], Yang Yu[1], Sidharth Mishra[2], Laiton Steele[1], Katherine Cook[3], Hariom Yadav[2], Yusuke Shiozawa[1]. [1]Department of Cancer Biology, Wake Forest University Health Sciences, United States. [2]University of South Florida Morsani College of Medicine, United States. [3]Department of Hypertension, Wake Forest University Health Sciences, United States

In a state of dysbiosis, the physical, biochemical, and immune barriers separtating gut bacteria from systemic circulation become compromised. This loss of gut barrier integrity, referred to as “leaky gut”, has been implicated in the pathogenesis of numerous diseases including cancer. The translocation of the gut derivatives as a result of leaky gut has been shown to drive tumorigenesis and cancer progression, including prostate cancer (PCa). Despite this link to tumor formation/progression, the relationship between leaky gut and metastasis, specifically to the bone, remains unexplored. To begin understanding the complex mechanisms between the gut and bone metastasis, the leading cause of death in PCa patients, we intrafemorally inoculated murine PCa cell line RM-1 cells into C57BL/6 mice. Bulk RNA sequencing of intestinal tissue from these mice revealed that markers of intestinal tight junctions (physical barrier) and gut mucosal membranes (biochemical barrier) were downregulated in the intestinal tissue of PCa-bearing mice. This data suggests that bone metastasis alone is capable of inducing leaky gut. To validate these findings, serum ELISAs for LPS binding protein (LBP) and sCD14, well-established markers of leaky gut, were performed. Significantly higher levels of LBP and sCD14 were observed in the serum of PCa-bearing mice, compared to that of sham mice, further supporting the notion that leaky gut occurs as a result of bone metastasis. Then, to examine whether bone metastasis induces changes in gut microbial composition,16s rRNA sequencing of the mouse stool was conducted. Interestingly, elevated levels of Dorea formicigenerans and Ruminococcus gnavus, mucin degrading bacteria known to enhance leaky gut, were found in the stool of PCa-bearing mice. Several butyrate generating bacteria were found to be upregulated in the stool of PCa-bearing mice. Butyrate is a short chain fatty acid known to contribute to bone formation. Clostridum scindens, known to convert glucocorticoids into androgen, was also elevated in the stool of PCa-bearing mice. Conversely, Faecalibaculum rodentium, known to be protective against intestinal tumor growth, was significantly enhanced in the stool of sham mice. Collectively, these results suggest that bone metastasis alters the gut microbiota composition by enhancing gut leakiness. Future studies are clearly warranted to further reveal the mystery of gut-bone metastasis axis.

Effect of Autologous Dendritic Cell Vaccine and Anti-MDSC Treatment Against 4T1 Breast Cancer Cells in Mice *Pierrick Fournier[1], Paloma Almeida Luna[2], Danna Arrellano[2], Samanta Jimenez[3], Patricia Juarez[4]. [1]Centro de Investigacion Cientifica y de Educacion Superior de Ensenada (CICESE), Mexico. [2]Posgrado en Ciencias de la Vida, CICESE, Mexico. [3]Centro de Investigación Cientifica y de Educacion Superior de Ensenada (CICESE), Mexico. [4]Center for Scientific Research and Higher Education, Mexico

Immunotherapies can cause long-term response in cancer patients. Autologous dendritic cell (DC) vaccines (DC-Vax) can induce T and B cell-mediated anti-tumor response. However, its efficacy still seems limited in breast cancer and has not been assessed for bone metastases. We sought here to test the effect of an autologous DC-Vax in the 4T1 breast cancer syngeneic model, and whether its efficacy could be improved by increasing DC maturation with natural PAMP or combining with 5-Fluorouracil (5FU) to decrease the immunosuppressive myeloid-derived suppressor cells (MDSC).Bone marrow cells from Balb/C mice were differentiated to DC cells ex vivo (>80%). Loading DC with antigens (Ag) from 4T1 mammary fat pad (mfp) tumors did not induce their maturation, assessed by MHC-II, CD80 and CD86 expression by flow cytometry. However, combined treatment with LPS or Ag from a vaccine against rabies increased MHC-II and CD86 expression. In mice, 2 doses of LPS-treated DC increased the levels of anti-4T1 antibodies without increasing T cell infiltration, resulting in a modest decrease of 4T1 mfp tumor volume (-16%). The combined treatment LPS/rabies Ag of the DC did not improve their anti-tumor efficiency.5FU was reported to decrease MDSC levels in other cancer models, so we tested its efficacy against MDSC in 4T1 mfp tumors. 5FU at 25mg/kg decreased polymorphonuclear (PMN-) MDSC, but not monocytic (M-) MDSC in 4T1 tumors and increased infiltrating CD4+ T cells. While 50mg/kg 5FU decreased both PMN- and M-MDSC, it decreased the levels of T cells infiltrating the tumors. However, both doses decreased the volume of 4T1 mfp tumors (-18% and -33%, respectively). In 4T1 bone metastases, 5FU had similar effects on MDSC and T cells in bone.Consequently, we tested the effect the autologous DC-Vax combined with 5FU at 25mg/kg. However, although the combined treatment decreased of the amount of circulating MDSC and increased circulating levels of CD4+ and CD8+ T cells as wells as the levels of anti-4T1 antibodies in plasma, it did not decrease the volume of 4T1 mfp tumors.Based on these results, we conclude that while autologous DC vaccines are a promising personalized treatment option for patients with breast cancer, its efficacy remains limited at the pre-clinical level. Further research is needed to improve the preparation and maturation of the DC and combined treatment to increase the immune response is needed in order to support patients suffering from breast cancer.

Bone-derived Dickkopf-Related Protein 1 promotes primary breast cancer tumor growth and supports hematopoietic stem and progenitor cells *Emily Eul[1], Biancamaria Ricci[1], Seunghyun Lee[1], Giulia Furesi[1], Roberta Faccio[1]. [1]Washington University in St. Louis , United States

Dickkopf-related protein 1 (Dkk1), a Wnt/?-catenin signaling inhibitor, is produced in the bone, and is best known for suppressing bone formation and increasing bone resorption. Interestingly, Dkk1 is upregulated in cancer patients and correlates with poor prognosis. Recent work has shown that Dkk1 can exert immune suppressive effects by altering the frequency and function of immune cell subsets in various cancer models. However, the role of Dkk1 in breast cancer progression and the mechanisms by which Dkk1 can affect so many immune cell types remain unclear.We found that mice bearing luminal B, ER+ PyMT-B6 tumors exhibit increased Dkk1 expression in the bone and higher systemic serum levels compared to no tumor bearing controls. To assess the role of Dkk1 during breast cancer tumor progression, female C57BL/6 mice were orthotopically injected with PyMT-B6 cells and treated with Dkk1 neutralizing antibody (?Dkk1) or IgG control antibody (10mg/kg every 48 hrs). We observe a striking reduction in tumor growth of ?Dkk1 treated mice, and systemic alterations to immune cell population frequencies. We also find similar results in mice bearing the metastatic basal-like ER- EO771-LMB breast tumors. To study the effects of bone-dervied Dkk1 we utilized osteoblast lineage specific Dkk1 overexpressing mice (2.3kbCol1?1Dkk1Tg) injected with PyMT-B6 cells and observed increases in tumor growth and changes in the immune landscape.To uncover how Dkk1 can modulate a variety of immune cell populations, we investigated the impact of tumor progression and Dkk1 on hematopoietic stem and progenitor cells (HSPCs) in the bone marrow of tumor bearing mice. Based on previous reports indicating that Dkk1 can influence HSPC regeneration and exhaustion, we performed noncompetitive bone marrow transplantation (BMT) assays using Dkk1 overexpressing mice and osteolineage conditional ckO mice, tTA-TetOFFOsx-Cre; Dkk1fl/fl and saw an increase in the engraftment of HSPC populations from over expressing mice. Additionally, we treated mice with PyMT-B6 or EO771-LMB with ?Dkk1 or IgG and discovered that Dkk1 strickingly reduced HSPC frequencies only in the EO771-LMB model, suggesting that Dkk1 may regulate hematopoiesis in a breast cancer subtype dependant manner.Together this data demonstrates that Dkk1 expression is upregulated in the bones and supports breast cancer tumor growth and hematopoiesis, overall, highlighting the existence of a bone-tumor crosstalk to promote tumor progression.

Bone-derived Osx+ Cells Infiltrate Mammary Tumors and Contribute to Extracellular Matrix Reorganization and Tumor Progression *GIULIA FURESI[1], Roberta Faccio[2]. [1]Washington University in St. Louis, School of Medicine, United States. [2]Washington University in St Louis School of Medicine, United States

Osterix (Osx) is a crucial transcription factor for osteoblast differentiation and bone mineralization. Interestingly, we detected expression of Osx in the stroma of various breast tumors (PyMT, E0771, 4T1) in adult mice, as well as in patients with advanced breast carcinomas. Using lineage tracing TdT-Osx+ mice, we demonstrated that tumor-infiltrating Osx+ cells support tumor growth when co-injected with cancer cells. To determine if ectopic Osx+ cells at the tumor site are derived from the bone marrow (BM), we lethally irradiated CD45.1 WT recipient mice and transplanted BM from CD45.2 TdTOsx+ mice to generate TdTOsx+>WT chimeric mice. After tumor inoculation, TdTOsx+ cells were detected both in circulation and at the primary tumor site, thus confirming a bone origin. Next, we wanted to assess the tumor-promoting abilities of bone resident Osx+ cells. In contrast to the tumor-infiltrating Osx+ cells, TdT-Osx+ populations isolated from the BM did not increase tumor growth when co-injected with PyMT cells. To further elucidate the identity of tumor-infiltrating Osx+ cells, we orthotopically injected PyMT cells into TdTOsx+ mice and performed Immunofluorescence and FACS analysis. Tumor sections showed the presence of TdTOsx+ stromal cells with elongated morphology, a common feature of cancer-associated fibroblasts (CAFs). RNA-seq and flow cytometry analyses of these cells confirmed the expression of CAF markers, such as alpha-SMA, Fsp1, PDGFR?, PDGFR?, Ly6C, and CD146, as well as genes associated with ECM reorganization and skeletal development. Next, to determine whether Osx directly drives the pro-tumorigenic effects of tumor-infiltrating Osx+ cells or merely marks BM mesenchymal populations at the tumor site, we ectopically expressed Osx or empty vector in murine mammary fibroblasts (MMF+Osx or MMFctr) and co-injected them with PyMT cells into WT mice. MMF+Osx significantly increased PyMT growth ($p>0.001$) compared to MMFctr or tumor cells alone. Interestingly, expression of Osx in mammary fibroblasts resulted in the upregulation of matrix-related genes. In line with these observations, second-harmonic generation imaging revealed higher collagen deposition ($p>0.05$) in the tumors co-injected with MMF+Osx compared to MMFctr. In conclusion, our findings demonstrate the existence of BM-derived osteolineage Osx+ cells in extra-skeletal tumors, which possess tumor-promoting effects and may represent a novel subset of matrix-producing CAFs.

Breast cancer bone metastasis is mediated by the PTHrP NLS and C-terminal domain in a TGF-?/SNAI2/ZEB1 cascade *DEJA GRANT[1], Julia Ahn[2], Courtney Edwards[3], Jasmine Johnson[4], T. John Martin[5], Rachelle Johnson[4]. [1], United States. [2]Vanderbilt University, United States. [3]Vanderbilt University , . [4]Vanderbilt University Medical Center, United States. [5]St. Vincent s Institute of Medical Research, Australia

Breast cancer cells frequently metastasize to bone, where they may proliferate or enter a dormant state. Parathyroid hormone-related protein (PTHrP) expressed by breast cancer cells promotes tumor outgrowth in bone by increasing bone resorption and stimulating tumor cell exit from dormancy. PTHrP has multiple biological domains that determine its autocrine, paracrine, and intracrine functions, but the role of the PTHrP nuclear localization signal (NLS) and C-terminus is not well understood. To assess the role of PTHrP biological domains in breast cancer bone colonization, we stably expressed full-length secreted PTHrP, PTHrP with deletion of the NLS, or PTHrP with deletion of the NLS and C-terminus in human MCF7 breast cancer cells, which normally lay dormant in bone. MCF7 cells expressing these proteins were termed FLSEC, DNLS, and DNLS+CTERM mutant cell lines, respectively, and inoculated into athymic nude mice by intracardiac injection to facilitate bone colonization (n=8-10/group). Osteolytic lesion area and number, assessed by radiography, and tumor burden in the bone marrow quantified by flow cytometry, were significantly higher in mice inoculated with DNLS (5.9-fold, $p<0.05$) and DNLS+CTERM (4.19-fold, p77% decrease, $p<0.0023$), while ZEB1 was significantly upregulated in DNLS+CTERM cells (2.19-fold, $p<0.05$), compared to MSCV controls. Crosstalk within the TGF-?/Slug/ZEB-1 pathway is exceedingly complex, with bi-directional regulation, depending on the cell type and context. It is also well established that TGF-? positively regulates PTHrP; however, our data suggest that downregulation of Slug may be important for breast tumor progression in bone downstream of PTHrP, and this pathway may or may not converge on ZEB1. Taken together, our data indicate that PTHrP-mediated breast cancer-induced osteolysis involves the NLS and C-terminal domains signaling through EMT-associated pathways.

These alterations reduce the response to chemotherapy, and lead to reduced quality of life and survival due to muscle loss and weakness ADDINEN.CITE vonHaehling201450[4]505017vonHaehling, S.Anker, S.D.Instituteof Innovative Clinical Trials, Department of Cardiology and Pneumology,University of Gottingen Medical School, Robert-Koch-Strasse 40, 37075,Gottingen, Germany, stephan.von.haehling@web.de.Prevalence,incidence and clinical impact of cachexia: facts and numbers-update2014J Cachexia SarcopeniaMuscleJCachexia SarcopeniaMuscle261-3542014Dec2190-5991(Print) 2190-6009 (Electronic) 2190-5991(Linking)25384990https://www.ncbi.nlm.nih.gov/pubmed/25384990PMC424841110.1007/s13539-014-0164-8PubMed-not-MEDLINENLM[4]. Unfortunately, little is known regarding the consequences of non-bone metastatic HNC on bone homeostasis. For this reason, this study is aimed to elucidate the bone alterations associated with a non-bone metastatic model of HNC.C57BL/6J male mice (8-week-old) were intrascapularly and subcutaneously injected with 3 × 106 MLM3 HNC cells. The MLM3 tumor growth caused body and skeletal muscle wasting as previously described [5]. In addition, tumor hosts displayed severe loss of trabecular and cortical bone as suggested by the reduction of the Tb.BV/TV, Tb.Th, Tb.N. and Ct.BV/TV and Ct.Th. The assessment of mechanical properties of the femur reveled that HNC bearers have weaker bones as suggested by the reduced ultimate force, stiffness, and energy to failure. Since osteocytes are key regulator of bone resorption, we analyzed the mRNA expression of important pro-resorptive genes such as Tnfsf11, Tnf-? and IL-6 and found them increased in the osteocyte enriched samples from MLM3 bearers. To determine if these changes also characterized human HNC, mRNA was isolated from bone derived from patients who underwent HNC ablation followed by osseous free tissue reconstruction. As a control tissue, we used bone samples derived from patients who underwent trauma surgery. These data showed increased mRNA expression of Tnfsf11 (RANKL) whereas Tnfrsf11b (OPG) was unchanged, resulting in an increased Rankl/Opg ratio. Interestingly, also the mRNA expression of IL-6 was increased in the bone of the HNC patients.Our study clearly shows that HNC, even in the absence of direct metastases to the bone, has severe detrimental effects on the musculoskeletal system. For the first time, we are showing that osteocytes acquire a pro-inflammatory phenotype that could directly drive bone and muscle loss in HNC patients. Consideration of co-treatments that maintain musculoskeletal health as well as assessment of the presence of osteoporosis should be taken in non-bone metastatic HNC patients.

Elevated Lactate in Acute Myeloid Leukemia (AML) Contributes to Bone Marrow Microenvironment Dysfunction through GPR81-Mediated Macrophage Polarization and Leukemia Cell Growth *Benjamin Frisch[1], Maggie Lesch[2], Joshua Munger[2], Celia Soto[2]. [1]University of Rochester School of Medicine and Dentistry, United States. [2]University of Rochester, United States

Acute myeloid leukemia (AML) has a survival rate of ~30% at five years due to bone marrow dysfunction and relapse following treatment. Metabolomics revealed higher metabolite levels in the bone marrow of AML patients at diagnosis compared to healthy controls, including lactate (mmol/L = 3.62 vs 1.31, $p < 0.05$, n = 5). We hypothesized that excess lactate advances leukemia progression by polarizing macrophages to an immunosuppressive (M2-like) phenotype and promoting cancer aggressiveness. Further, as bone marrow is a unique tumor microenvironment, research is needed on the contribution of lactate to altered hematopoiesis. This study used: (i) a murine AML model of blast crisis chronic myelogenous leukemia (bcCML) that recapitulated the metabolomic analysis of human AML, and (ii) C57BL/6J wild type mice or a transgenic knockout of the extracellular lactate receptor GPR81 (GPR81-/-). Leukemia-associated macrophages (LAMs) were found to overexpress the mannose receptor CD206, an M2-like marker. LAMs in GPR81-/- bcCML mice had a reduced expression of CD206 (fold-change MFI compared to non-leukemic = 4.98 vs 2.06, $p < 0.05$, n = 11). RNA sequencing of LAMs detected multiple upregulated T cell pathways. Expression of arginase-1 RNA, a functional M2-like protein, was observed in lactate-polarized bone marrow-derived macrophages (BMDMs) in vitro and was substantially lower in GPR81-/- BMDMs. Next, leukemia progressed more slowly when bcCML was initiated using GPR81-/- leukemia cells compared to wild type (% leukemic bone marrow cells at day 13 = 11.75 vs 45.54, p 7 passages, n = 2). These results suggest that GPR81 is critical for LAM polarization, leukemia cell growth, and repopulation. Lastly, bone marrow support for hematopoiesis was assayed by coculturing murine hematopoietic stem and progenitor cells (HSPCs) over a stromal monolayer of macrophages and mesenchymal stem cells, a key cell type of the hematopoietic stem cell niche; exposure to physiologically-relevant elevated lactate levels (10 mmol/L) reduced HSPC colony-forming ability when plated in methylcellulose-containing media (fold-change colonies = 0.41, $p < 0.001$, n = 14). This research identifies lactate as a critical driver of AML progression, highlighting GPR81 as an exciting and novel therapeutic target for both AML cells and LAMs.

Targeting S1PR1 and p62-mediated signaling as a therapeutic approach to multiple myeloma bone disease *Daniela N. Petrusca[1], Silvia Marino[2], Attaya Suvannasankha[1], Judith Anderson[1], Evgeny Berdyshev[3], Kelvin P. Lee[1], G. David Roodman[1], Deborah L. Galson[4]. [1]Department of Medicine, Hematology/Oncology Division, Indiana University School of Medicine, United States. Multiple myeloma (MM) is an incurable plasma cell malignancy that causes osteolytic bone lesions in most patients. Thus, novel treatments which effectively target both the MM cells and the bone microenvironment are needed. We previously reported that MM-induced upregulation of GFI1 in bone marrow stromal cells (BMSC) causes prolonged suppression of osteoblast (OB) differentiation. In addition, we described the pivotal role of GFI1 in MM proliferation via intracellular S1P-dependent increased c-Myc stability and enhanced extracellular release of S1P for a pro-survival autocrine and paracrine feedback loop through S1PR1. We employed XRK3F2, a p62-ZZ domain competitive inhibitor that can decrease GFI1 expression in both MM cells and in MM-educated BMSC in vitro, in combination with Ozanimod (Oza), a selective S1PR1 functional antagonist. We found S1P levels significantly elevated in the BM plasma of MM patients when compared to healthy donors. Also, S1PR1 and p62 are highly expressed in MM primary cells when compared with healthy donors and negatively correlate with overall survival of MM patients. Microenvironmental soluble factors (IL6, S1P, TNF?, hypoxia) and the direct co-culture of MM cells with BMSC cells, significantly increase S1PR1 transcription as well as GFI1 (mRNA and protein expression) levels in both cell types. We found that XRK3F2 significantly downregulated both p62 and GFI1 levels in MM cells even in the presence of IL-6, and Oza significantly decreased S1PR1 levels even in the MM cells overexpressing GFI1. Each drug alone significantly reduced viability in MM cells and their combination further enhanced the pro-death effect. Either drug alone significantly decreased GFI1 and P-cMyc protein levels in MM cells as well as c-Myc chromatin bound levels. These effects were further accentuated by the drugs in combination. We found that XRK3F2 and OZA, alone and in combination, improve differentiation of pre-OB. Moreover, either drug alone significantly rescued TNF? suppression of OB differentiation, and their combination completely restored it as measured by Col1a1 levels. Oza treatment of MM downregulated IL6 and RANKL levels even in MM cells overexpressing GFI1. IL6 and RANKL increase MM viability and osteoclast recruitment and activation, respectively. These data support the idea that p62 and S1PR1 might be effective targets in MM treatment and the potential of using the Oza-XRK3F2 combination as a novel therapeutic approach for treating MMBD.

Adult T cell Leukemia (ATL), caused by chronic infection of human CD4+ T cells with HTLV-1, is associated with hypercalcemia and osteolytic lesions. To study the direct effect of HTLV-1-infected T cells (HTLV/T) on osteoclasts (OC), we generated a panel of clonal HTLV/T (n=9 from 2 donors) and ATL patient cell lines (ATL/P) (n=3). Supernatants (sup) from HTLV/T and ATL/P were added to murine and human OC precursors cultured in suboptimal osteoclastogenic conditions. HTLV/T sup variably stimulated OC differentiation (4 high, 1 medium, 4 low), but showed identical effects on murine and human cultures. ATL/P sup all stimulated OC generation. Expression of RANKL and OPG mRNAs by HTLV/T and ATL/P was variable, but we found no correlation between OC effects and either RANKL levels or RANKL/OPG ratio, suggesting an alternative mechanism. Concordantly, we previously showed that osteolysis in a humanized mouse model of HTLV-1 infection was only partially blocked by anti-RANKL antibodies. HTLV/T and ATL/P produce small extracellular vesicles (sEV), known to facilitate HTLV-1 infection. We hypothesized that these sEV also mediate bone loss by targeting OC. We isolated sEV from both HTLV/T and ATL/P, and found they carried most of the activity of sup. In contrast, sEV from uninfected activated T cells had little effect. Pre-treatment of HTLV/T by exosome inhibitor GW4869 blunted the OC stimulatory activity of sup. We further characterized the sEV, finding no viral particles using transmission EM. LC-MS/MS of HTLV/T sEV (n=7) showed no RANKL, but ~18% of sEV proteins correlated with strength of osteoclastogenic effect; gene ontogeny analysis of this group showed increased representation of proteins involved in bone resorption such as cytoskeletal proteins and GTPases. MicroRNA profiling of HTLV/T sEV with high osteoclastogenic activity revealed top microRNAs (mir 21, mir 155, mir 92a1) with previously noted effects on OC. To determine if in vitro findings correlate with true osteolysis, HTLV/T lines (2 high and one low effect) were injected into tibias of immunodeficient NCG mice, and trabecular bone mass was followed by vivaCT. HTLV/T with high in vitro activity caused profound bone loss by 4-8 weeks regardless of RANKL expression ($p<0.01$), while bone injected with the low effect line was not significantly different from uninjected controls. Our study suggests that sEV, which lack RANKL, directly stimulate OC, likely mediated by multiple components of their cargo.

Blocking PTH1R inhibits prostate cancer metastases *Yawei Zhao[1], Xiaohong Li[1]. [1]The University of Toledo, United States

The causative effects of parathyroid hormone-related protein (PTHrP) in bone metastases have been demonstrated. However, clinical trials on blocking PTHrP have not yet been successful. On the other hand, parathyroid hormone receptor 1 (PTH1R) is the only receptor that PTHrP binds to. PTH1R belongs to the G protein-coupled receptor (GPCR) family. In general, GPCRs comprise 35% of the current clinical drug targets. Therefore, we explore

the effects of blocking PTH1R in prostate cancer metastases using both genetic and pharmacological approaches.Physiologically, PTH1R is expressed in the mesenchymal lineage of cells. To determine the paracrine effect of PTH1R in advanced prostate cancer metastases, we crossed the floxed Pth1r (Pth1rFloxE2) mouse with the Col1?2 CreERT mouse. This mouse line was further bred into immunodeficient NSG background. We then xenografted the human castration-resistant prostate cells, PC3 (labeled with luciferase), intracardially into the Pth1rFloxE2 and Pth1rColCreERT KO littermates. Note that we did not observe phenotypic changes in the Pth1rColCreERT KO mice, compared to the Pth1rFloxE2 littermates or wild-type controls. Luminescent signals and bone lesions were monitored weekly. We found metastases in multiple organs, including bone and liver. The overall and organ-specific metastases, such as bone metastases, were significantly inhibited in the Pth1rColCreERT KO, compared to the Pth1rFloxE2 littermates. These data showed that blocking the paracrine effects of PTH1R inhibits prostate cancer metastases. Furthermore, prostate cancer cells also express PTH1R. To determine the autonomous effect of PTH1R inhibition, we treated the prostate cancer cells with either a small molecule inhibitor, XC039, or the peptide antagonist, (Asn10,Leu11,D-Trp12)-PTHrP(7-34) amide [PTHrP(7-34) amide]. We found that XC039 significantly inhibited prostate cancer cell growth but not PTHrP(7-34) amide, although both PTHrP(7-34) amide and XC039 can significantly suppress the ligands (PTH or PTHrP) induced downstream cAMP signaling. Furthermore, our preliminary study in mice also showed a trend of bone metastasis inhibition of C4-2B-induced bone lesion development by PTHrP(7-34) amide. Taken together, these studies prove the concept and demonstrate potential efficacy in blocking PTH1R for prostate cancer metastases.

Osteocytes Induce Drug Resistance via the NOTCH3-CXCL12 Signaling Axis in Multiple Myeloma *Hayley Sabol[1,] Cody Ashby[1,] Manish Adhikari[1,] Japneet Kaur[1,] Aric Anloague[1,] Sharmin Khan[1,] Samrat Roy Chodhury[1,] Michela Palmieri[1,] Lawry Barnes[1,] Elena Ambrogini[1,] Carolina Schinke[1,] Intawat Nookaew[1,] Jesus Delgado-Calle[1,] [1]University of Arkansas for Medical Sciences, United States

Multiple myeloma (MM) remains incurable due to disease relapse and drug resistance. Notch signals between MM cells and cells of the tumor niche (TME) confer drug resistance, but the cellular/molecular mechanisms are not entirely known. Using in silico analysis of clinical and transcriptomic public and internal databases, we found that 1) NOTCH3 is upregulated in MM cells from newly diagnosed MM patients (NDMM) vs. healthy donors, 2) increases in relapsed/refractory MM (RRMM) vs. NDMM patients, and 3) NDMM patients with high NOTCH3 expression have worse responses to Bortezomib (BOR)-based therapies. Because NOTCH3 mRNA levels did not correlate with somatic mutations in NOTCH3, we tested if NOTCH3 is regulated by TME cells and its role in responses to chemotherapy. Osteocytes (Ots), recently defined as key cells in the TME, increased NOTCH3 in MM cells and protected them from apoptosis induced by BOR or VRd (BOR+Lenalidomide+Dexamethasone) in vitro. This protection was lost by NOTCH3 knockdown (NOTCH3KD) and enhanced by NOTCH3 activation (NOTCH3OE) in MM cells. Next, we compared BOR (0.1 mg/kg, 5x/wk) responses in control (C) vs NOTCH3OE MM cells in vivo. All untreated mice bearing C or NOTCH3OE cells died at 4 wks. In mice injected with C MM cells, BOR reduced tumors by 65%, improved survival (7/10 alive), and had 38% more bone mass, 25% more P1NP, and 29% less CTX than untreated mice. In contrast, in NOTCH3OE-bearing mice, BOR only reduced tumors by 23% and did not improve survival (1/10 alive), bone mass, or serum markers, supporting NOTCH3 confers BOR resistance. We then compared the MM cell transcriptome of NDMM patients with high vs. low NOTCH3 expression to find the mechanism for BOR resistance. We found that high NOTCH3 NDMM and RRMM patients had enrichment in chemokine and cell adhesion pathways and CXCL12 upregulation. Ots upregulated CXCL12 and activated the CXCR4/ERK pathway in MM cells in vitro. These effects were blunted in NOTCH3KD and enhanced in NOTCH3OE MM cells. Genetic inhibition of CXCL12 in NOTCH3OE cells prevented Ot's protection and restored BOR/VRd sensitivity, supporting CXCL12 works in an autocrine fashion. Lastly, Plerixafor, a CXCR4/CXCL12 inhibitor, restored NOTCH3OE MM cells sensitivity to BOR/VRd in vitro and in human bones bearing NOTCH3OE tumors cultured ex vivo. Our clinical and experimental data show Ots transmit drug resistance signals and unravel a novel targetable NOTCH3-CXCL12 pro-survival signaling axis in the MM TME.

Osteoblasts are a source of bone metastases-associated fibroblasts (BMAFs) *Jennifer Zarrer[1,] Marie-Therese Haider[2,] Nicole Ridlmaier[2,] Rafael Preuer[2,] Daniel J. Smit[3,] Hiroaki Saito[1,] Eric Hesse[1,] Hanna Taipaleenmäki[1,] [1]Institute of Musculoskeletal Medicine, University Hospital, LMU Munich, Munich, Germany, Germany, [2]Molecular Skeletal Biology Laboratory, Department of Trauma, Hand and Reconstructive Surgery, University Medical Center Hamburg-Eppendorf, Hamburg, Germany, Germany, [3]Institute of Biochemistry and Signal Transduction, University Medical Center Hamburg-Eppendorf, Hamburg, Germany, Germany

In breast cancer bone metastases the abundance of adjacent osteoblasts (OBs) is diminished. To determine the fate of OBs, we combined a lineage-tracing model (Osx-creERt+;Ai9) with intracardiac injection of 4T1 breast cancer cells and performed single cell RNA sequencing (scRNAseq) of tdTomato-positive (tdTom+) OBs in metastases-bearing and healthy control animals. Bioinformatic analysis revealed a distinct cluster of tdTom+ OBs in metastases-bearing mice that express genes related to tumor microenvironment, fibrosis and cancer-associated fibroblast (CAF) proliferation (e.g. Cxcl12, Tnc, Mmps, Pdgfr-?, Pdgfr-?). CAFs reside inside tumors providing a micro-milieu that supports tumor growth. However, little is known about metastasis-associated fibroblasts (MAFs), in particular in bone metastases. Based on our findings, we hypothesized that OBs might abandon the bone surface and become MAFs. Supporting our hypothesis, histological analysis demonstrated elongated tdTom+ OBs within metastases, which we termed bone metastases-associated fibroblasts (BMAFs), while only a few OBs were present on nearby bone surfaces. Consistently, MC3T3-E1- and primary OBs acquired a spindle shape morphology upon stimulation with medium conditioned by 4T1 or MDA-MB-231 breast cancer cells (CCM), which also increased OB migration and OB-induced collagen remodeling. Furthermore, in an ex vivo co-culture model, OBs in the vicinity of cancer cells became elongated and migrated in-between tumor cells. Immunoblot, qRT-PCR, scRNAseq and histological analyses revealed a reduction of OB markers (Runx2, Osx) and an increase of BMAF-associated genes (e.g. Pdgfr-?, Pdgfr-?) in CCM-stimulated OBs and cancer-associated tdTom+ OBs. To elucidate the mechanisms transitioning OBs to BMAFs, we performed RNA sequencing and identified an activated IL-17A signaling pathway in CCM-stimulated OBs compared to controls, which was confirmed by immunoblot and qRT-PCR analyses of downstream targets (C/ebp, Ccl2). Furthermore, recombinant IL-17A promoted OB migration and acquisition of a BMAF phenotype while inhibition of IL-17A signaling using an anti-IL-17 antibody restored the CCM-induced morphological changes and OB migration. In vivo, anti-IL-17A reduced the number and growth of bone metastases determined by bioluminescence imaging and histology. Together, these results demonstrate that OBs give rise to BMAFs at least in part through IL-17A, which might contribute to metastatic growth.

DDRGK1 regulates proteostasis by modulating the ribosomal protein RPL26 during chondrocyte differentiation in spondyloepimetaphyseal dysplasia *Yangjin Bae[2,] Monika Weisz-Hubshman[2,] Carolina Leynes[2,] Sung Yun Jung[2,] Brendan Lee[2,] [2]Baylor College of Medicine, United States, [2]Baylor College of Medicine,

DDRGK1 is a substrate of the ufmylation process, a post-translational modification mediated UFM1.It is required for subsequent ufmylation of other substrates by forming complex with ULF1 (E3 ligase). The physiological importance of DDRGK1 was elucidated by the finding of mutations in Shohat-type Spondyloepimetaphyseal dysplasia (SEMD). Moreover, other genes in this pathway have since been associated with this spectrum of skeletal dysplasias. We previously showed that osteochondroprogenitor-specific (Prx1-Cre; Ddrgk1f/f) and mature chondrocyte- specific (Agn1-CreERT2; Ddrgk1f/f) knockout mouse models recapitulated the SEMD phenotype. In brief, Prx1-Cre; Ddrgk1f/f mice showed severe chondrodysplasia including progressive shortening of the limbs with an abnormal growth plate and a delayed epiphyseal ossification. In Agn1-CreERT2; Ddrgk1f/f mice, we consistently found disorganized growth plate and reduced level of proteoglycan in growth plate and articular cartilage. These in vivo results highlight the essential role of UFM1 modification in cartilage development and homeostasis. Hence, to uncover the potential cartilage-specific complexes and novel substrates of the ufmylation, we have generated ATDC5 (murine chondrocyte cell line) stably expressing the components of the ufmylation machinery, i.e., UFC1-FLAG; UFL1-MYC; HA-HIS-UFM1 via doxcyclin induction and performed IP-MS assay. Based on GO analysis, we found proteins enriched in protein ufmylation (as internal control), ER stress, protein translation pathways and ribosome. Among these, ribosomal protein RPL26 was previously reported as the substrate of UFM1 modification and also the cause of with a human ribosomopathy. Similar to the function of Ddrgk1 in proteostasis, we found that total protein synthesis was reduced by SUnSET assay (Surface Sensing of Translation) when Rpl26 was knockdown in ATDC5, with associated impairment of ATDC5 chondrocyte differentiation. We also found that Sox9 protein level was decreased similarly when Ddrgk1 was knockdown in ATDC5. These data suggest that ufmylation may be a critical post-translational modification for cartilage homeostasis by modulating the protein stability/function of subset of ribosomal proteins such as RPL26. Furthermore, this

mechanism underscore the evidence of tissue-specific ribosomal function as a pathological cause of human chondrodysplasia.

Loss of function variant in histone reader SPIN4 causes a new X-linked overgrowth syndrome *Julian Lui[1], Jacob Wagner[1], Elaine Zhou[1], Kevin Barnes[1], Lijin Dong[2], Youn Hee Jee[1], Jeffrey Baron[1]. [1]Section on Growth and Development, NICHD, United States. [2]National Eye Institute (NEI), United States

Overgrowth syndromes can be caused by pathogenic genetic variants in epigenetic writers, such as DNA and histone methyltransferases. However, no overgrowth disorder has previously been ascribed to variants in a gene that acts primarily as an epigenetic reader. Here, we studied a male individual with generalized overgrowth of prenatal onset. Exome sequencing identified a hemizygous frameshift variant in Spindlin 4 (SPIN4), with X-linked inheritance. We found evidence that SPIN4 binds specific histone modifications, promotes canonical WNT signaling, and inhibits cell proliferation in vitro and that the identified frameshift variant had lost all of these functions. Ablation of Spin4 in mice recapitulated the human phenotype with generalized overgrowth, including increased longitudinal bone growth. Growth plate analysis revealed increased cell proliferation in the proliferative zone and an increased number of progenitor chondrocytes in the resting zone. We also found evidence that loss of Spin4 in mice led to decreased canonical Wnt signaling in growth plate chondrocytes, potentially contributing to increased pool of progenitor cells in the resting zone.Taken together, our findings provide strong evidence that SPIN4 is an epigenetic reader that negatively regulates mammalian body growth, and that loss of SPIN4 causes an overgrowth syndrome in humans, expanding our knowledge of the epigenetic regulation of human growth.

DNA methylation determines bone length through growth plate mineralization by regulating chondrocyte energy metabolism *Yuta Yanagihara[1], Masatomo Takahashi[2], Yoshihiro Izumi[2], Takeshi Bamba[2], Yuuki Imai[1]. [1]Division of Integrative Pathophysiology, Proteo-Science Center, Ehime University, Japan. [2]Division of Metabolomics/Mass Spectrometry Center, Medical Research Center for High Depth Omics, Medical Institute of Bioregulation, Kyushu University, Japan

Chondrocytes differentiated from mesenchymal stem cells play a role in determining skeletal patterns by ossification. However, it is still unclear how the maintenance DNA methylation regulates chondrocyte differentiation and skeletal formation. Dnmt1 is recruited to hemi-methylated DNA sites by Uhrf1 and is essential for maintenance DNA methylation. In Musculoskeletal Knowledge Portal from IFMRS, common variant gene-level of Dnmt1 was significantly associated with “Height” (p=4.22e-35). Therefore, we analyzed the function of Dnmt1 in chondrocytes using limbs specific Dnmt1 deficient (cKO) mice. cKO mice exhibited remarkably short long bones about 45-60% of control (Ctrl) mice. Histological analyses revealed that cKO showed thinner proliferative zone, wider and more calcified hypertrophic zone than Ctrl littermates at 1 week old. Surprisingly, growth plate of cKO mice was disappeared at 6 weeks old. These results suggested that Dnmt1 regulate skeletal formation via controlling chondrocyte differentiation. Then, to identify factors that are directly regulated by Dnmt1 and influence chondrocyte differentiation, candidate genes were identified by integrated analysis of RNA-Seq and MBD-Seq. Among candidate genes, ossification related genes were significantly enriched. Consistent to this result, mineralization of cKO primary cultured chondrocyte was remarkably facilitated. In addition, the top 4 genes increased by reduction of DNA methylation were related to energy metabolism. cKO chondrocytes showed enhanced mitochondrial respiratory function compared to Ctrl chondrocytes by flux analyzer. Furthermore, metabolomic analysis revealed that almost all metabolites in TCA cycle and glycolytic process, including ATP, were increased in cKO chondrocytes. ATP is well known important metabolite for mineralization. Moreover, Ctrl chondrocytes completely failed to mineralize in culture media without glucose and glutamine, however, cKO chondrocytes could successfully mineralize under same condition. These results indicate that Dnmt1 mediated maintenance DNA methylation governs chondrocyte mineralization by regulating energy metabolism through both gene expression and metabolite supply. Finally, the expression of Dnmt1 was decreased and TETs expression was increased along with chondrocyte differentiation. These data totally suggested that appropriate DNA methylation status in chondrocytes can organize growth plate mineralization, followed by determine bone length.

Piezo1 activation accelerates endochondral osteogenesis-mediated fracture healing and the targeted intervention effect of resveratrol *Donghao Gan[1], Wenjing Zhang[2], Qingyun Jia[3], Guozhi Xiao[1]. [1]Southern University of Science and Technology of China, China. [2]Shenzhen Institute of Advanced Technology, China. [3]Linyi People’s Hospital, China

Background Fracture is one of the most common injuries in humans, and despite advances in surgical treatment, approximately 5-10% of patients will progress to delayed union or nonunion. Therefore, it is urgent to explore therpeutic targets for promoting fracture healing and shorten the healing time.Objectives To investigate the effects of Piezo1 activation on bone fracture healing and to explore Piezo1-targeting fracture healing treatment.Methods The expression levels of Piezo1 were determined in human and mice fresh callus tissue. Mice with genetic Piezo1 deletion in chondrocytes or local injection of the Piezo1 activator Yoda1 were utilized to determine the effects on fracture healing. In an effort to define Piezo1-targeting drugs for potential fracture treatment, via virtual docking technology in the constructed compound library, we found that Resveratrol (RSV) may be a PIEZO1-targeting drug. Then, we developed an injectable RSV loaded hydrogel platform as a high payload and sustainable release for fracture treatment.Results Piezo1 expression was elevated in callus tissue chondrocytes in human and bone fracture mouse model. Piezo1 deletion in chondrocytes largely delays fracture healing and callus mineralization. In contrast, local injection of Yoda1 markedly accelerated fracture healing in bone fracture mice. PIEZO1 activation increases, while PIEZO1 siRNA knockdown decreases, expression of osteogenic markers such as RUNX2, Col1a1 and Osterix in primary human articular chondrocytes (HACs) induced by osteogenesis and fluid shear stress stimuli. Interestingly, we found that Yoda1 reduced, while Piezo1 deletion increased, the expression of Runx2-degraded E3 ligase smurf1 in HACs, inhibits ubiquitin-proteasome degradation of Runx2, and promotes Runx2 transcription and osteogenic phenotype. virtual docking simulation revealed Piezo1 molecule with strong binding ability to RSV. Results from primary HACs showed that RSV activates the PIEZO1-mediated calcium flux. Results from in vitro experiments confirmed that RSV decreased the Runx2 degradation and reversed by Piezo1 deletion in HACs. Hydrogel conjugated with RSV were stable and nontoxic, with long time slow release, high cartilage uptake, and penetration capabilities, and is used for in vivo research. When compared with control mice, the RSV-treated mice displayed marked accelerated fracture healing, and upregulated osteogenic genes. Importantly, RSV-induced increases in the bone trabeculae formation, callus mineralization and fracture gap union were dramatically delayed or completely abolished by Piezo1 deletion.Conclusions We establish a critical role of Piezo1 in promoting bone fracture healing and define RSV, Piezo1-targeted compound, as a potential bone fracture treatment.

SDHA inhibition is involved in Lin28a osteoarthritic chondrocyte reprogramming *ZOHRA BOUCHEMLA[1], Inès Slitine[2], Valentin Duong[2], Fawaz Alzaid[3], Lucie Orliaguet[3], Augustin Latourte[4], Pascal Richette[4], Hang-Korng EA[4], MARTINE COHEN-SOLAL[5], Eric Hay[6]. [1], France. [2]U1132 Inserm, France. [3]Cordeliers Research Center, INSERM, France. [4]U1132 Inserm and Lariboisière APHP hospital, France. [5]Inserm U1132 Bioscar and université Paris-Cité, France. [6]INSERM u1132, France

We have previously shown that Lin28a induces cartilage regeneration during osteoarthritis by inhibiting Let7. Loss of hypoxia is associated with OA progression, inducing energetical metabolism dysfunction. We focused here on the effect of Lin28a on this process and how energetical metabolism is involved in cartilage reprogramming.We performed RNAseq, RT-qPCR, WB, and immunofluorescent staining on murine primary chondrocytes overexpressing or not Lin28a in control or osteoarthritic (Wnt3a) conditions. For ex vivo analysis we used mouse femoral heads and human cartilage explants. Osteoarthritis was induced in WT or TgLin28aflox/flox/Col2CreERt2 by meniscectomy or aging. Knee joints were used for qPCR and histological analysis.In vitro RNAseq analysis showed that Wnt3a induces an increase in oxidative stress associated genes and mitochondrial impairment. Seahorse assay demonstrated a dramatic decrease of the spare respiratory capacity, indicating mitochondrial failure induced by Wnt3a treatment. On the other hand, reduced mitochondrial respiration and increased glycolysis were found with Lin28a overexpression (RNAseq and Seahorse). RNAseq indicates that the mitochondrial enzyme SDHA is oppositely regulated by Wnt3a and Lin28a. In vitro, Wnt3a increases SDHA gene and protein expression whereas Lin28a reduces it. This result was confirmed ex vivo on mouse femoral head explants. In OA mice (meniscectomized or aged), we observe an increase of SDHA expression whereas it is dramatically decreased in TgLin28a mice. This result was confirmed in human OA cartilage samples. To investigate the role of SDHA in chondrocyte protective effect, we used Aptenin5, an SDHA inhibitor. Aptenin5 inhibits the increased expression of mmp13 and adamts5 induced by Wnt3a. This effect was also found in human explants cultured with Wnt3a and Aptenin5. Because SDHA is involved in the conversion of succinate to fumarate, we hypothesized that the accumulation of succinate is responsible for the protective effect on chondrocytes. To demonstrate this, we treated murine chondrocytes and explants with Wnt3a with and without succinate. We found that succinate blocks the pro-catabolic and anti-anabolic effects of Wnt3a.Alltogether, these data indicate that energetic metabolism reprogrammed by Lin28a overexpression participates in cartilage protection during OA through SDHA inhibition. These results suggest that chondrocyte energy metabolism could be a new insight on OA therapeutics.

Apolipoprotein E Is a Novel Marker for Chondroprogenitor Cells in The Murine Growth Plate *JOE KODAMA[3], Kevin Wilkinson[2], Takeshi Oichi[3], Masahiro Iwamoto[4], Motomi Enomoto-Iwamoto[5], Satoru Otsuru[2]. [3]University of Maryland, Baltimore, United States. [2]University of Maryland, United States. [3]University of Maryland, Baltimore, . [4]University of Maryland School of Medicine, United States. [5], United States

Recent studies suggest that the progenitor cells are located in the resting zone of the murine growth plate and consist of heterogeneous cell populations such as Pthlh+ cells and Foxa2+ cells. However, neither the spatial distribution nor the temporal hierarchy of these different cell populations is fully understood. We newly identified that Apolipoprotein E (encoded by Apoe) specifically and ubiquitously marks the progenitor cells in the resting zone of the murine growth plate after the formation of the secondary ossification center. We generated Apoe-mCherry reporter mice and confirmed the specific expression of mCherry in the resting chondrocytes (Fig.A). Sorted mCherry-positive chondrocytes have demonstrated the potential to differentiate into the trilineage in vitro culture. Single-cell RNA sequencing (scRNAseq) analysis and flow cytometry analysis of Apoehigh growth plate chondrocytes revealed at least two distinct progenitor populations (cluster 0 and cluster 1 in Fig.B). Cluster 0 had the highest Apoe and Clu expressions, whereas Cluster 1 had lower Clu expressions (Fig.C). Trajectory analysis suggested that the Cluhigh population gave rise to the other Apoehigh cells (Fig.B). RNA in situ hybridization of the growth plate of Apoe-mCherry mice identified that the Cluhigh population was located in the upper layer of the mCherry-positive resting zone (Fig.A). Pulse-chase experiments with daily injection of EdU for 8 days during the growth spurt demonstrated that mCherry+ progenitors were slow cycling compared to the columnar chondrocytes. Interestingly, mCherry+Cluhigh progenitors were barely incorporated with EdU, suggesting that they are more quiescent than mCherry+Clulow progenitors. These findings are also supported by our scRNAseq analysis showing that Cluhigh cells (Cluster 0) express the lowest Ccnd1, a cell cycle marker, further indicating that they are quiescent cells. These results suggest that mCherry+Cluhigh progenitors are upstream of the mCherry+Clulow progenitors in the hierarchy. Future characterization of these two populations may lead to a better understanding of the dynamic role of chondroprogenitors in the resting zone during longitudinal bone growth.

Hedgehog activation promotes osteogenic cell fates of growth plate resting zone chondrocytes *Shion Orikasa[1], Noriaki Ono[1]. [1]University of Texas Health Science Center at Houston School of Dentistry, United States

The resting zone of the postnatal growth plate is organized by slow-cycling chondrocytes expressing parathyroid hormone-related protein (PTHrP), which include a subgroup of skeletal stem cells that contribute to the formation of columnar chondrocytes. The PTHrP-Indian hedgehog (Ihh) feedback regulation is essential for sustaining growth plate activities; however, molecular mechanisms regulating cell fates of PTHrP+ resting chondrocytes and their eventual transformation into osteoblasts remain largely undefined. In this study, we hypothesized that Hedgehog signaling facilitates osteogenic cell fates of PTHrP+ resting chondrocytes through multiple mechanisms. We utilized a tamoxifen-inducible PTHrP-creER line that can exclusively mark PTHrP+ chondrocytes in the resting zone of the postnatal growth plate without marking any other cell types in long bones. To specifically activate Hedgehog signaling in PTHrP+ resting chondrocytes and visualize the fate of their descendants within growth plate and bone marrow, we also used Patched-1 (Ptch1 encodes a Hedgehog receptor which inhibits its downstream Smoothened signaling) floxed and R26R-tdTomato reporter alleles. All mice received a single dose of tamoxifen at postnatal day (P) 6 and were chased for up to 3 months. Histological and three-dimensional micro-computed tomography (3D micro-CT) analyses were performed at P14, 21, 28, 36, 42, 56, 70, 96. Hedgehog-activated PTHrP+ chondrocytes formed large concentric clonally expanded cell populations within the resting zone (‘patched roses’) at P21 and generated significantly wider columns of chondrocytes, resulting in hyperplasia of the growth plate at P36. Interestingly, Hedgehog-activated PTHrP+ cell descendants migrated away from the growth plate and eventually transformed into trabecular osteoblasts in the diaphyseal marrow space, leading to increased trabecular bone mass in the diaphysis at P96. Therefore, Hedgehog activation drives resting zone chondrocytes into transit-amplifying states as proliferating chondrocytes and eventually converts these cells into osteoblasts, unraveling a novel Hedgehog-mediated mechanism that facilitates osteogenic cell fates of PTHrP+ skeletal stem cells. These findings provide a solid foundation to understand how therapeutic intervention to the Hedgehog signaling pathway may impact a group of stem cell populations residing in the resting zone of the growth plate of growing individuals and subsequently affect bone formation.

Identification of Novel Somatic Pathogenic Menin 1 Mutations without Germline Origin in an Atypical Parathyroid Tumor *An Nguyen[1], Dolores Shoback[2], Roubin Wu[3], Quan-Yang Duh[4], Janet Chiang[1]. [1]UCSF Endocrinology, United States. [2]UCSF Endocrinology, SFVA Medical Center, United States. [3]UCSF Pathology, United States. [4]UCSF Endocrine Surgery, SFVA Medical Center, United States

Atypical parathyroid tumors (APTs) are rare lesions and can have worrisome features even without invasion or metastases like PT cancer. The loss of parafibromin staining in these tumors suggests a germline or somatic mutation that produces either hyperparathyroidism (HPT)-jaw tumor or familial HPT syndromes. However, parafibromin expression does not exclude a possible mutation.A 69-year-old woman with end-stage renal disease received a living donor kidney transplant after being on peritoneal dialysis for 16 months. While on dialysis and cinacalcet 120mg daily, serum Ca was ~9.0 mg/dL (normal, 8.6-10.4), and PTH values were 1100-1500 pg/mL (normal, 16 -77). One-month post-transplant, PTH remained elevated to 600 pg/mL, serum Ca to 11.8 mg/dL. Neck ultrasound identified a 1.9 x 1.8 x 2.2 cm left posterior hypoechoic candidate lesion with heterogeneity and irregular borders which was co-localizied on Sestamibi scan. PTH level in the washings of the fine needle aspiration of this lesion was >2500 ng/L. At left neck exploration, a large superior parathyroid gland was found to be embedded in the thyroid, requiring lobectomy with parathyroidectomy. Histology revealed a markedlyn enlarged glandtumor with 95% cellularity, without significant mitotic activity, necrosis or infiltration into surrounding tissue. There was retention of nuclear parafibromin staining, consistent with APT. Postoperatively, PTH decreased to 140 pg/mL (serum Ca 9.7 mg/dL) off cinacalcet. The patient denied any family history of MEN. Molecular testing of the tumor revealed pathogenic missense Menin 1 mutation MEN1 p.P320L (40% allele frequency) and pathogenic frameshift MEN1 p.V80W (38% allele frequency) - the latter being a novel mutation. Germline genetic testing was negative for both variants.For molecular testing for somatic mutations, the general cutoff of at least 50% allele frequency strongly supports a germline origin. The MEN1 p.P320L missense mutation is known to result in reduced protein stability leading to rapid degradation and is a germline mutation in hereditary MEN1 and a somatic mutation in sporadic endocrine tumors. The p.V80W mutation in MEN1 is novel and predicted to be pathogenic, given its truncating effect potentially early in protein translation. Overall, this case unites several concepts of recognition, diagnosis, and treatment, as well as application of molecular and genetic testing to identify somatic and germline mutations in APT and in endocrine tumors.

Bone microarchitecture and disorganized bone tissue in a young woman with pycnodysostosis and an atypical femur fracture: A case report *Cat Shore-Lorenti[4], Heshan Witanachchi[4], Colin Chen[4], Simon Zhang[4], Hanh Nguyen[2], Christian Girgis[3], Roger Zebaze[4], Peter Ebeling[5]. [4]Monash University, Australia. [2], Australia. [3]Westmead Hospital , . [4]Monash University, . [5]School of Clinical Sciences, Monash University, Australia

Abstract: Pycnodystosis (PYCD) is a rare autosomal recessive lysosomal storage disorder, involving a loss of function mutation of the gene encoding cathepsin K (CTSK). The loss of function of this osteoclastic lysosomal protease reduces bone resorption, increases bone mineral density (BMD), but impairs the structure and material properties of bone. This case report demonstrates that bone fragility in a young woman with PYCD, presenting with an atypical femur fracture (AFF), was not explained by changes in bone density but by microarchitectural defects, disorganized bone and microcracks.Clinical Case: A 24-year-old woman with PYCD presented with an AFF in 2020 following a long history of prior minimal trauma fractures (MTF). PYCD was diagnosed in childhood and as an adult this patient displayed several signs and symptoms, including, but not limited to: short stature; dystrophic nails; short fingers; prominent forehead; prognathism, and; a significant history of 10 peripheral MTFs. Her first MTF occurred at 6-years-of-age. No other medical conditions or significant family history were identified. Her parents were consanguineous.At the time of the AFF, the patient was treatment naïve. Three years prior she gave birth via Caesarean-section and was able to breastfeed her baby for 12 months. Following the AFF, her vitamin D was slightly reduced (45 nmol/L), while P1NP and CTX were high, at 124 ug/L and 518 ng/L, respectively. Other pathology results were unremarkable.In the year following the AFF, BMD was high at the spine (T-score = +3.3), total hip (+5.4); and femoral neck (+6.7). High-resolution peripheral quantitative computed tomography (HR-pQCT) of the distal tibia detected unexpected cortical lucencies and sclerotic lesions in the trabecular compartment of the distal tibia (Fig1). Both total and trabecular volumetric BMD (vBMD) were high and trabecular numbers were increased in both the distal radius and tibia. Disorganization analysis using a novel software showed chaotically disorganized femoral shaft with spike shape masses at locations corresponding to a pseudofracture and sclerotic lesions.Clinical Conclusion: These imaging techniques detected disorganized bone and microarchitectural defects in a treatment naïve patient with PYCD and an AFF. The suppression of bone resorption in PYCD allows the accumulation of microdamage and disorganized bone that produces bone fragility. Antiresorptive therapy should be avoided.

Evidence of Reduced Dentin Sialophophoprotein Expression and Impaired Cell Process Formation in Odontoblasts in Patients with Hypophosphatasia *Akira Nozoe[1], Kazuaki Miyagawa[1], Chiho Nakano[1], Shinji Takeyari[2], Makoto Fujiwara[4], Yasuhisa Ohata[4], Keiichi Ozono[2], Takuo Kubota[2], Susumu Tanaka[1]. [1]First Department of Oral and Maxillofacial Surgery, Osaka University Graduate School of Dentistry, Japan. [2]Osaka University Graduate School of Medicine, Japan. [4]Osaka University, . [4]Osaka University, Japan

Background: Hypophosphatasia (HPP) is a genetic disorder characterized by the premature loss of deciduous teeth due to defects in cementum formation. In addition, insufficient calcification of mantle dentin, which is essential for cementum formation, is also observed. But the underlying pathology remains unclear. Our objective of this study is to elucidate the underlying pathogenesis of dental defect in patients with HPP.Methods: We utilized induced pluripotent stem cells (iPSCs) from healthy individuals to generate odontoblast-like cells (ODs) via neural crest cells and mesenchymal stem cells (MSCs). We then examined various parameters, including odontoblastic differentiation markers and protein expressions, morphology, and calcification function using RT-qPCR, western blotting, immunostaining, and alizarin red staining. As a control group, we also induced osteoblast-like cells (OBs) from the same healthy MSCs. In addition, we created an HPP-iPSC from a patient with perinatal severe-type HPP (c.1559delT/c.1559delT: Perinatal), genetically rescued Perinatal-iPSCs by repairing both alleles using the CRISPR-Cas9 system (WT/WT: resHPP), and an odonto-type HPP model (WT/c.550C>T: odonto) from the resHPP-iPSCs using prime editing.

We then assessed their isogenic odontogenesis.Results: In WT-ODs, we observed significant increase in DSPP and NES protein expressions, compared to MSCs. The expression of RUNX2 protein increased in the early differentiation stages and then decreased in the late differentiation stages. Additionally, calcification and ALP activity increased over time. We also noted significant increase in MAPT and NEFL gene expressions, in WT-ODs compared to WT-OBs. Moreover, WT-ODs displayed a polarized nucleus and elongated cell process in one direction, Compared to Perinatal-ODs and Odonto-ODs, resHPP-ODs showed significant increase in ALP activity, DSPP protein expression, and mineralization during odontogenesis. Notably, RUNX2 protein expression was sustained until the late differentiation stage in Perinatal-ODs. The length of cell processes in Perinatal-ODs and Odonto-ODs were shorter than that in resHPP-ODs.Conclusion: We successfully established ODs differentiated from iPSCs. Our findings suggested that reduced DSPP expression, decreased ability to form cell process and lower calcification ability may be involved in the underlying pathogenesis of dental defect in HPP.

Comparison of Cd11b+ cells of the mandibular and femoral bone marrow at single-cell resolution *Rachel Phillips[1], Elizabeth Bradley[1], Kim Mansky[2], Amy Tasca[1]. [1]University of Minnesota , United States. [2]University of Minnesota, United States

Osteoclast activity within craniofacial bones orchestrates critical processes such as tooth eruption and skull modeling. Recent lineage tracing experiments in mice demonstrate that proper tooth eruption and skull generation requires embryonic but not adult myeloid cells. These data suggest that cellular ontogeny imparts fundamental differences between adult bone marrow-derived as compared to embryonic-derived tissue resident osteoclast progenitor cell populations; however, we lack essential knowledge about the osteoclast progenitors found in the marrow of craniofacial bones. Moreover, we completely lack transcriptomic data describing craniofacial-derived osteoclast progenitors. This knowledge gap impairs our understanding and treatment of pathological conditions including osteonecrosis of the jaw, primary or metastasized facial bone malignancies and osteomyelitis. Our lab has demonstrated that mandible-derived osteoclast precursors proliferate less, have increased osteoclast size and upregulation of osteoclast genes including Nfatc1, Dc-stamp, Ctsk, and Rank compared to osteoclasts derived from the femur bone marrow. To develop a better understanding of the transcriptome differences between mandible- and femur-derived osteoclast precursors, we performed scRNA sequencing of CD11b+ cells from mandible and femur bone marrow. CD11b+ cells were isolated from the femur and mandible derived bone marrow of 2-month-old male C57Bl/6 mice using Cd11b+ isolation microbeads. Six samples (3 femoral and 3 mandibular) were submitted for single-cell RNA sequencing. Six single cell captures targeting 10,000 cells each were performed by ST G chip for 3' gene expression. Using two-dimensional t-SNE representations of the expression levels of each of the samples, unique cell populations and differentially expressed genes were identified. Femur gene expression levels were used as the baseline for analysis. Differentially expressed genes pathways included up-regulation of TNF-?, AGE-RAGE and FOXO signaling pathways. While genes involved in cell adhesion, Fc gamma R mediated phagocytosis and autophagy pathways were down regulated in mandible derived cells. Currently expression of genes within these pathways are being verified by qRT-PCR. Together this data suggests that mandible derived osteoclast precursors have a unique gene signature compared to femur derived osteoclast precursors.

Conditional Knockout of Neural Sarm1 Improves Body Mass and Metabolic Health with High Fat Diet *Lila Dabill[3], IVANA SHEN[2], XIAO ZHANG[2], Aaron DiAntonio[3], Erica Scheller[4]. [3]Washington University in St. Louis, , [2], , [3]Washington University in St. Louis, United States. [4]Washington University, United States

Sterile alpha and TIR motif containing 1 (Sarm1) is a toll-like receptor, highly expressed in the nervous system, that is activated with injury, inflammation, and oxidative stress to promote axon degeneration and dysfunction. Previous findings with global knockout of Sarm1 showed evidence of metabolic improvements in high-fat diet (HFD) induced type 2 diabetes (T2D) as well as reduced peripheral axon degeneration. We hypothesize that this is due to the actions of Sarm1 in the nervous system. To test this hypothesis, we used Baf53b-Cre to knock out Sarm1 in all neurons throughout the body (Sarm1-cKO). Both control and Sarm1-cKO mice were fed HFD for 24 weeks, starting at 4-6 weeks of age. Quantitative PCR (qPCR) analysis confirmed high Sarm1 expression in the dorsal root ganglia (DRG) with a significant decrease in Sarm1-cKO mice; no significant difference in Sarm1 expression was observed in bone, testis, liver, or iWAT tissue between control and Sarm1-cKO mice. Over the 24-week study period, Sarm1-cKO mice fed HFD gained 20% less body mass than controls (20.8g mass gain on average in cKO vs 26g mass gain in control mice). Furthermore, subcutaneous inguinal fat, but not visceral gonadal fat, was preferentially reduced by 26% in Sarm1-cKO mice. Sarm1-cKO mice on HFD also showed evidence of metabolic rescue with smaller livers and less steatosis. Lastly, insulin tolerance testing (ITT) results show that Sarm1-cKO mice on HFD were more sensitive to insulin than controls. Micro-computed tomography and biomechanical testing are pending to determine if Sarm1-cKO mice have improved bone microarchitecture or strength with HFD feeding, respectively. Sarm1 inhibitors are currently under clinical development for the treatment of neurodegenerative disease. These results show that inhibition of Sarm1-dependent neurometabolic regulatory pathways also has the potential to support metabolic health in settings of obesity and T2D.

The NAD salvage pathway in osteoblast lineage cells is indispensable for skeletal homeostasis *Olivia Reyes-Castro[1], Aaron Warren[1], Ha-Neui Kim[2], Maria Jose Almeida[3]. [1]University of Arkansas for Medical Sciences, United States. [2]Univ. Arkansas for Medical Sciences, Central Arkansas VA Healthcare System, United States. [3]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, United States

Nicotinamide adenine dinucleotide (NAD+) - a critical cofactor for cellular energy metabolism and numerous cellular processes, including cell division, DNA damage repair, and mitochondrial function - can be synthesized via several pathways. NAD+ levels and the expression of nicotinamide phosphoribosyltranferase (Nampt), the rate limit enzyme of the NAD+ salvage pathway, are lower in osteoblastic cells from old when compared to young mice. Moreover, administration of NAD+ precursors to aging mice attenuates the loss of bone mass and the involution of many other tissues. To examine the role of Nampt in osteoblastic cells and whether a decline in Nampt could contribute to skeletal aging, we initially generated mice lacking Nampt in Prx1-cre targeted cells. However these mice exhibited severe developmental phenotypes due to effects in chondrocytes, which precluded the examination of effect of Nampt on bone formation. In the work reported herein, we crossed Nampt-flox and Osx1-Cre mice to generate Nampt?Osx1 and Osx1-cre control mice. Nampt?Osx1 mice were born at the expected Mendelian ratio and were grossly undistinguishable from Osx1-Cre control littermates at birth. Evaluations of body weight, as well as spine and femur DXA BMD at 4 weeks of age revealed no differences between Nampt?Osx1 female or male mice when compared to the respective littermate controls. In contrast, femoral BMD in male and female Nampt?Osx1 mice was decreased at 12 weeks of age compared with Osx1-cre mice. Cultures of bone marrow derived osteoblastic cells from Nampt?Osx1 mice had lower NAD+ levels and exhibited decreased mineralization, as determined by Alizarin Red staining. Micro-CT analysis of femur from male and female Nampt?Osx1 revealed a decrease in cortical thickness due to a decrease in periosteal circumference. No changes were detected at the endosteal circumference. Trabecular bone volume at the distal femur and vertebrae (L5) was also lower in male Nampt?Osx1. These changes were due to a decrease in both trabecular number and thickness. No differences in trabecular bone were found in female. These results indicate that in osteoblast lineage cells Nampt contributes to bone homeostasis. Together with the earlier findings in Nampt?Prx1 mice, these results highlight that the dependency of osteoblast on Nampt is of much lower magnitude than that of chondrocytes.

Effects of Carboxylated and Uncarboxylated Osteocalcin on Glucose Sensitivity in Severe Osteoporotic Non-Diabetic Patients and In Vitro on Human ?-cells and Primary Adipocytes *Veronica Sansoni[1], Laura Gerosa[1], Chiara Verdelli[1], Marta Gomarasca[1], Martina Faraldi[1], Giovanni Mennuni[2], Riccardo Pasquali[3], Giuseppe Banfi[1], Sabrina Corbetta[4], Giovanni Lombardi[1]. [1]Laboratory of Experimental Biochemistry, IRCCS Istituto Ortopedico Galeazzi, Italy. [2]Laboratory Medicine Service, IRCCS Istituto Ortopedico Galeazzi, Italy. [3]Endocrinology and Diabetology Service, IRCCS Istituto Ortopedico Galeazzi, Italy. [4]Bone Metabolism and Diabetes Unit, IRCCS Istituto Auxologico Italiano, Italy

Extra-skeletal roles of carboxylated (GlaOC) and uncarboxylated (GluOC) forms of osteocalcin (OC) have been described in heterologous in vitro models and in vivo in rodents, where GluOC has been reported to affect glucose metabolism by stimulating pancreatic ?-cells proliferation, insulin expression and secretion and by improving insulin sensitivity and glucose uptake by skeletal muscle and adipose tissue. However, data in humans and human cells are limited and contrasting.This study aims at investigating: i) the relationship between GlaOC, GluOC and the indexes of glucose metabolism and insulin resistance in severe osteoporotic non-diabetic women randomized to either teriparatide (TPT) treatment or TPT associated with vitamin K (TPT+MK7) supplementation; ii) the effects of GlaOC and GluOC on human ?-cell function, and iii) on adipogenic differentiation of human subcutaneous adipose-derived stromal cells (ASCs).At present, 65 patients out of 82, aged >=65 years, have been enrolled. Six TPT and 6 TPT+MK7 patients completed the 18-month follow-up. At baseline, circulating GlaOC and GluOC do not associate with the indexes of glucose metabolism, while GlaOC positively correlates with waist circumference. GlaOC increases and GluOC/GlaOC decreases, both consistently although not significantly, in TPT+MK7 patients. Oral glucose insulin sensitivity (OGIS) significantly increases and fasting glycaemia decreases after TPT treatment, together a higher GluOC/GlaOC.The putative receptor for OC, GPRC6A, is expressed in immortalized human EndoC-?H1 ?-cell; 72h treatment with either GlaOC or GluOC (5, 20, 40 ng/mL) do not affect the glucose-stimulated insulin secretion (glucose: 0, 2.8, 5.6, 11, 20 mM). Further, 6h treatment with OC forms do not affect the expression of key genes in ?-cell function and sensitivity to glucose.GPRC6A is also ex-

pressed in ASCs. OC forms do not affect the adipogenic differentiation potential of ASCs; indeed, GluOC 40ng/mL induces a significantly increased expression of UCP1 gene, marker of brown adipocyte, without affecting LPL gene expression, marker of white adipocytes. UCP1 induction is independent from PGC1? expression, while associates with Cited1 induction, marker of the beige intermediate phenotype.In conclusion, human in vivo and in vitro data suggest no direct effects of OC on insulin secretion while supporting mild positive effects on peripheral insulin sensitivity and potential stimulation of a brown-like adipocytic phenotype.

Bone fracture causes long-term impairment of the bone marrow niche for hematopoietic stem cells *Elise Jeffery[1,] Sean Ahler[1,] Bethany Davis[1,] Sean Morrison[1.] [1]UT Southwestern Medical Center, United States

Bone fracture is estimated to occur in 2.3% of people every year (GBD Fracture Collaborators, The Lancet, 2021). In addition to damaging bone, fracture also significantly damages the bone marrow (BM), which is the primary site of hematopoiesis in healthy adults. Hematopoietic stem cells (HSCs) in the BM reside adjacent to sinusoidal blood vessels and perivascular stromal cells, which secrete chemokines essential for HSC maintenance and survival (Crane et al, Nat Rev Immun, 2017). During fracture repair, the BM stroma is regenerated in part by periosteal cells that contribute to the formation of the fracture callus (Jeffery et al, Cell Stem Cell, 2022). However, it's unclear to what extent the regenerated BM stroma supports hematopoiesis. To investigate this, we analyzed the frequency of HSCs, restricted progenitors, and mature lineages in mice five weeks after tibial fracture, a time point when the bone cortex has fully re-formed and the marrow has regenerated (Jeffery et al, Cell Stem Cell, 2022). We found a striking three-fold reduction in the frequency of HSCs in post-fracture BM compared to that of the contralateral uninjured tibia. In contrast, there was no difference in the frequencies of lineage restricted progenitors or of mature hematopoietic populations. These data suggest that post-fracture BM is specifically toxic to HSCs. The degree of fracture stabilization did not affect the phenotype, as we observed a similar reduction in HSC frequency after non-stabilized fracture and pin-stabilized fracture. Surprisingly, the reduction in HSC frequency was maintained for at least six months post-fracture, suggesting that fracture has a long-term effect on the hematopoietic microenvironment. We hypothesized that this reduction in HSC frequency was due to impaired niche cell function in the regenerated BM. However, we found no significant changes in stromal cell number, morphology, or niche factor expression in stromal cells from regenerated BM compared to stromal cells from normal BM. In contrast, when we analyzed the morphology of endothelial cells following fracture, we found a significant increase in the number of arterioles, as well as irregular organization of sinusoids with high variability in sinusoid width. These data suggest that the sinusoidal niche for HSCs may be compromised in regenerated BM, and that the regrowth and remodeling of blood vessels in the BM is a limiting factor for the proper resumption of hematopoiesis following fracture.

Rhythmic Circulating Glucocorticoid Levels Play a Critical Role in Bone Loss Driven by Chronic Disruption of Circadian Rhythms *Eugenie Macfarlane[1,] Lauryn Cavanagh[1,] Colette Fong-Yee[1,] Markus Seibel[1,] Hong Zhou[1.] [1]Bone Research Program, ANZAC Research Institute, University of Sydney, Sydney, Australia, Australia

Chronic disruption of circadian rhythms (CR) from shiftwork or sleep disorders is associated with bone loss and low bone mineral density. However, the mechanisms that drive these detrimental effects on bone are unknown. Adrenal glucocorticoid (GC) secretion follows a diurnal rhythm and is a potent regulator of CR by synchronizing the cellular clocks throughout the body. We therefore asked whether GC signaling in osteoblasts/osteocytes mediates bone loss induced by chronic CR disruption using conditional glucocorticoid receptor (GR) knockout mice. Col2.3Cre/GRf/f (obGRKO) mice and their wild-type (WT) littermates were exposed to an established model of chronic CR disruption for 22-weeks. Mice were maintained on either a normal 12:12hr light-dark cycle (non-shifted) or exposed to weekly 12hr phase-shifts, equivalent to spending alternate weeks in Sydney and London (shifted; Fig.1A). Chronic disruption of CR abolished the diurnal rhythmicity of circulating corticosterone, characterised by a loss in the normal daily peak of serum corticosterone (prior to wakening at 6pm) in all shifted mice (regardless of genotype, $p<0.0001$). Consequently, rhythmic expression of the major clock gene Bmal was absent in tibiae of shifted WT mice ($p=0.0004$) but maintained in shifted obGRKO mice (Fig.1B-C, $p=0.0409$). This indicates that blocking arrhythmic osteoblastic GC signaling allows a self-sustaining rhythm in Bmal1 expression to persist in these bone cells. Micro-CT analysis revealed that chronic CR disruption caused pronounced trabecular bone loss ($p=0.005$) and reduced volumetric bone mineral density (vBMD, $p<0.0001$) in shifted compared to non-shifted WT mice. While non-shifted obGRKO mice had lower trabecular BV/TV than non-shifted WT mice ($p<0.0001$), chronic disruption of CR increased trabecular BV/TV in obGRKO mice ($p<0.0001$), with vBMD maintained (Fig. 1D-E). Notably, shifted WT mice displayed significantly greater numbers of empty osteocyte lacunae compared to non-shifted WT mice ($p=0.0464$), suggestive of cellular apoptosis. In contrast, no such changes in osteocyte lacunae were observed in shifted compared to non-shifted obGRKO mice (Fig. 1F-G). In conclusion, chronic circadian rhythm disruption abolishes glucocorticoid rhythmicity which thereby disturbs skeletal circadian gene expression and induces bone loss. These novel findings provide valuable insight into how chronic disruption of circadian rhythm drives detrimental effects on skeletal health in shift workers.

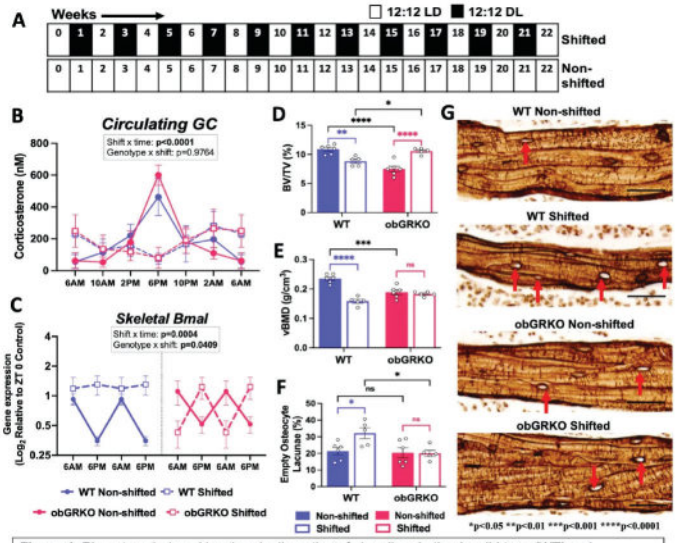

Figure 1. Phenotype induced by chronic disruption of circadian rhythm in wild-type (WT) and osteoblast/osteocyte glucocorticoid receptor knockout (obGRKO) mice. GC, glucocorticoid; Bmal, brain and muscle ARNT-Like protein; LD, Light:Dark. Analysed by two- or three-way ANOVA, n=5-6/group.

Two-Pronged Mediation of Adrenal Steroidogenesis by Oxytocin *Uliana Cheliadinova[2,] Georgii Pevnev[2,] Vitaly Ryu[2,] Tal Frolinger[2,] Steven Sims[2,] Ofer Moldavski[2,] Funda Korkmaz[2,] Orly Barak[2,] Judit Gimenez Roig[2,] Farhath Sultana[2,] Natan Kramskiy[2,] Soleil Wizman[2,] Michelle Orloff[2,] Tony Yuen[2,] Daria Lizneva[2,] Mone Zaidi[3,] Anisa Gumerova[2.] [2]Icahn School of Medicine at Mount Sinai, United States [2]Icahn School of Medicine at Mount Sinai, [3]Mount Sinai Medical Center, United States

Stress-stimulated glucocorticoid release affects diverse biological processes, including pregnancy and childbirth. The controversy surrounding effects of OXT on stress prompted us to investigate its actions on adrenal cortical function in mice. RNAscope and immunohistochemistry provided unequivocal evidence for abundant OXT receptor (OXTR) expression in the adrenal cortex, predominantly in zona fasciculata and zona reticularis. Female mice displayed higher adrenal cortical Oxtr expression, more than a range of other tissues under study. Oxtr expression was also detected in the adenohypophysis solely in female mice, while both male and female mice expressed Oxtr in the pars intermedia of the hypophysis. Aging impressively attenuated Oxtr expression in female mice in both the adrenal gland and adenohypophysis. For loss-of-function studies, we generated tissue-specific Star-CreERT2/Oxtrfl/fl mice in which the Oxtr was deleted from steroidogenic tissues, namely adrenals and ovaries. Deletion was confirmed by RNAscope and immunohistochemistry. We found no difference in serum corticosterone between tamoxifen-induced and uninduced mice; however, the elevation of serum corticosterone upon ACTH stimulation or after four weeks of stress was attenuated in tamoxifen-induced mice. Bulk RNAseq of adrenals from tamoxifen-induced mice revealed the downregulation of key steroidogenic genes, namely Cyp17a1, Hsd3b3, Hsd17b2, Cyp3a41b, and Serpina6 (a corticosteroid-binding globulin). In gain-of-function studies, a single OXT injection led to a rise of serum ACTH in tamoxifen-induced mice, which was greater in magnitude than uninduced controls. However, after five days of OXT injections, corticosterone levels became elevated, whereas ACTH levels declined to baseline. This suggests that OXT acts directly on OXTRs on corticotropes to initiate a stress-like response, with a negative feedback loop that inhibits further ACTH secretion. Of note is that male mice did not display any difference between tamoxifen-induced and uninduced groups, consistent with their low hypophyseal Oxtr expression. In all, we describe a novel gender-specific two-pronged circuit through which OXT may precisely regulates the production of corticosterone from the adrenal cortex. In the first arm, OXT directly stimulates ACTH secretion through adenohypophysis OXTRs. In the second arm, OXT prevents excessive stress-induced adrenal stimulation by downregulating steroidogenic genes. Our discovery lays the foundation for the emergence of new physiology that may relate to a fundamental role for oxytocin in the stress response during procreation, notably, when levels are elevated during pregnancy and lactation.

Dio3-Dio3os regulatory function in thyroid hormone linked bone formation
*Quamarul Hassan[1], Yuechuan Chen[2]. [1]University of Alabama, United States. [2]Univerisity of Alabama At Birmingham,

Consumptive hypothyroidism, a skeletal consequence due to aberrant deiodinase 3 (Dio3) expression, delays adolescent bone development, inhibits adult bone turnover due to defective thyroid hormone (TH) signaling. The long non-coding (lncRNA) Dio3os and coding Dio3 genes overlap and transcribe in opposite directions; however, we lack the knowledge of how Dio3os activates neighboring gene Dio3 (in cis) and silences osteoblast (OB)-specific genes at a distance (in trans) to inactivate TH signaling in osteoblast cells. The proposed research investigates the osteoblast-specific functions by which Dio3os controls cis and trans transcriptional activities in maintaining thyroid hormone (TH) signaling and bone formation in vivo. Recently, we found that the Dio3os is a critical regulator for osteogenesis, and CRISPR-mediated Dio3os transcriptional repression or exon deletion significantly decreased local Dio3 expression and increased non-local OB-specific gene expression. Preliminary RNA and chromatin accessibility (ATAC) sequencing analysis from Dio3os-deleted OBs further revealed that Dio3os directly controls the chromatin accessibility and modifications of TH-controlled bone-forming genes through a trans-regulatory mechanism by recruiting nucleosomal remodeling deacetylase (NuRD) complex. Furthermore, RNA immunoprecipitation with Dio3os followed by mass spectrometry analysis identified a group of nucleosome remodelers associated with deacetylase activity and belonging to the NuRD complex. Our central hypothesis is that Dio3os functions as a critical regulator of TH signaling during bone synthesis and maintenance by activating Dio3 locally and by repressing transcription of distant OB-specific genes.

Comparative Analysis of PTH (1-34), PTHrP (1-36), and Abaloparatide Effects on Murine Osteoblast Transcriptome
*ZHIMING HE[4], Michael Mosca[2], Florante Ricarte[3], CAROLE LE HENAFF[4], Nicola Partridge[5]. [4]New York University, . [2]NYU Langone Medical Center, . [3]Department of Molecular Pathobilogy, New York University college of Dentistry, United States. [4]New York University, United States. [5]New York University College of Dentistry, United States

Teriparatide (PTH (1-34)) and its analogs, PTHrP (1-36) and abaloparatide (ABL) have been used for the treatment of osteoporosis, but their efficacy over long-term use is significantly limited. Our laboratory has shown that PTH (1-34), PTHrP (1-36), and ABL exert time and dose-dependent differential responses in osteoblasts, leading us to hypothesize that they may also differentially modulate the osteoblast transcriptome. Here, we treated mouse calvarial osteoblasts with 1 nM of the 3 peptides for 4 h and analyzed the resulting RNA-Seq data. Gene-set enrichment analysis revealed that PTH (1-34) regulated 367 genes, including 194 unique genes; PTHrP (1-36) regulated 117 genes, including 15 unique genes; and ABL regulated 179 genes, including 20 unique genes. There were 74 genes shared exclusively between PTH (1-34) and ABL, 16 genes shared exclusively between PTH (1-34) and PTHrP (1-36), and 83 genes shared among all 3 peptides. The significant differences in the expression of various genes from the 3 peptides indicate gene ontology specific differences, including differences in Wnt signaling, cAMP-mediated signaling, bone mineralization, morphogenesis of a branching structure in biological processes; cytokine receptor/binding activity, ligand-activated transcription factor activity, cAMP phosphodiesterase activity in molecular functions. The 3 peptides increased Vdr, Cited1 and Pde10a mRNAs in a differential fashion similar to Rankl expression. These findings were confirmed via qRT-PCR with additional cultured samples. mRNA abundance of other genes of interest based on gene/pathway analyses, including Wnt4, Wnt7, Wnt11, Pde10a, Sfrp4, Dkk1, Kcnk10, Hdac4, Epha3, Tcf7, Crem, Fzd5, Pp2r2a, and Dvl3 were also examined; some genes were stimulated similarly by all 3 peptides; others were not. Finally, experiments with siRNA knockdowns of SIK1/2/3 and CRTC1/2/3 in PTH (1-34) treated cells showed that some of these genes are regulated by SIKs and CRTCs (Vdr, Wnt4), while others are not. Although many studies have examined PTH signaling in the osteoblast/osteocyte, ours is the first to examine the global effects of these peptides on the osteoblast transcriptome. Further delineation of which signaling events are attributable to PTH (1-34), PTHrP (1-36) and ABL exclusively and which are shared among all 3 will help improve our understanding of the effects these peptides have on the osteoblast and lead to the refinement of PTH-derived treatments for osteoporosis.

Calorie Restriction Profoundly Suppresses Bone Remodeling and Causes Cortical but not Trabecular Bone Loss in Mice
*Linyi Liu[1], Phuong T. Le[1], Roland Baron[2], Victoria DeMambro[1], Samantha Costa[1], Ziru Li[1], Clifford J. Rosen[1]. [1]MaineHealth Institute for Research, United States. [2]Harvard School of Dental Medicine, United States

Weight loss, by most means, causes bone loss, although the mechanism for that loss is unclear. Some studies have shown increased bone resorption, such as in anorexia nervosa while others have demonstrated uncoupled remodeling with reduced bone formation and enhanced bone marrow adiposity. Several lines of evidence from our previous studies suggested there was differential loss of cortical but not trabecular bone mass. To characterize the mechanisms inherent in weight loss-induced bone loss, we performed 30% calorie restriction (CR) for 8 weeks in both male and female 8-week-old C57BL/6J mice compared to a control diet. We examined areal BMD, micro-architecture, histomorphometric parameters, in vitro trajectories of osteoblast and adipocyte differentiation, and stromal cell bioenergetics using Seahorse technology. After 8 weeks, both CR male and female mice lost weight and exhibited femoral and whole body loss of BMD vs. controls ($p<0.05$). By uCT, CR males and females both had lower cortical bone volume fraction vs. control diet mice ($p<0.05$) (Figure 1), but trabecular parameters increased by diet in female mice vs. controls. Histomorphometric analysis revealed that CR male and female mice had a profound suppression in trabecular MAR, BFR/BV, and MS/BS ($p<0.001$ vs control), and very reduced EC and PS MAR, BFR/BV and MS/BS in cortical bone vs. control ($p<0.001$ for all parameters). These features were due to reduced osteoblast and osteoclast numbers on the endosteal, endocortical and periosteal surfaces. Importantly, there was a 6-fold increase in bone marrow adipocytes; Cfd (adipsin) was one of the top up-regulated bone marrow genes by qRT-PCR vs. control marrow. In vitro, the pace of adipogenesis in BMSCs was greatly accelerated with more oil red O staining, whereas osteogenic differentiation was reduced. CR BMSCs had a bioenergetic profile that revealed marked suppression in both oxidative phosphorylation and glycolysis (Figure 2) vs. controls ($p<0.001$). Taken together, these lines of evidence support the tenet that calorie restriction causes cortical bone loss due to a profound suppression in bone turnover, almost certainly related to a reduced supply of energy substrates. The increase in marrow adipocytes is related to both progenitor recruitment and lipid storage in the face of widespread nutrient insufficiency. Long term dietary restrictions may lead to a greater risk of cortical bone fractures.

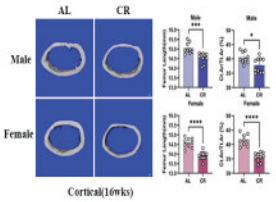

Fig1. Caloric restriction decreased cortical bone area fraction in both male and female mice

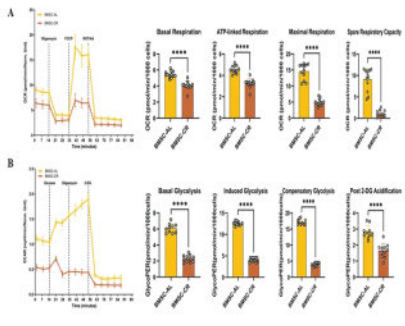

Fig2. Caloric restriction suppressed both oxidative phosphorylation and glycolysis in female mice

EXT608 for the Treatment of Hypoparathyroidism: Phase 1 Trial Design and Results *Laura Hales PhD[1], Kate Didio MBA[1], Leon Shi PhD[2], Daniel Hall PhD[1], Poul Strange MD PhD[2], Daniel Dickerson MD PhD FAAFP[3], Tarik Soliman PhD[1]. [1]Extend Biosciences, United States; [2]IMD, United States; [3]ICON plc, United States

Extend Biosciences is developing EXT608, a long-acting parathyroid hormone (PTH 1-34)-based therapy designed to replace the physiological effects of PTH with significantly less frequent dosing and improved bioavailability. EXT608 was developed using the company's D-VITylation® platform, which harnesses the biology of vitamin D and the reversible binding properties of the serum-circulating vitamin D binding protein. By utilizing this natural pathway, D-VITylation prevents a vitamin D-conjugated therapeutic from renal clearance, thereby significantly extending its half-life. Bioactivity is not compromised and as such, EXT608 is fully active as-is at the PTH receptor.A double-blind, randomized, placebo-controlled Phase 1 trial involving 24 healthy participants (3:1 active:placebo) across 6 cohorts was conducted with EXT608. The primary endpoint was to characterize the safety and tolerability profile of escalating dose levels of EXT608 when administered to healthy adult subjects as a single injection by 1) observing the incidence, nature, and severity of adverse events (AEs) and withdrawals due to treatment emergent AEs, 2) noting the frequency and severity of post-dose change from baseline in hematology, serum chemistries, urinalysis, electrocardiogram, vital signs, and physical examination findings, and 3) determining the percentage of subjects with injection or infusion site reactions. Secondary endpoints included 1) determining plasma pharmacokinetic parameters, and 2) assessing the pharmacodynamic profile by measuring post-dose change from baseline in serum chemistries and urinalysis. The results show that EXT608 was safe and well tolerated, with no serious adverse events reported. It also shows a dose dependent increase in serum calcium. A prolonged suppression of endogenous parathyroid hormone was also observed, as anticipated. The pharmacokinetic analysis suggests that EXT608 can be effective when dosed once-weekly. The data provide a strong rationale to proceed to the next stage of clinical development and also offer valuable guidance for selecting a starting dose in the Phase 2 trial.

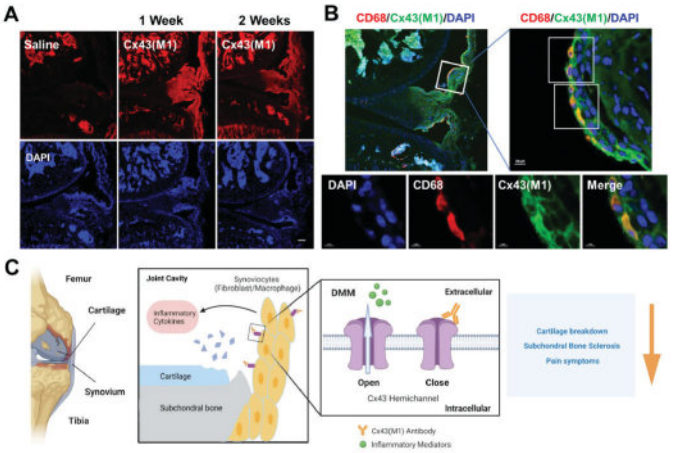
Targeting Synovial Connexin Hemichannels Ameliorates Osteoarthritis Progression *Rui Hua[1], Yi Tian[1], Manuel A. Riquelme[1], Xuewei Wang[1], Liang Ma[1], Sumin Gu[1], Jean X. Jiang[1]. [1]UT Health San Antonio, United States

Osteoarthritis (OA) is a degenerative joint disease characterized by progressive articular cartilage deterioration, subchondral bone sclerosis, and synovial inflammation. The gap junction protein connexin 43 (Cx43), a key regulator of musculoskeletal homeostasis, is overexpressed in cartilage and synovium of OA patients. However, the contributions of Cx43 to OA pathogenesis remains largely elusive. Cx43 forms hemichannels (HCs) and mediate the release of small molecules (< 1.2 KDa), such as ATP and PGE2, into the extracellular environment. To determine whether deletion of Cx43 in joint tissue could ameliorate OA symptoms, we adopted adeno-associated virus (AAV) mediated Cre expression in Cx43 fl/fl mice using a destabilization of the medial meniscus (DMM) surgery induced OA model. Intra-articular injection of AAV-Cre decreased Cx43 level, with a higher efficiency in the synovium (p=0.001) than in the cartilage (p=0.065). MicroCT analysis showed reductions in subchondral BV/TV, Tb.Th, and BMD with AAV-Cre mediated Cx43 deletion. Moreover, reduced Cx43 expression mitigated OA-related pain behaviors evaluated by von Frey and open-field tests. To further investigate the role of Cx43 HCs in OA progression, a monoclonal Cx43(M1) antibody that specifically blocks Cx43 HCs was developed. In vivo Evens blue dye uptake assay showed that DMM increased HCs opening by 2 folds, which was inhibited by the antibody. Impeded Cx43 HCs by the antibody improved cartilage structure as quantified by OARSI score, decreased degree of synovitis, along with reduction of MMP13 and Collagen X levels. Subchondral sclerosis and OA pain symptoms were also alleviated in the Cx43 antibody treated group. Remarkably, in vivo distribution of this antibody is predominantly in synovium, including macrophages and fibroblasts, with sustained presence for over 2 weeks. In addition, OA induced increase of M1 macrophages, as indicated by the iNOS/CD68 double positive cells, was attenuated after antibody treatment. In vitro study using mouse macrophages or human synovial fibroblasts demonstrated the inhibition of LPS or IL1?-induced HCs opening and inflammatory genes expression (COX2, ADAMTS 4/5, and MMP3/13) by Cx43 HC-blocking antibody. In summary, our results highlight the crucial role of Cx43 and HCs in regulating pro-inflammatory mediators under OA conditions. Targeting synovial Cx43 HCs, thus, is a potential therapeutic strategy to mitigate the inflammatory environment during OA progression.



Targeting synovial connexin 43 hemichannel as a potential therapeutic target of OA

PTH Stimulates Osteoblast Secretion of Slit3 to Repel Aberrant Vertebral Innervation and Relieve Low Back Pain Associated with Spinal Degeneration *Weixin Zhang[1], Arryn Otte[2], Sisir Kumar Barik[3], Mei Wan[2], Xu Cao[2], Janet Crane[2]. [1]Johns Hopkins university, , [2]Johns Hopkins University, United States; [3],

Low back pain (LBP) is the leading cause of disability globally, affecting one out of every four people. Nonspecific LBP is associated with spinal degeneration, particularly with vertebral endplate bone expansion and sclerosis. We have analyzed two mouse models with spinal degeneration, aging mice and lumbar spine instability (LSI) and found that parathyroid hormone (PTH) treatment reduced vertebral endplate sclerosis and improved pain behaviors. Most notably, porosity of the vertebral endplate significantly decreased while the tolerance of mechanical pressure significantly increased in PTH treated (40 µg/kg/day) groups relative to the vehicle groups in both aging mice and wild type (WT) LSI mice. Aberrant innervation noted in the vertebral body and endplate during spinal degeneration was reduced with PTH treatment as quantified by PGP9.5+ nerve fibers. Beta-3tubulin+ and CGRP+ neurons also significantly decreased in dorsal root ganglion within PTH treatment relative to vehicle control in both mice models. To explore the mechanism of PTH-reduction of innervation, we screened multiple axon guidance cues. The neuronal repulsion factor Slit3 significantly increased in the endplate after PTH treatment in WT LSI model. E47 and Foxa2, two transcription factors of Slit3, were significantly increased after PTH treatment (100 nmol for 3 days) in MC3T3 cells with osteoblast differentiation inducible culture medium. CHIP assay further indicated that the expression of Slit3 was significantly increased by Foxa2 with PTH stimulation in vitro. In vivo models deleting PTH type 1 receptor (PPR) in osteoblasts (OsteocalcinCrePPRf/f LSI mice) prevented PTH-reduction of endplate porosity and improvement in pressure tests, whereas PPR deletion in chondrocytes (Col2aCreERt2P-PRf/f LSI mice) continued to improve to PTH in regard to porosity and pressure tests. Furthermore, deletion of Slit3 in osteoblasts (OsteocalcinCreSlit3f/f LSI mice) did not differ between PTH and vehicle treatment in regard to total endplate porosity nor pressure test. Altogether, PTH stimulates Slit3 to repel sensory nerve innervation and provides symptomatic relief of LBP associated with spinal degeneration.

Differential osseous gene expression in swim-trained anosteocytic and osteocytic teleost fish *JOSEPHINE T. TAUER[1], Tobias Thiele[2], Catherine Julien[3], Lior Ofer[4], Paul Zaslansky[5], Ron Shahar[4], Bettina Willie[6]. [1]Shriners Hospital, Canada; [2]Julius Wolff Institute, Charité - Universitätsmedizin Berlin, Germany; [3]Shriners Hospital for Children-Canada, Montreal; Faculty of Dental Medicine and Oral Health Sciences, McGill University, Canada; [4]Koret School of Veterinary Medicine, The Robert H. Smith Faculty of Agriculture, Food and Environmental Sciences, The Hebrew University of Jerusalem, Israel; [5]Department of Operative and Preventive Dentistry, Charité - Universitätsmedizin Berlin, Germany; [6]McGill University, Canada

Introduction: Osteocytes are considered mechanosensory bone cells that regulate bone (re)modeling in response to mechanical stimuli. Surprisingly, evolutionarily advanced fish

lack osteocytes but still exhibit bone formation in response to loading. While there is knowledge of the molecular mechanisms controlling mammalian mechanoadaptation, fish data is lacking. Thus, we aimed to identify molecular mechanisms in anosteocytic bones (ricefish; RF) and osteocytic bones (zebrafish; ZF) after loading.Methods: Fish were trained by swimming for 5 minutes against a current and sacrificed after 1-, 8-, or 24 hours (h). Vertebrae were analyzed using RNA sequencing and compared to non-trained controls (n=6 fish/genotype).Results: At each time point, 26,099 and 21,129 gene reads for ZF and RF have been identified, respectively. After filtering non-skeletal genes (Ayturk et al. JBMR, 2013:28), 14, 54, and 977 differentially expressed genes (DEGs) have been identified in ZF, and 353, 284, and 763 DEGs in RF at 1h, 8h, and 24h, respectively. Enrichment analysis showed in ZF that upregulated DEGs were related to protein translation at 1h, and to DNA transcription and cell cycle processes at 24h, while downregulated DEGs were linked to muscle function, circadian rhythm, and metabolic processes at 24h. In RF, upregulated DEGs were associated with ion channel activity related to metabolic processes in muscle at 8 and 24h, while downregulated DEGs were related to cytoskeletal organization at 8h. Osteoblast differentiation associated enriched DEGs were identified in ZF at 8 and 24 h, but not in RF. Applying a customized 'osseous analysis panel' identified 87 'osseous DEGs' (oDEGs) in ZF and 71 in RF, primarily upregulated in ZF and downregulated in RF. Only one upregulated oDEG was identified in RF, myocilin, a regulator of osteoblast differentiation, at 1h and 24h post-training.Conclusion: Zebrafish benefited from numerous osteocytes for bone formation in response to mechanical stimuli, while ricefish exhibited delayed skeletal modeling after swim training. It's speculated that in anosteocytic bone, non-osteocytic cells, such as bone lining osteoblasts, chondrocytes, and chordoblasts, sense and respond to mechanical load differently over time (Ofer et al. PLoS Biol, 2019:17). Our findings challenge the current paradigm of osteocytes as the exclusive regulators of bone remodeling and suggest the existence of multivariate feedback networks involved in bone remodeling.

Osteocyte-Specific Endocannabinoid Receptor 1 (CB1) Deficiency Influences Cancellous Bone Mass, But Does Not Affect Bone Response To Disuse *Rachel DeNapoli[1], Evan Buettmann[2], Aron Lichtman[2], Henry Donahue[2], [1], United States, [2]Virginia Commonwealth University, United States

Disuse-induced bone loss during prolonged bedrest, injury, or paralysis, is a major health and financial concern for the general population. Endocannabinoid receptor 1 (CB1) influences bone in an age, sex, and strain dependent manner. In particular, our lab found skeletally mature male C57BL/6J mice with a global CB1 deletion (KO) are more sensitive to disuse-induced bone loss than male wildtype, while disuse-induced bone loss was mitigated in female KO mice during single limb immobilization [1]. To further determine CB1's role in bone, we hypothesized that mice with a conditional knockout of CB1 in osteocytes, the predominate mechanoregulatory cell in bone, would be more sensitive to bone loss than wildtype during hindlimb suspension (HLS).All animal procedures were conducted with approval of the VCU IACUC. We generated novel homozygous DMP1-Cre(+); CB1flox/flox mice (cKO) and DMP1-Cre(-); CB1flox/flox mice (WT) for this experiment. 20-week-old male and female mice (n=7-9/group) were assigned to either HLS or control group for three weeks. Skeletal phenotype was assessed using in vivo micro-CT scans following 21 days of HLS. Cancellous bone at epiphyseal and metaphyseal regions were analyzed. Data were analyzed using repeated measures 3-way ANOVA with Sidak post-hoc test ($p<0.05$).MicroCT analysis at D21 demonstrated that loss of CB1 in DMP1 expressing cells led to lower metaphyseal and epiphyseal BV/TV versus WT. HLS resulted in all groups experiencing bone loss from baseline in the femoral metaphyseal and epiphyseal region. However, genotype had no influence on disuse-induced bone loss. Interestingly, in the epiphyseal region, there was an interaction of HLS and sex, with male mice having greater disuse-induced decreases in BV/TV from baseline than female mice.These results suggest for the first time that CB1 expression in DMP1 lineage cells plays an important role in bone mass within the epiphyseal and metaphyseal regions, but not in the response to disuse. These results, when compared to our previous studies, suggest CB1 receptor in osteocytes controls bone mass under basal conditions, while deficiency in earlier osteoblastic cells may control response to disuse.[1] DeNapoli, R. C. et al. Journal of Biomechanics (2023)

Osteocytic Connexin 43 Deficiency Attenuates HLS-Induced Epiphyseal Bone Loss in Female, but not Male, C57Bl/6J Mice *Gabriel Hoppock[1], Evan Buettmann[2], Jolene Windle[2], Henry Donahue[2], [1], [2]Virginia Commonwealth University, United States

Preceding research has shown that gap junction communication and mechanical stimulation, or lack thereof, influence bone development and remodeling, however, the mechanisms by which this occurs remain unclear. Our lab and others have shown deficiency of connexin 43 (Cx43), bone's predominant gap junction protein, in early osteoblasts/osteocytes protects against unloading-induced bone loss in mice.1,2 It is unclear, however, if this protection is due to Cx43 deficiency in osteoblasts or osteocytes, the latter being the most abundant and primary mechanosensory bone cell. To address this, we used a Cx43-deficient mouse targeting later osteoblasts/osteocytes to test the hypothesis that osteocyte-specific Cx43 deficiency protects against hindlimb suspension (HLS)-induced bone loss.All animal procedures were approved by the VCU IACUC. At 6 months of age, male and female osteocyte-specific Cx43 deficient mice (Cx43?OCY) and their wildtype littermates (WT) with C57Bl/6J backgrounds underwent HLS or normal ambulation (control) for 21 days (n=8-11 per group). MicroCT scans were taken on days 1 and 22 and images the left femur was analyzed. Separate 2-way ANOVAs with Bonferroni's post-hoc tests were used to assess female and male mice for significant effects of genotype and HLS ($p<0.05$).At baseline Cx-43?OCY mice had decreased diaphyseal cortical bone compared to WT (Figure 1A). In the epiphysis and metaphysis, male mice showed an increase in bone volume due to Cx43 deficiency, but female mice did not. The basal differences between WT and Cx43?OCY mice show osteocytic Cx43 plays a sexually dimorphic role in postnatal bone volume. After 21 days of HLS, significant effects of HLS were found in all female and male epiphyseal and metaphyseal changes as well as in Ct.Ar/T.Ar (Figure 1B). Interestingly, osteocyte-specific Cx43 deficiency protected against HLS-induced decreases in epiphyseal BV/TV in female but not male mice. Cx43 deficiency did not affect HLS-induced decreases in metaphyseal or cortical bone in either male or female mice. These results suggest osteocytic Cx43 deficiency causes increased trabecular and decreased cortical bone basally. The data also show osteocytic Cx43 deficiency protects against HLS-induced epiphyseal bone loss in female mice whereas early osteoblast Cx43 deficiency likely also protects against metaphyseal bone loss, as shown previously by our lab.21. Grimston et al. J Bone Miner Res. 2011. 2. Lloyd et al. J Bone Miner Res 2012.

Gene expression profiles in fibroblast growth factor 23 (FGF23)-producing tumors provide new insights on diagnostics and therapeutic intervention. *Sofya Gronskaia[1], Ruslan Devitiarov[2], Sergey Popov[1], Svetlana Rodionova[3], Yuriy Buklemishev[3], Liudmila Rozhinskaya[1], Oleg Gusev[2], Zhanna Belaya[1]. [1]Endocrinology Research Centre, Russian Federation. [2]Regulatory Genomics Research Center, Kazan Federal University, Russian Federation. [3]National Medical Research Center of Traumatology and Orthopedics named after. N.N. Priorov, Russian Federation

Background: Fibroblast growth factor 23 (FGF23)-producing tumors are histologically known as phosphaturic mesenchymal tumors (PMT). A PMT causes an oncogenic osteomalacia (OOM), which is associated with multiple fractures, severe pain, and muscle weakness.Aim: To analyze gene expression profiles of PMT versus control tissue.Methods: PMT and surrounding control tissue samples were obtained during tumor resection in 5 patients (Age 62 [45; 65], iFGF23 (ELISA Kit Biomedica BI-20700 -113 [50; 203] pg/ml (ref. range 14.8 [3.8;25.0]pg/ml), serum phosphorus 0.51 [0.4; 0.53]mM/L (ref. range 0.74-1.52 mM/l)). Based on histological verification we obtained 4 PMT samples (2 -mandibular bones, 1 - femur bone, 1 - metatarsal bone) and performed bulk RNA sequencing. We used Gene Ontology (GO) and the Kyoto Encyclopaedia of Genes and Genomes (KEGG). Results: A total of 976 genes were differently expressed between PMT and control samples. The four PMT samples were homogeneous according to their gene expression profiles. The genes most up-regulated (n=10) in PMT were LOC105377323/FGF1/MB/SPRY2/LOC105378029/DMP1/FGF23/BMP7/PHEX/LOC124903699. The genes most negatively regulated in PMT were LOC102724638/LOC124901874/LOC124901875/IGLL5/IGKC/IGLC1/LOC105377460/LOC105376032/IGK/IGHG1 (FDR < 0.05). We found that PMT overexpressed genes that are typical for osteoblast activity and differentiation including the most known OPG, RANKL (KEGG: p-value 0.03). We also found increased expression of the Wnt signaling antagonists SOST, DKK1 (KEGG: p-value 0.02). In PMT we found upregulated genes that are typical for secretory active osteocytes surrounded by high phosphate(FGF23/DMP1/ENPP1/PHEX/GALNT3/FAM20C/AKNA/DSPP/MEPE/EN1). Genes and pathways related to mineral ion transport were also up-regulated: Phospholipase D signaling pathway (KEGG p-value 0.003); signaling receptor binding (GO p-value < 0.001); solute: sodium symporter activity (GO p-value 0.004); calcium ion binding (GO < 0.001) and PiT1 (SLC20A1), which encodes the inorganic phosphate transporter. We found that PMT highly expressed osteopontin, CENPK and genes involved in PI3K/AKT (KEGG: p-value 0.006); ERK1/2 pathways (KEGG p-value 0.02) that are associated with castrate-resistant prostate cancer. The most up-regulated pathways in PMT were ECM-receptor interaction and gastric cancer related genes. We identified human membrane protein genes that were highly expressed in the PMT compared to control tissue PHEX/SYT12/PCDH7/RAMP1/CD44/NRG3/ILDR2/ECEL1/CHST3/ LRFN4/PCDH9, FGFR1/EVA1A/AREG/PTGIS/VSIG2/ENPP1/NRCAM/WSCD2.Conclusion: PMT expresses gene that are typical for secretory active osteoblast cells, including RANKL/OPG, phosphaturic genes, and wnt signaling antagonists. Newly identified gene expression profiles may expand our knowledge on diagnostics and therapeutic intervention in PMT.

Phosphate Signaling Is Mediated via Parathyroid Hormone Receptor 1-PLC-PKC Pathway in Committed Osteogenic Cells *Nadine Robert[1], Sandeep Chaudhary[2], Mairobys Socorro[1], Sana Khalid[1], Catherine Roberts[1], Juan Taboas[1], Dobrawa Napierala[1]. [1]University of Pittsburgh, United States. [2]Institute of Oral Health Research, University of Alabama at Birmingham, United States

Phosphate (Pi) is a main component of hydroxyapatite crystals that form the skeletal tissues. Pi also acts as a signaling molecule to regulate mineralization. Previous studies demonstrated the involvement of Na+/Pi cotransporters, FGFR1 and Erk1/2 kinase in Pi signaling. However, the molecular mechanisms of Pi sensing and cellular mediators of Erk1/2 activation in response to Pi have not been elucidated. Our goal is to decipher Pi signaling in cells producing bone (osteoblasts) and dentin (odontoblasts). Hence, we selected two committed osteogenic cell lines, the 17IIA11 odontoblast and MLO-A5 osteoblast/pre-osteocytes, which rapidly undergo mineralization in standard osteogenic conditions. From two independent lines of experiments, we observed the 17IIA11 cells failed to respond to Pi, as evaluated by Erk1/2 activation, when the parathyroid hormone receptor 1 (Pth1r) expression is downregulated. Therefore, we hypothesized that Pth1r is required for Pi signaling in committed osteogenic cells. To test this hypothesis, we used shRNA technologies to generate Pth1r-deficient 17IIA11 and MLOA5 stable cell lines. Unlike WT and shScr controls, Pth1r-deficient cells failed to activate Erk1/2 in response to stimulation with Pi nor mineralized under osteogenic conditions. As Pth1r can modulate various signaling cascades, including protein kinase A (PKA)-cAMP and phospholipase C (PLC)-protein kinase C (PKC), we analyzed which signaling axis downstream of Pth1r transmits the response to Pi in the presence and absence of specific pharmacological inhibitors. PKA inhibition with H-89 did not prevent Erk1/2 phosphorylation (pErk1/2) whereas inhibition of phospholipase C (PLC) with D609 attenuated that response. In addition, we observed a dose-dependent decrease of pErk1/2 levels in comparison to untreated controls when PKCs were inhibited by pan-classical PKC inhibitor Bisindolylmaleimide I (GF109203X). To identify which PKC isoform is involved in Pi signaling, we utilized two selective PKC inhibitors Sotrastaurin (inhibits classical PKCs- PKC? and PKC?, but not PKC?) and Staurosporine (inhibits PKC? and PKC?, but not PKC?). We observed a dose-dependent decrease in Erk1/2 activity only with Staurosporin, while Sotrastaurin had no effect on pErk1/2. Our in vitro studies in committed osteogenic cells propose the Pth1r as a candidate receptor/sensor of Pi, that mediates Pi signaling through PLC-PKC? axis.

Genome-wide Analyses Reveal TGF? Signaling as a Regulator of Osteogenic Phosphate Sensing *Dylan Kuennen[1], Long Tran[2], Michael Mannstadt[3], Lauren Surface[2]. [1]University of Michigan, United States. [2]University of Michigan School of Dentistry, United States. [3]Massachusetts General Hospital Harvard Medical School, United States

Organismal phosphate (Pi) is an essential regulator of many cellular processes necessary for healthy tissue and organismal function. The skeleton is a key regulatory site in the control of organismal Pi homeostasis. However, the mechanisms of the Pi-sensing circuitry in osteogenic cells are poorly understood. Using in vitro approaches, our goal is to elucidate how the factors responsible for serum Pi sensing in osteogenic cells enable the endocrine Pi response to inform future therapeutics.To understand the transcriptional response in osteogenic cells during exposure to Pi, we performed an RNA-seq time course on MC3T3-E1, a pre-osteoblast cell line, and OCY454, an osteocytic cell line. We observed differential expression of gene categories related to bone mineralization as well as TGF?, MAPK, and EGF signaling. Based on these findings, we developed two flow cytometry-based readouts of the response to increased extracellular Pi; a Dmp1-2A-mCherry fluorescent reporter and a cell surface antigen stained with an antibody (SEMA7A). Using flow cytometry, we confirmed that inhibiting FGFR1 and ERK signaling blocks these responses to Pi. To identify factors that mediate Pi sensing, we combined our reporters with genome-wide CRISPRi screens and identified ~38 hits common to screens in both reporters. To prioritize physiologically relevant pathways, we intersected these hits with loci associated with circulating Pi and FGF23 levels by GWAS, and identified TGFB2 as a hit that is also top genetic polymorphism associated circulating FGF23 levels, supporting a potential physiological role for TGF? signaling in controlling the endocrine Pi response.We find that TGF-?2 co-treated with Pi enhances the response of osteogenic cells both increasing early Erk phosphorylation and the response of our reporters after 24 hours. We observe that TGF? signaling affects calcium (Ca2+) flux, leading to an increase in extracellular Ca2+, and that an inhibitor of store-operated calcium entry (SOCE) blocks the effect of TGF-?2 suggesting that SOCE mediates this response. Ca2+ may boost the response of osteogenic cells to Pi, likely through calciprotein particle (CPP) formation. We hypothesize that TGF-?2 increases the available extracellular Ca2+ to form CPP with Pi, thereby boosting the Pi response. These results may provide critical insights into Pi homeostasis, particularly in the setting of chronic kidney disease in which both circulating TGF? and FGF23 levels are increased.

FRI-206

A novel approach combining in vitro and in vivo RNAseq/ATACseq identified key FGF23 target genes dysregulated with loss of Klotho in kidney single-cell subpopulations *Emmanuel Solis[1], Kayleigh Jennings[1], Yamil Marambio[1], RAFIOU AGORO[1], Megan Noonan[2], Sheng Liu[1], Jun Wan[1], Kenneth White[1]. [1]Indiana University School of Medicine, United States. [2]Indiana University , United States

Background: The osteocyte-produced hormone FGF23 controls phosphate and vitamin D synthesis in the kidney via its co-receptor ?Klotho (KL), however, the cellular responses to FGF23 during normal and disease states are not fully understood. We hypothesize that

FGF23 induces unique and generalized changes in transcription and genomic accessibility within specific nephron cell populations.Methods: An HEK293 cell line stably expressing membrane Klotho (HEK-mKL cells) was treated with FGF23 (50 ng/mL) for 4 and 16 hours, then processed for ATACseq and RNAseq libraries. Differentially expressed genes were validated by qPCR as well as in an independent single-cell 10X Multiomics dataset from KL-KO mice. Dimensionality reduction via Uniform Manifold Approximation and Projection (UMAP) was used to identify distinct nephron cell types.Results: HEK-mKL cell groups treated with FGF23 displayed clear segregation for both RNAseq and ATACseq following principal component analysis (PCA), with 9 and 7-fold increases in MAPK target genes EGR1 and FOS. Both vitamin D 24-hydroxylase CYP24A1 (2-fold) and VDR (1.5-fold) were increased at 4 and 16h, supporting this model. ATACseq showed FGF23 rapidly influenced genomic regions to control MAPK signaling as demonstrated by opening chromatin accessibility of an EGR1 distal enhancer by 4h. In confirmation, HOMER motif discovery predicted enrichment in transcription factor binding for MAPK targets FOS, JUN, AP1, and EGR1 (P<0.01) across the genome. At both 4 and 16h, FGF23 bioactivity was associated with novel induction of ETV transcription factor family mRNAs (ETV1 (3.7 fold), ETV4 (8-fold), and ETV5 (7.5 fold)), known to serve important roles in kidney development, mitochondrial biogenesis, and acute kidney injury repair. Furthermore, FGF23 bioactivity increased the expression of ETV1/4/5 target genes MMP1(7.3-7.7 fold), PTGS2 (3.5-4.2 fold), and VEGF (1.3-1.4 fold). Conversely, in vivo, 10X Multiome analysis of KL-KO mouse kidney proximal tubule-S1/S2 cells showed a 27% decrease in Etv5 mRNA. Further, Etv1 expression and chromatin accessibility decreased by 70% and 92%, respectively, contrary to the increase of these key factors with FGF23 treatment.Conclusion: A unique combination of unbiased in vitro ATACseq/RNAseq pinpointed novel FGF23-induced transcriptional and genomic reprogramming. Translation to in vivo kidney cell subpopulations demonstrated these changes may influence cell-specific outcomes in FGF23-related diseases.

FRI-213

Bone alterations in ALS mice appear earlier than muscle atrophy and correlate with reduced expression of complement factors and interferon signaling in osteocytes *Melanie Haffner-Luntzer[1], Stefano Antonucci[2], Baiba Vilne[3], Jan-Moritz Ramge[4], Anita Ignatius[4], Francesco Roselli[4]. [1]University Medical Center Ulm, Germany; [2]Ulm Unversity, Germany; [3]Riga University, Latvia; [4]Ulm University, Germany

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease characterized by progressive muscle atrophy. It is well known that muscle loss and thereby reduced mechanostimulation of the skeleton leads to bone loss. Therefore, it was proposed that mice suffering from ALS display severe osteoporosis after the onset of muscular symptoms, while presymptomatic mice do not show bone alterations. However, it was recently investigated that human SOD1 mutation carriers already display metabolic alterations before the onset of muscular symptoms. Therefore, we aimed to analyze the bone phenotype in a mouse model of ALS-associated SOD1 mutation in more detail before and after the onset of muscular symptoms in order to understand pathogenic mechanisms. Femurs of SOD1(G93A)-mutated male mice and respective wildtype controls were analyzed at p45 and p110 of age (pre- and post-symptomatic) using bending test, µCT, histomorphometry and RNA sequencing. We found that force to failure was significantly reduced in pre- and postsymptomatic ALS mice. Furthermore, both cortical and trabecular bone parameters were significantly diminished in pre- and postsymptomatic ALS mice, with the effect being more pronounced in older mice (cortical thickness WT p45: 0.183+/-0.007mm vs. SOD1 p45: 0.172+/-0.009mm; WT p110: 0.227+/-0.014mm vs. SOD1 p110: 0.184+/-0.009mm; trabecular BV/TV WT p45: 25.5+/-1.8% vs. SOD1 p45 20.1+/-1.9%; WT p110: 26.5+/-4.9% vs. SOD1 p110: 17.3+/-3.7%). Cellular analysis revealed reduced osteoblast numbers in pre- and postsymptomatic ALS mice, while osteoclast numbers were only increased in postsymptomatic mice. RNA sequencing and GO term analysis of flushed femurs (mainly containing osteocytes) revealed that genes related to the complement system and interferon signaling were significantly downregulated in pre- and postsymptomatic ALS mice (e.g. C3, C6, Ifit1). Immunohistochemical staining confirmed osteocytic expression of complement markers. Our data shows that in contrast to previous reports, SOD1-mutated mice do already display bone alterations before the onset of muscular symptoms. Reduced bone mass correlated with reduced expression of complement and interferon-associated factors. Because it has already been shown that the complement system plays an important role in bone cells, this might be an interesting target to further explore treatment options for human mutation carriers. It remains to be studied which role interferon-related signaling plays in this context.

FRI-217

Age-related decline of TNF receptor-associated factor 3 expression in skeletal muscle causes sarcopenia and remotely stimulates bone loss *Xing Li[1], Yaning Xing[1], Brendan Boyce[2], Hailin Zhang[1], Jinbo Li[1]. [1]Hebei Medical University, China; [2]University of Rochester Medical Center, United States

Skeletal muscles supply contraction forces and stem cells to bone to help maintain bone homeostasis and regeneration; however, how the aging process in skeletal muscle itself affects age-related bone loss remains poorly understood. To study this, we first performed bulk RNASeq and found that inflammatory cytokine/receptor interaction, involved in TNF receptor and interleukin receptor super families were significantly upregulated in gastrocnemius muscles from aged (20-mon-old) than young (4-mon-old) mice (KEGG; p=0.0006). Protein levels of TNF receptor-associated factor 3 (TRAF3), an adaptor protein of these receptors, was decreased during aging in mouse and human skeletal muscles, and in mouse skeletal muscle stem cells (MuSCs; Integrin ?7+CD45-CD31-CD11b-Sca1-) and myocytes (CD45-CD31-CD11b-Sca1-). To examine the function of TRAF3 in MuSCs and myocytes, we generated MCKCreTRAF3fl/fl (M-cKO) and Pax7CreERTRAF3fl/fl (P7-cKO) mice with Traf3 deletion in myocytes and MuSCs, respectively. Both cKO mice developed obvious sarcopenia by 3-mon-old, with shrinkage of MyHC IIA+ myofibers in particular, loss of myocytes per fiber, and impaired myotube formation capacity in-vitro. This sarcopenic phenotype in M-cKO mice was more marked than in age-matched P7-cKO mice and does not appear to be mediated by non-canonical NF-?B signaling because RelB and p100/p52 double knockout mice have normal muscle mass. Surprisingly, the M-cKO mice also developed early onset osteoporosis with significantly lower tibial trabecular bone mass (BV/TV: (10.8+/-3.0)% vs. (17.4+/-5.5)% in WT; p=0.010) and cortical bone thickness (143+/-7 vs. 204+/-9 ?m in WT; p2; p<0.05) elevated in both naturally aged C57 mice and young M-cKO mice; mRNA and protein levels of musclin (also known as osteocrin), a novel exercise-responsive myokine, were significantly higher in gastrocnemius from aged and M-cKO mice than in controls. In addition, osteoclast precursors treated with musclin formed more osteoclasts (11.2+/-2.6 vs. 6.3+/-2.5/mm2 in vehicle; p=0.002). These findings implicate TRAF3 reduction causes age-related sarcopenia and osteoporosis via an NF-?B-independent mechanism and suggest that increased musclin expression by aging muscles may enhance osteoclastic bone resorption to promote age-related bone loss.

Progranulin inhibits C5a/C5aR1 signaling via direct binding to C5a and its deficiency exaggerates osteoarthritis due to hyper-activation of the complement system *Wenyu Fu[1], Guiwu Huang[1], Chuan-ju Liu[1]. [1]New York University Grossman School of Medicine, United States

The prevalence of osteoarthritis (OA) is increasing globally, with significant economic impacts and negative effects on quality of life. Accumulating evidence demonstrates that complement activation is involved in the pathogenesis of OA, although the molecular events involved remain to be elusive. While previous research has shown that C5 deficiency can attenuate arthritis in mouse OA model, the mechanisms of C5/C5a in OA have not been understood. Our lab has long-standing interest in investigating the role of progranulin (PGRN), a growth factor like molecule, in the pathogenesis of OA. The findings that PGRN bind to cysteine-rich domains (CRDs) of various proteins, together with the fact that complement proteins contain CRDs, suggesting that PGRN may interact with and affect the complement system. We thus conducted solid-phase binding assays to screen the interactions between PGRN and central complement components, including C1-C9, C5a and C3a. Our results showed that PGRN strongly binds to C5 and dose-dependently binds and saturates C5a. Additionally, PGRN/C5a complex formation in mouse sera was confirmed by Co-IP, and PGRN binds to C5a with a high affinity of KD 7.18+/-0.07nM measured by Analytical Surface Plasmon Resonance. Further functional assays demonstrated that PGRN inhibits C5a binding to C5aR1 and effectively blocks C5a binding to cell surfaces, indicating that PGRN acts as a natural antagonist of C5a signaling. PGRN was also found to antagonize C5a's effect on macrophage polarization.ELISA analysis showed a significant increase in C5a levels in the synovial fluid of OA patients than healthy controls, indicating hyperactivation of the complement cascade in OA synovial fluid. PGRN levels were also significantly higher in the synovial fluid of OA patients compared to healthy controls. Furthermore, a positive correlation was found between the levels of PGRN and C5a in OA patients ($r = 0.5475$, $P < 0.0001$). The interaction and interplay of PGRN/C5a were also investigated in vivo using various genetically deficient mice with surgically induced DMM model. The results showed that deletion of C5aR1 partially reversed the exaggerated OA phenotype, including severe cartilage loss and increased OA-associated pain observed in PGRN-/- OA mice. These findings suggest that PGRN interacts with C5a/C5aR1 signaling to regulate macrophage function, and PGRN mitigates OA by suppressing proinflammatory activities of C5a through interrupting C5a/C5aR1 signaling (Fig.1).

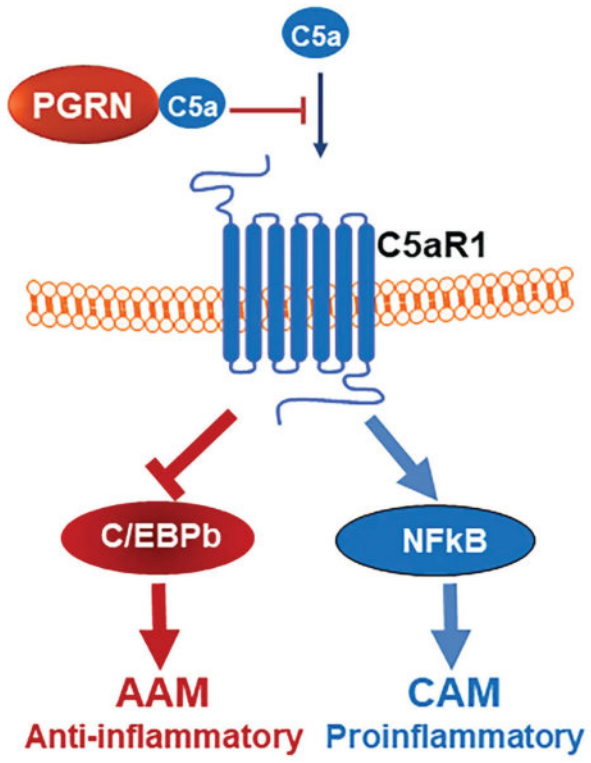

Fig1. A proposed model illustrating the interplays between PGRN and C5a/C5aR1 signaling in regulating macrophage polarization. PGRN directly binds to C5a and inhibits C5a/C5aR1 signaling, and resultant macrophage polarization regulation and OA progression.

Blocking CCN2 Reduces Established Palmar Muscle Fibrosis and Entheseal Damage following Repetitive Overuse Injury *Alex Lambi[1], Robert DeSante[2], Steven Popoff[3], Mary Barbe[4]. [1]University of New Mexico, [2]Center for Translational Medicine, Lewis Katz School of Medicine of Temple University, United States. [3]Lewis Katz School of Medicine at Temple University, United States. [4]Temple University School of Medicine, United States

Upper extremity overuse injuries are a leading cause of long-term pain and disability. Underlying tendinopathies, muscle fibrosis, and joint disorders occur. We have shown that the matricellular protein connective tissue growth factor (CTGF/CCN2) is critical to early progression of chronic forelimb muscle fibrosis and grip strength declines in a rat model of overuse injury. Here we tested whether an anti-CCN2 antibody reduces established forepaw and entheseal changes corresponding to improved grip strength. All experiments were approved by the Institutional Animal Care and Use Committee. Adult female rats (3 mo at onset) performed a high repetition high force (HRHF) task for 18 wks, consisting of 4 reaches/min, at 1.22N, 2hr/d, 3d/wk. One subset was euthanized after 18 wks of task performance (HRHF-Untreated, n=9). Two subsets were provided 6 wks of rest post-task, with concurrent treatment with anti-CCN2 monoclonal antibody FG-3019 (HRHF-Rest/anti-CCN2, n=8) or an IgG as a vehicle control (HRHF-Rest/IgG, n=9). Results were compared with age-matched controls (Control-IgG, n=11). We analyzed histologic data from forepaw muscles (thenar, hypothenar, and deep intrinsic) and wrist/forepaw entheses. Muscle fibrosis (% muscle area with collagen) in combined forepaw muscles was significantly increased in HRHF-Untreated and HRHF-Rest/IgG rats, but not HRHF-Rest/anti-CCN2, compared to Controls ($p<0.01$). Forepaw and carpal entheses were graded on six domains: tidemark, fissuring, void space, vascular invasion, attachment site holes, and underlying bone remodeling. Each domain was graded binarily (1 indicating present). The overall enthesis score of damage was significantly increased in HRHF-Untreated rats compared to Controls and HRHF-Rest/anti-CCN2 ($p<0.05$), with tidemark changes showing the greatest change ($p<0.05$). We found an inverse correlation between muscle fibrosis and grip strength ($r=-0.33$, $p=0.01$). Analyzed for percent grip strength change by group, we found a significant decrease in HRHF-Untreated compared to Controls ($p=0.02$), and significant increases in HRHF rest groups, more so in HRHF-Rest/anti-CCN2 ($p<0.05$). These studies demonstrate for the first time that anti-CCN2 treatment reduces established forepaw muscle fibrosis and entheseal damage following overuse injury. As these findings alone do not account for the percent change in grip strength, ongoing work seeks to determine what other factors contribute to functional changes in these forepaws.

Foxc1 and Foxc2 Function in Osteochondral Progenitors for the Progression Through Chondrocyte Hypertrophy and Mineralization of the Primary Ossification Center *Fred Berry[1], Asra Almubarak[1]. [1]University of Alberta, Canada

The forkhead box transcription factor genes Foxc1 and Foxc2 are expressed in the condensing mesenchyme of the developing skeleton prior to the onset of chondrocyte differentiation. To determine the roles of these transcription factors in limb development we deleted both Foxc1 and Foxc2 in lateral plate mesoderm using the Prx1-cre mouse line. Resulting compound homozygous mice died shortly after birth with exencephaly, and malformations to this sternum and limb skeleton. Notably distal limb structures were preferentially affected, with the autopods displaying reduced or absent mineralization. The radius and tibia bowed and the ulna and fibula were reduced to an unmineralized rudimentary structure. Molecular analysis revealed reduced expression of Ihh leading to reduced proliferation and delayed chondrocyte hypertrophy at E14.5. At later ages, Prx1-cre;Foxc1?/ ?;Foxc2 ? / ? embryos exhibited restored Ihh expression and an expanded COLX-positive hypertrophic chondrocyte region, indicating a delayed exit and impaired remodeling of the hypertrophic chondrocytes. Osteoblast differentiation and mineralization were disrupted at the osteochondral junction and in the primary ossification center (POC). Levels of OSTEOPONTIN were elevated in the POC of compound homozygous mutants, while expression of Phex was reduced, indicating that impaired OPN processing by PHEX may underlie the mineralization defect we observe. Together our findings suggest that Foxc1 and Foxc2 act at different stages of endochondral ossification. Initially these genes act during the onset of chondrogenesis leading to the formation of hypertrophic chondrocytes. At later stages Foxc1 and Foxc2 are required for remodeling of HC and for Phex expression required for mineralization of the POC

Elevated PDGFR? Signaling Causes Knee Joint Fusion by Disrupting Synovial Progenitor Differentiation *John Woods[1], Lorin Olson[1]. [1]Oklahoma Medical Research Foundation, United States

Mouse knee joint development begins at E11.5-E13.5 when a cartilage template is divided in two by the formation of an interzone, an anlage that gives rise to all the structures of a mature joint. Before interzone formation, the cartilage template expresses cartilage genes Sox9 and Col2a1. These genes are downregulated upon interzone formation and replaced by Gdf5, a member of the bone morphogenic protein family. Platelet-derived growth factor receptor-? (PDGFR?) is not expressed in the cartilage template of the limb, but it is expressed in the perichondral mesenchyme and Gdf5+ interzone cells. Based on this expression pattern, we hypothesized that tight regulation of PDGFR? signaling may be crucial for joint development. To investigate this role of PDGFR?, we used gain-of-function (?GOF) and loss-of-function approaches with Prx1-Cre, which is active in the early limb bud mesenchyme. Loss-of-function did not affect joint formation. However, ?GOF mice were born with knee joints fused by ectopic cartilage and lacking ligaments and menisci. Interzone specification occurred normally in ?GOF mutants up to E13.5, but Gdf5 expression was decreased. Further, there was expansion of Sox9 protein expression into domains that are normally Sox9-negative. These results suggest that elevated PDGFR? signaling interferes with joint progenitor differentiation by redirecting Gdf5+ interzone cells from a synovial connective tissue fate to a Sox9+ chondrogenic fate. Thus, PDGFR? signaling has pro-chondrogenic properties that must be tightly regulated to allow differentiation of ligaments, menisci, and

other connective tissue cell types. This property of PDGFR? signaling may be important in other contexts such as de novo cartilage formation in fracture healing.

Racial disparities in osteoporosis screening and treatment among older adults in a centralized, secondary prevention Fracture Liaison Service

*Richard Lee[1], Cathleen Colon-Emeric[2]. [1]Duke University, United States. [2]Duke University Medical Center, United States

Background: Published studies have shown significant racial disparities in osteoporosis screening and treatment. We evaluated whether our well-established Fracture Liaison Service (FLS) may mitigate these disparities.Method: This is a retrospective analysis of patients in the VISN6 Bone Health Service (BHS), a centralized FLS, located at the Durham VA Medical Center, serving 4 medical centers within the VA Integrated Service Network 6. The BHS identifies adults > age 50 years, who have sustained a recent low-trauma fracture and reviews their medical record for risk factors of osteoporosis. Recommendations are provided the electronic health record to the patient's primary care provider and implemented by a dedicated BHS Nurse. Recommendations may include DXA screening, initiation of calcium/vitamin D supplementation, initiation of bisphosphonate therapy, and/or referral to a metabolic bone specialty clinic. Data were obtained from the BHS clinical database from Oct 2012 to Mar 2022, regarding osteoporosis recommendations. Statistical analysis for differences was performed by chi square by race.Results: 2552 patients with incident low-trauma fracture were identified during the study period, among whom 72.9% were White, 21.2% were Black, and 5.9% were other racial groups. 12.2% of Black adults sustained a hip fracture, compared to 11.1% White and 17.2% other groups; however, only 6.5% of Black adults had vertebral fracture, compared to 16.2% White and 11.9% other groups ($P < 0.01$). After controlling for fracture location, Black adults were more likely to be recommended for DXA screening (82.3%, vs. 72.9% White and 72.8% other groups), but less likely to be recommended for initiation of calcium/vitamin D (18.9%, vs. 31.1% White and 25.2% other groups) and of bisphosphonates (15.7%, vs. 26.0% White and 25.2% other groups) [$P < 0.01$ for all comparisons]. There were no significant differences in referral to Metabolic Bone Clinic ($P = 0.50$). Additionally, there were no differences among racial groups regarding implementation of BHS recommendations, with 85.5% among White, 85.2% among Black, and 88.7% among other racial groups ($P = 0.53$).Conclusion: The BHS program improved osteoporosis screening among older adults with recent low-trauma fracture, with no significant differences in implementation of recommendations among racial groups. Similar FLS programs may help reduce racial disparities and improve guideline-based treatment in osteoporosis care.

Role of Discoidin Domain Receptor 2 in Tooth Socket Healing

*RENNY FRANCESCHI[1], Rajay Kamath[1]. [1]University of Michigan, United States

Discoidin Domain Receptor 2 (DDR2) is a collagen-activated tyrosine kinase required for skeletal development and regeneration of the calvaria and long bones, however, possible functions in alveloar bone have not been examined. The present study used lineage tracing, as well as global and conditional knockout approaches, to examine functions of Ddr2 in alveolar bone regeneration during tooth socket healing. The following mouse lines were used: DDR2LacZ (where the bacterial LacZ gene is inserted into the Ddr2 locus creating an effective null allele), Ddr2CreERT2; Rosa26GtTdtomato and Gli1CreERT2 Rosa26GtTdtomato for lineage tracing, and the Gli1CreERT2; DDR2fl/fl mice for the selective knockout of Ddr2 in GLI1+ skeletal progenitors. For lineage tracing, 4w old Ddr2CreERT2; Rosa26GtTdtomato and Gli1CreERT2 Rosa26GtTdtomato mice were induced with one dose of tamoxifen and the 1st molars were extracted after 2 or 7 days. In both cases, TdTomato+ cells migrated into the sockets where they co-localized with OSX, a preosteoblast marker. Thus, both DDR2 and GLI1+ cells contribute to socket healing. The considerable overlap observed between DDR2+ and GLI1+ cells suggested that DDR2 largely functioned in GLI1+ cells, which are known to have skeletal progenitor properties. Consistent with localization data, both global Ddr2 (Ddr2LacZ/LacZ) or conditional knockout (Gli1CreERT2; Ddr2fl/fl) mice exhibited reductions in socket healing 1-week post extraction as measured by µCT, but not after 2 or 4 weeks. However, analysis of collagen fibril orientation by picrosirius red staining revealed that collagen fibril orientation was disrupted in tooth sockets at all times examined, suggesting that even though loss of DDR2 only had a transient effect on socket bone fill, it has long-term effects on ECM structure and, potentially, mechanical properties. In summary, this work demonstrates a role for DDR2 in alveolar bone regeneration, a finding that may have therapeutic implications for the treatment of alveolar bone loss assciated with periodontal disease and other disorders.

Spatial Transcriptomics and Bulk-RNA Sequencing show distinct spatial and time-dependent effect of Abaloparatide at the sites of Fracture Repair

*ASHUTOSH PARAJULI[1], Andre van Wijnen[2], Daniel Bikle[3]. [1], [2]University of Vermont, United States. [3]Endocrine Research Unit, Division of Endocrinology UCSF and VAMC, United States

Fracture repair involves multiple cell types from periosteum, bone cortex, and bone marrow. Our study (Wang 2020, JBMR) identified three distinct repair sites (Site 1, 2 & 3; Fig. 1), but the underlying interaction mechanism between progenitors at these sites remains unclear. Abaloparatide (Abl), a PTHrP analog for osteoporosis treatment, enhances bone formation at these sites (Parajuli, ASBMR 2021; Fig. 1) by activating specific osteoblast and chondrocyte genes (Parajuli, ASBMR 2022). In this study, we investigated the effect of Abaloparatide (Abl) on the gene expression patterns at the specific sites (Spatial transcriptomics) as well as the whole callus (Bulk RNA-Seq) at day 10, 15 and 28 post Fx. Closed-unstabilized fracture model (12-wk C57BL/6J mice, 3-pt. bending) was used to create the fracture (midshaft of tibia). Mice received subcutaneous Abl (40ug/kg/day) or vehicle for 28 days. We performed RNA-Seq on the whole callus at day 10, 15, and 28 post Fx. Spatial transcriptomics was performed on paraffin sections using 10x Genomics Visium kit at the same time points. PCA and heatmap analysis (Fig. 2) revealed significant Abl-induced changes in gene expression within the healing callus at all time points. Differential gene expression analysis (Fig. 3) showed increasing Abl effects over time (8 DGEs at day 10, 305 at day 15, and 5351 at day 28). Spatial transcriptomics confirmed Abl's distinct effects at Site 1, 2, and 3 (Fig. 4). Heatmap analysis of selected osteogenic and chondrogenic markers (Fig. 5) showed site and time-specific responses to Abl. At day 10, Abl increased osteogenic activity at Site 1, while chondrogenic activity remained stable. At Site 2 and 3, Abl upregulated cartilage markers and downregulated osteogenic markers. At day 15, osteogenic markers increased, while chondrogenic markers decreased across all sites (compared to Day 10), with minimal Abl impact. By day 28, osteogenic marker expression decreased compared to day 15, but all three sites showed slightly higher osteogenic activity and decreased chondrogenic activity with Abl. These findings indicate distinct effects of Abl on all three sites during Fx repair. Further investigation aims to elucidate the molecular pathways involved at these sites and understand how Abl selectively promotes Fx repair.

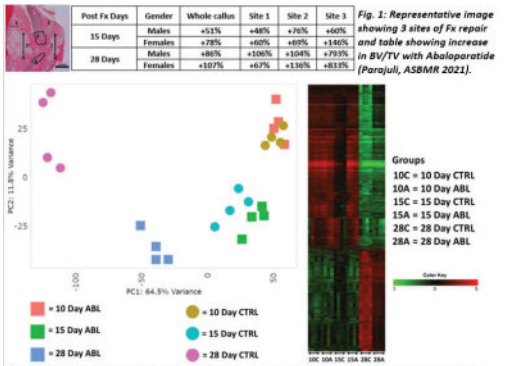

Fig. 1: Representative image showing 3 sites of Fx repair and table showing increase in BV/TV with Abaloparatide (Parajuli, ASBMR 2021).

Fig.2: (Left) PCA and (Right) Heatmap of top 1000 genes' expression profile in each of the samples. Heatmap columns left to right : 10D CTRLS, 10 D ABL, 15D CTRL, 15D ABL, 28D CTRL, 28D ABL (4 samples each).

10 Days (ABL - CTRL)	Down-Regulated	4
	Up-regulated	4
15 Days (ABL - CTRL)	Down-Regulated	283
	Up-regulated	22
28 Days (ABL - CTRL)	Down-Regulated	2129
	Up-regulated	3222

Fig. 3: Number of differentially expressed genes at Day 10, 15 and 28 with Abl treatment.

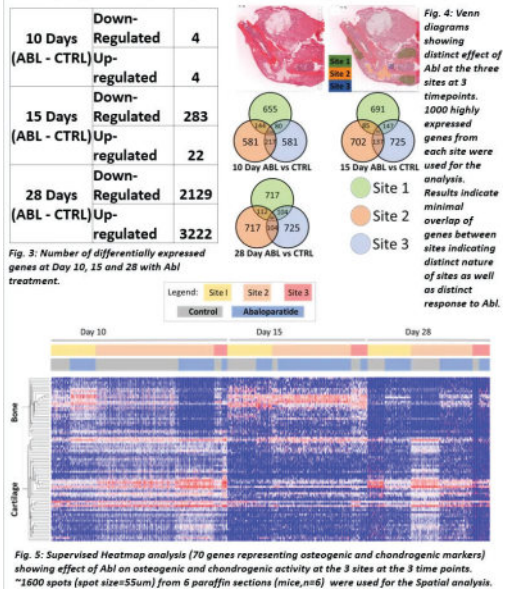

Fig. 4: Venn diagrams showing distinct effect of Abl at the three sites at 3 timepoints. 1000 highly expressed genes from each site were used for the analysis. Results indicate minimal overlap of genes between sites indicating distinct nature of sites as well as distinct response to Abl.

Fig. 5: Supervised Heatmap analysis (70 genes representing osteogenic and chondrogenic markers) showing effect of Abl on osteogenic and chondrogenic activity at the 3 sites at the 3 time points. ~1600 spots (spot size=55um) from 6 paraffin sections (mice,n=6) were used for the Spatial analysis.

The periosteum, the outer layer of bones, is a crucial source of skeletal stem/progenitor cells (SSPCs) for bone healing. The role of periosteum in bone repair disorders is poorly understood but suspected in congenital pseudarthrosis of the tibia (CPT). CPT is a severe pathology marked by tibial bowing leading to spontaneous fractures and fibrous non-union. Half of CPT cases are linked to Neurofibromatosis type 1 (NF1), a genetic disorder caused by mutations in the NF1 gene, encoding the RAS negative regulator neurofibromin. NF1 is characterized by a wide range of symptoms, such as tumors (neurofibromas, NFBs), skin hyperpigmentation and skeletal manifestations, including CPT. While NF1 neurodermatological manifestations are known to arise from NF1 biallelic inactivation in Schwann cells and melanocytes, the cellular origin of CPT remains unknown. Recently, analysis of the Prss56-Nf1 KO mice, revealed that boundary-cap cells, a transient population of neural-crest derivatives, is the population responsible for both neurofibromas and skin hyperpigmentation (Radomska et al.). These results raised the question of a possible common cellular origin of NF1 neurodermatological and skeletal symptoms.In this study, we unraveled the cellular origin and pathogenic mechanisms of CPT through analyses of bone samples from 17 CPT patients and Prss56-Nf1 KO mice. We showed that CPT is associated with NF1 biallelic inactivation in human periosteum. SSPCs in pathological periosteum exhibit NF1 biallelic inactivation and a pro-fibrotic phenotype. We identified an increased proportion of pERK+ Schwann cells (SCs) in pathological periosteum. Overall, analyses of CPT patients revealed SSPCs and SCs as affected cell types in CPT. In parallel, we described the pseudarthrosis phenotype of Prss56-Nf1 KO mice, due to Nf1 loss in boundary cap-derived SSPCs and SCs in periosteum. Single nuclei analyses of the periosteum showed that Nf1 KO SSPCs fail to undergo chondrogenic differentiation leading to fibrogenic differentiation. More strikingly, we identify Nf1 KO SCs as the main driver of fibrotic accumulation in CPT as they acquire a pro-fibrotic function and promote fibrotic fate of wild-type SSPCs via TGF?. We demonstrate that TGF? inhibition prevents pseudarthrosis in Prss56-Nf1 KO mice. These results establish the pro-fibrotic role of boundary cap-derived SCs and SSPCs causing CPT in NF1. This study suggests new therapeutic strategies targeting SC-derived pro-fibrotic factors, including TGF?, for CPT.

Evidence of Bisphosphonate-Conjugated Fluoroquinolone Analog Eradication of Established Methicillin-Resistant S. aureus Infection with Osseointegration in Murine Models of Implant-Associated Osteomyelitis *F Hal Ebetino[1], Shuting Sun[1], Youliang Ren[2], Jason Weeks[2], Thomas Xue[3], Joshua Rainbolt[3], Karen de Mesy Bentley[3], Ye Shu[3], Yuting Liu[3], Elysia Masters[3], Philip Cherian[4], Charles E McKenna[5], Jeffrey Neighbors[6], Edward M Schwarz[2], Chao Xie[2]. [1]BioVinc, United States. [2]University of Rochester Medical Center, United States. [3]University of Rochester Medical School, United States. [4]BioVinc LLC, United States. [5]University of Southern California, United States. [6]Pennsylvania State University, United States

Eradication of methicillin-resistant Staphylococcus aureus (MRSA) infection of bone requires elimination of distinct biofilms including bacteria within osteocyte-lacuno-canalicular networks (OLCN) and Staphylococcus abscess communities (SAC) in the bone marrow. To overcome the limited efficacy of standard of care (SOC) vancomycin(vn) therapy, we developed bisphosphonate(BP)-conjugated sitafloxacin analogs (BCS, BV600072 and HBCS, BV63072), to achieve "target-and-release" drug delivery proximal to the bone infection. We evaluated their efficacy in a murine 1-stage exchange femoral plate model with bioluminescent MRSA (USA300LAC::lux). Chronic osteomyelitis was confirmed by CFU on the explants and bioluminescent imaging (BLI) after implant exchange surgery on day 7, and mice were randomized into 7 groups: 1) Baseline (day 7, no trtmt); 2) HPBP (BCS BP control) + vn; 3) HPHBP (HBCS BP control) + vn; 4) vn; 5) sitafloxacin; 6) BCS + vn; and 7) HBCS + vn. BLI prior to euthanasia on day 21 (day 14 post-revision) confirmed that MRSA infection persisted in all groups except for mice treated with BCS or HBCS + vn. X-ray and micro-CT analyses revealed catastrophic femur fractures in all groups except for mice treated with BCS or HBCS + vn which also displayed significant decreases in peri-implant bone loss, osteoclast numbers, and biofilm as assessed by histomorphometry ($p<0.05$ via 1-way ANOVA). (Figure 1.) TEM images of the bacteria within SACs or canaliculi of the infected bone are shown at low power (×5,000) (Fig 2A,C,E,G,I) and with high-power images (×25,000) (Fig 2B,D,F,H,J). Regions of interest (Fig 2A,C,E,G,I) illustrate the morphology of the bacteria on day 14 post 1-stage revision. TEM demonstrated strong evidence of HBCS- and BCS- induced bacterial cytotoxicity (cell swelling with large numbers of vacuoles). We also assessed the efficacy of vancomycin, sitafloxacin, and HBCS monotherapy in a transtibial implant model of chronic MRSA osteomyelitis. X-ray, histology, and transmission electron microscopy analyses confirmed that all mice treated with vancomycin remained infected, while all mice treated with HBCS had evidence of infection control including SAC's, and some had evidence of osseous integrated septic implants, suggesting biofilm eradication. This is the first evidence that biofilms within SACs and the OLCN can be eradicated in chronic models and demonstrates the potential of HBCS to eradicate MRSA osteomyelitis as an adjuvant to SOC therapy.

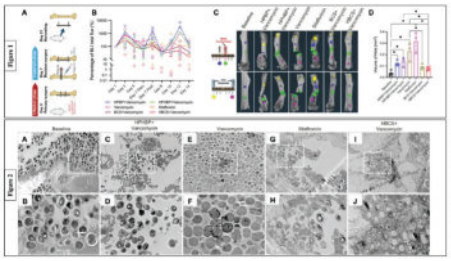

Figure 1. *In vivo* BLI and quantifiable Micro-CT and histological evaluation show a promising antimicrobial efficacy of BCS and HBCS in a 1-stage revision murine model. (A) Schematic illustration of the surgical procedure (Fig 1A). Longitudinal BLI (B) and micro-CT (C,D) images and data are presented for each animal with mean +/-SD (*p<0.05).

Figure 2. TEM evidence of BCS and HBCS killing of MRSA within SACs and biofilm within the bone marrow space. Histological section from the infected femurs were processed for subsequent TEM. Representative TEM images of the bacteria within bone marrow space of the infected bone are shown at low power (A, C, E, G, I), and high-power images of the dashed boxed region of interest (B, D, F, H, J) are shown to illustrate the morphology of the bacteria within SACs on day 21 post-infection.

Lumbar instability initiates endplate remodeling via Hippo signaling activation *Hao Chen[1], Hanwen Li[2]. [1]Yangzhou University, China. [2]The First Affiliated Hospital of Soochow University, China

Introduction: Protic endplates with sensory innervation contribute to low back pain. However, the origin and developing mechanism of the porotic endplate remain unclear.Objectives: This study aims to explore the regulatory mechanism of cartilage endplate (CEP) remodeling caused by abnormal stress.Methods: In vivo, we constructed lumbar spine instability (LSI) model in mice. We then analyzed the forces on the CEP using finite element analysis (FEA). In vitro, we used a mechanical tensile machine to simulate the abnormal stress conditions of the endplate cartilage cells (ECs). WB, RT-qPCR, and immunofluorescence staining were used to analyze the cell status. We use high-throughput sequencing to find out the key signaling regulating this process. Then, we created cartilaginous YAP elimination mice (Col2a1-CreER::YAPfl/fl). After that, we used YAP agonists both in vivo and in vitro to rescue CEP remodeling. Finally, we conducted therapeutic experiments by using AAV5-carrying Yap1 plasmids.Results: Here in this report, we discovered lumber instability-induced cartilage endplate remodeling is responsible for making the cheese-endplate and subsequent lumber disc degeneration by employing the lumbar spine instability (LSI) model in vivo and the mechanical tensile model in vitro. We confirmed that lumbar instability-induced abnormal stress and initiated cartilage endplate remodeling. Transcriptome analysis revealed Hippo signaling was enriched in this process. Activation of Hippo signaling or knock out of YAP in the cartilage endplate impressively severed the endplate and disc degeneration after LSI surgery, while blocking the Hippo signaling reversed this process. Meanwhile, we observed osteoclast differentiating factors were also enriched in the endplate chondrocytes under lumbar instability-induced abnormal stress stimulation, in which the release of CCL3 helped to form osteoclasts and proceed for cartilage remodeling. Finally, we successfully rescued LSI-induced lumbar degeneration by local injection of AAV5-Yap1 over-expression plasmid.Conclusions: Our study sought to demonstrate that YAP is like the guard for the endplate cartilage, which can maintain CEP homeostasis. We also confirmed that this may be related to the CCL3-regulation of osteoclast activation, which is induced by YAP. These findings suggest that the Hippo signaling activation in the cartilage endplate by lumbar instability is a potential new target for the management of lumbar degeneration and low back pain.

Epigenetic modification to prevent heterotopic ossification *Tao Yue[1], ji Hae Choi[1], Alec Bancroft[1], yuxiao sun[1], Conan Juan[1], Robert Tower[2], Pranathi Dasari[1], Sowmya Ramesh[3], Aaron W James[3], Katherine A Gallagher[4], Benjamin Levi[1]. [1]University of Texas Southwestern, United States, [2]University of Texas Southwestern Medical Center, , [3]Johns Hopkins University, United States, [4]University of Michigan, United States

Heterotopic ossification (HO) is defined by the abnormal formation of bone tissue outside of the skeleton, accompanied by chronically progressive pain and limited mobility. However, identifying evolutionally conserved epigenetic modifiers that regulate the formation of HO is challenging due to our limited understanding of the molecular and cellular mechanisms implicated in HO. Here, a proven burn-tenotomy (BT) mouse model was used to investigate the role of epigenetic modification in traumatic HO formation. Our single-cell RNA sequencing (scRNA-seq) analysis of 150 human-conserved epigenetic modifiers from the injury site of this mouse model revealed that the histone demethylase Kdm6b had the most dramatic upregulation in HO-driving macrophages (Fig.1 A-B), with expression peaking by day 7 and maintained at the highest levels until day 42 (Fig.1 C). We also found KDM6B protein highly expressed in myeloid cells in human HO tissues (Fig.1 D). Mechanistically, we first uncovered that Kdm6b expression is upregulated by the activation of toll-like receptor signaling in injury-site macrophages. Single-nucleus Assay for Transposase-Accessible Chromatin (sn-ATAC) and Chromatin immunoprecipitation-qPCR (Chip-qPCR) further demonstrated that increased Kdm6b levels in macrophages led to demethylation of the repressive trimethylated lysine 27 on histone H3 (H3K27me3) at genomic loci of its target genes (Il1b, Tnfa, Tgfb1, and Pdgfa), and enhanced chromatin accessibility for elevated transcription of these proinflammatory and HO-promoting genes. Of note, KDM6B, also expressed in injury-site mesenchymal progenitor cells (MPCs), remodels the epigenetic landscape of MPCs in response to inflammatory stimuli after injury, thereby promoting their osteochondral differentiation during traumatic HO formation (Fig.1 E). Targeted inhibition of KDM6B in vivo with myeloid-specific genetic inactivation (Kdm6bf/f; Lyz2Cre+) or pharmacological inhibition with GSK-J4 in the mouse model of HO, significantly reduced inflammation, and markedly attenuated HO formation (Fig.1 F). Thus, our findings show that KDM6B acts as a critical HO-promoting epigenetic factor in both macrophages and MPCs, and targeting KDM6B could be an effective therapeutic intervention to limit HO development and progression.

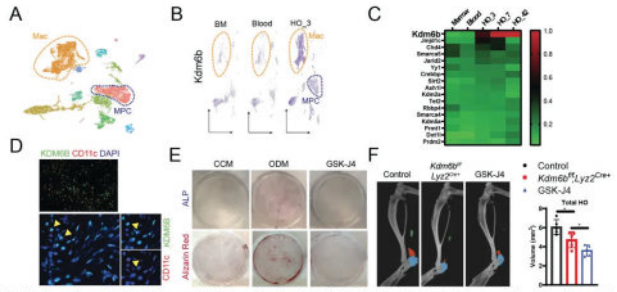

Fig.1 Epigenetic modification to prevent HO formation. (A and B) UMAP showing *Kdm6B* highly expressed in macrophages and MPCs. (C) Heatmap showing *Kdm6B* highly expressed in infiltrating macrophages at different time points after the traumatic injury. (D) Immunostaining showing that KDM6B is expressed in macrophages of human HO tissue samples. (E) ALP and Alizarin Red staining showing that GSK-J4 treatment inhibits osteogenic differentiation of MPCs in vitro. (F) Myeloid-specific genetic inactivation or pharmacological inhibition of JMJD3 in the mouse model mitigates HO formation.

The Role of Clec3b+ Muscle Cells in Fracture Healing and Heterotopic Ossification *JACOB MOORE[1], EZGI AYDIN[2], Ugur Ayturk[2, 1], [2]Hospital for Special Surgery, United States

Loss of Clec3b expression results in impaired healing of bone, connective tissue and skin injuries. We previously generated a Clec3b.creERT2 knock-in allele and found that Clec3b+ cells are located in muscle, outer periosteum and connective tissues, and are completely absent in the marrow, endosteum or growth plate. Further, Clec3b+ cells are osteogenically inactive during skeletal development and remodeling, but can contribute to the healing of drill hole injury or BMP2-driven heterotopic ossification (HO).Our goal with the current study was to determine the specific cell types Clec3b+ cells can convert to in trauma situations, and whether these changes are physiologically significant. We induced stabilized long bone fractures in Clec3b.creERT2; Ai14.R26.tdTomato; Bglap.eGFP mice. Using scRNA-seq, flow cytometry and fluorescent histology, we confirmed that Clec3b-lineage cells become fibroblasts, chondrocytes, osteoblasts, osteocytes, and bone marrow stromal cells in the fracture callus. To determine whether these Clec3b-lineage cells arise from the muscle or periosteum, we performed periosteum removal and bone graft transplantation experiments. All results indicated that muscle-resident Clec3b+ cells are the predominant contributors to bone healing. To test the significance of these contributions, we ablated Clec3b+ cells in Clec3b.creERT2; R26.DTA mice during fracture healing. MicroCT analysis showed that Clec3b+ cell-depleted fracture calluses had less bone volume (BV) than same-sex, littermate controls ($p < 0.05$).To determine whether Clec3b+ cells also play a significant role in HO, we activated the Acvr1.Q207D mutation in Clec3b+ cells (which results in BMP-gain-of-function) and confirmed muscle mineralization with microCT. To test loss of function, we depleted Clec3b+ cells with the DTA allele after inducing HO by intramuscular BMP2-injection. Surprisingly, Clec3b+ cell depletion (confirmed by histology) did not reduce but instead increase ectopic bone volume (both TV and BV, $p < 0.05$). These data suggest that Clec3b+ cell apoptosis during HO stimulates bone formation by cells that do not undergo Cre-recombination, either due to inefficient Cre-activation or lack of Clec3b-expression.Overall, our data show that Clec3b+ interstitial muscle cells play significant roles in regenerative and pathologic bone formation processes. Studying the mechanisms regulating Clec3b+ cells can lead to new strategies to promote fracture healing and prevent HO.

Fgfr3-expressing endosteal stromal cells form osteosarcoma-like lesions through unregulated self-renewal upon loss of p53 tumor suppressor *Yuki Matsushita[1], Noriaki Ono[2]. [1]Nagasaki University, Japan, [2]University of Texas Health Science Center at Houston School of Dentistry, United States

Skeletal stem cells (SSCs) are found in various bone marrow stromal compartments and provide an important source bone-forming osteoblasts. We recently described that bone marrow stromal cells expressing fibroblast growth factor receptor 3 (Fgfr3) reside in the endosteal space and actively participate in bone formation under homeostatic and regenerative conditions. However, how Fgfr3+ endosteal stromal cells participate in aberrant bone formation under pathological conditions remains unclear. First, we conditionally deleted p53 tumor suppressor in Fgfr3+ cells using Trp53-floxed allele. We pulsed cohorts of Fgfr3-creER; Trp53fl/+; R26RtdTomato (Control) and Fgfr3-creER; Trp53fl/fl; R26RtdTomato (Fgfr3-p53 cKO) mice at postnatal day (P) 21 and analyzed these mice at 9 months of age. Strikingly, a substantial fraction of Fgfr3-p53 cKO mice (5/17 mice) developed highly-trabecularized bone tumors radiating from the marrow space, which destroyed the pre-existing cortical bones. In all Fgfr3-p53 cKO bones examined (17/17 mice), the marrow space was dominated by unorganized trabecular bone-like structures entirely composed of Fgfr3CE-P21?p53 tdTomato+ cells. In contrast, conditional deletion of p53 by Osx-creER (pulsed at P21) or Lepr-cre did not induce apparent bone tumor-like lesions at 9 months, indicating that Fgfr3+ endosteal stromal cells, but not Osx+ or LepR+ cells, can transform into bone tumor cells upon p53 loss. Subsequently, we investigated mechanisms underlying tumorigenic potential of Fgfr3+ cells by colony forming unit-fibroblast (CFU-F) assays. Fgfr3CE-?p53 tdTomato+ clones exhibited substantially faster cell growth and higher passage-ability compared to wild-type tdTomato+ clones, associated with significant upregulation of osteoblast markers and cell proliferation genes as identified by RNA-seq, indicating that p53 loss introduces stem cell-like properties and an osteogenic bias in Fgfr3+ CFU-Fs. Further, transplantation of Fgfr3CE-?p53 tdTomato+ clones into the femoral marrow cavity of NSG mice resulted in the formation of highly trabecularized structures throughout the marrow space, which were reminiscent of early-stage osteosarcoma-like lesions. Therefore, Fgfr3+ endosteal stromal cells develop aggressive osteosarcoma-like lesions upon loss of p53 tumor suppressors through unregulated self-renewal and aberrant osteogenic fates.

Periosteal CD51+ progenitor cells contribute to local healing *YE CAO[1], IVO KALAJZIC[2], Brya Matthews[3, 1], New Zealand, [2]University of Connecticut Health Center, United States, [3]University of Auckland, New Zealand

The periosteum is a major source of cells that contributes to fracture healing. However, complexity of the fracture model includes response of bone marrow derived skeletal stem/progenitor cells (SSPCs). In this study, we evaluated the response of periosteum and defined populations of periosteal injury-responsive SSPCs using a periosteum-specific scratch injury.Following injury, periosteal progenitors expanded by day 3 and formed fibrocartilage by day 7. Fibrocartilage was gradually replaced by new bone formation with marrow infiltration from day 14 to day 21. Bone and periosteum were remodeled, and healing was complete by day 28.We used multicolor spectral flow cytometry combined with ?SMACreER/tdTom/Col2.3GFP, a lineage tracing model of skeletal progenitors (?SMA+) and osteoblasts (Col2.3+). Within total periosteal CD45- cells, enrichment of ?SMA and CD90 cells was detected on day 3 (10.4% and 27.9%) and day 7 (28.0% and 36.0%) after injury compared with uninjured (3.4% and 17.9%). Markers of progenitors Sca1+CD51+, Sca1-CD51+ were expanded by 7 days after injury.Histologically, most periosteal Sca1 cells were located on the outer periosteum layer. They showed minimal expansion with injury. CD51 and CD90 cells were more abundant in the inner layer and expanded immediately with injury. In contrast with flow result, Sca1+CD51+ cells were rare in the periosteum in situ. Some CD51+ cells were Col2.3+ on day 14 following injury, indicating the contribution of CD51+ cells to osteoblasts.Periosteal Sca1+CD51+ cells were multipotent, and Sca1-CD51+ cells were committed osteoprogenitors in vitro. We further examined the in vivo lineage potential of Sca1-CD51+ and, Sca1+CD51+ cells by subcutaneous transplant. In contrast to the in vitro results, Sca1-CD51+ cells exhibited greater engraftment and more osteoblast formation than the other populations tested.Stimulation of Notch signalling enhances bone healing. Using ?SMACreNICD mice, which have increased Notch signalling in ?SMA+ cells, we found the frequency of CD51+ was tripled in NICD+ mice compared to controls, indicating that CD51+ cells may improve healing at early stages.In conclusion, periosteal Sca1-CD51+ and CD90+ cells are multipotent progenitors that respond rapidly to local injury in vivo. Enhanced bone healing is correlated with the rapid expansion of CD51+ osteoprogenitors.

Refining the identity of mesenchymal cell types associated with murine bone *Intawat Nookaew[1], Jinhu Xiong[1], Melda Onal[1], Cecile Bustamante-Gomez[1], Visanu Wanchai[1], Qiang Fu[1], Ha-Neui Kim[1], Maria Almeida[1], Charles O'Brien[1], [1]University of Arkansas for Medical Sciences, United States

Single cell RNA sequencing (scRNA-seq) quantifies mRNAs in individual cells. The transcriptomic profile can be used to cluster cells with similar profiles. Combining this information with known gene expression patterns can be used to define clusters of cells as specific cell types. Several recent studies have used scRNA-seq to define mesenchymal cells associated with murine bone. However, these studies do not agree on the number of different cell types. To address this inconsistency in cell type designation, we created an atlas of murine bone-associated cells by harmonizing published datasets with in-house data from cells targeted by Osx1-Cre and Dmp1-Cre driver strains. Over 100,000 mesenchymal cells were mapped to reveal 11 major clusters designated fibro-1, fibro-2, chondrocytes, articular chondrocytes, tenocytes, adipo-CAR, osteo-CAR, pre-osteoblasts, osteoblasts, osteocytes, and osteo-X, the latter defined in part by Postn expression. In situ hybridization revealed that osteo-X, osteo-CAR, and pre-osteoblasts were closely associated with osteoblasts on trabecular bone, suggesting a continuum of cells spanning from osteoblast progenitors to mature osteoblasts. To determine if any of these cell populations are dependent on ongoing bone remodeling, we suppressed osteoclast formation using denosumab and examined the impact by scRNA-seq. To ensure our analysis produced cluster annotations consistent with the harmonized atlas, we constructed a reference-based mapping model using the Azimuth pipeline. Denosumab dramatically reduced osteoblast number, consistent with the suppression of bone remodeling. The abundance of pre-osteoblasts was also slightly reduced as was expression of the pre-osteoblast marker Spp1. In contrast, the abundance of osteo-CAR and adipo-CAR cells was not altered. Consistent with these results, in situ hybridization revealed an almost complete loss of Bglap-positive osteoblasts on trabecular bone in denosumab-treated mice. Pre-osteoblasts, as defined by Spp1 expression, showed robust staining on trabecular bone in vehicle-treated mice, which was reduced but not abolished after denosumab. In contrast, the osteo-CAR marker Limch1 and the osteo-X marker Postn displayed little change after denosumab administration. Thus osteoblasts, and to some extent pre-osteoblasts, are highly dependent on bone resorption and coupling factors for their existence but osteo-CAR and osteo-X cells, and their close association with the bone surface, are not.

SHP2 Regulation of the Plasticity of OSTERIX+ Bone Marrow Stroma and Hematopoietic Niches *Lijun Wang[1], Huiliang Yang[1], Nathalie Oulhen[2], Jiahui Huang[1], Gary M. Wessel[2], Vicki Rosen[3], Shaomeng Wang[4], Hicham Drissi[5], Douglas C. Moore[1], Wentian Yang[1], [1]Brown University, Department of Orthopaedic Surgery, United States, [2]Brown University, Departments of Molecular Biology, Cell Biology, and Biochemistry, United States, [3]Harvard School of Dental Medicine, United States, [4]University of Michigan, Departments of Internal Medicine, Pharmacology, and Medicinal Chemistry, United States, [5]Emory University, United States

Objective: Live-cell fate mapping has identified a pivotal population of bone marrow (BM) Osterix (Sp7)-positive mesenchymal stem and progenitor cells (O+MSPC). These O+MSPC also express variable levels of Nestin, Cxcl12, LepR and Pdgfr?/Sca-1, their functions in skeletal development and BM homeostasis remain elusive. SHP2 (encoded by PTPN11) is a widely expressed tyrosine phosphatase and has been implicated in MSPC maintenance. This study aims to understand how the self-renewal and lineage commitment of O+MSPC are regulated by SHP2, and how SHP2 in O+MSPC modulates osteogenesis and hematopoietic niche formation.Materials and Methods: Mice lacking SHP2 in O+MSPC were generated by crossing the Ptpn11 floxed allele to Tg(Sp7-cre) mice. Tg(Rosa26ZSG) was bred in as a lineage reporter in some studies. Control and SHP2 mutants were sacrificed at the indicated time points and examined via X-Ray, μ-CT, histological, biochemical, scRNA-seq, and biological analyses. All mice were maintained on the C57BL/6 background and studied in accordance with the IACUC-approved protocols.Results and Discussion: Phenotypic characterization of the SHP2 mutants and their cellular derivatives reveals that SHP2 is a critical regulator of O+BMPC. SHP2 ablation in O+BMSC substantially reduced bone mass. OB abundance and function were markedly reduced in affected mutants. These mice also exhibited delayed closure of the cranial sutures and fontanelles, phenotypically mimicking the features of human Cleidocranial Dysplasia in which RUNX2 loss-of-function mutations have been described1-3. SHP2 mutants also have increased BM adipocyte accumulation and altered BM vasculature, likely by impairing pericyte development. Importantly, SHP2 ablation in O+BMSC skewed hematopoiesis, significantly reducing common lymphoid progenitors (CLPs) and B cells in BM, although the number of HSC is comparable between control and SHP2 mutants. Mechanistically, SHP2 regulated the lineage commitment of O+BMSC by modulating the RUNX2 and OSTERIX expression, and CLP and B cell survival by promoting IL7 secretion. BM hematopoietic niches are 3D stromal complexes that contain MSPCs, their progeny, and cells of vascular origin. These cells are known to provide key signals that support HSC survival, proliferation, and differentiation. Our data and published literature4 together emphasize a crucial role for SHP2 in the formation and functional regulation of hematopoietic niches and osteogenesis.

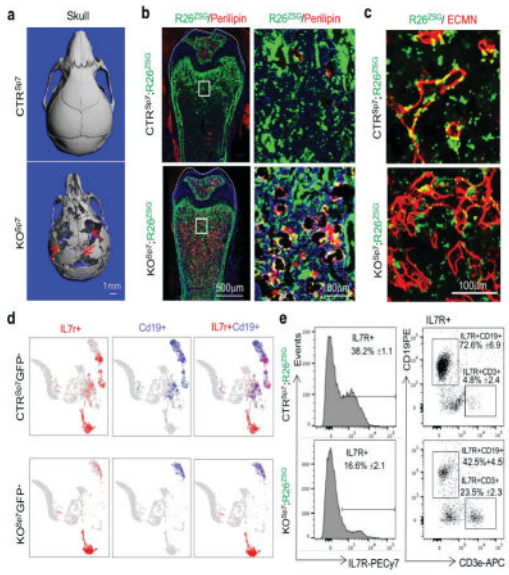

Fig.1 **a.** μCT images demonstrate the gross skull morphology of 4-week-old SHP2CTR^{Sp7} and SHP2KO^{Sp7} mice. Note that SHP2 deletion impairs frontal and parental bone mineralization (red arrows). **b-c.** Immunostained distal femoral sections show the massive accumulation of Perilipin+ adipocytes and altered BM vasculature (ECMN+) in SHP2KO^{Sp7};R26^{ZSG} mice, compared to SHP2CTR^{Sp7};R26^{ZSG} controls. **d.** scRNA-seq analysis and UMAP plots show the diminish of IL7r+Cd19+ pro- and pre-B cell clusters in FACS-enriched R26^{ZSG}- BM populations in SHP2KO^{Sp7};R26^{ZSG} mice, compared to age and sex matched SHP2CTR^{Sp7};R26^{ZSG} controls. **e.** Representative FACS data show a marked reduction of BM IL7R+CD19+ subpopulation in SHP2KO^{Sp7};R26^{ZSG} mice, compared to SHP2CTR^{Sp7};R26^{ZSG} controls.

AdipoQ lineage bone marrow progenitors are the major cellular source of M-CSF for bone marrow macrophage development, osteoclastogenesis and bone metabolism *Yongli Qin[1], Kazuki Inoue[1], Yuhan Xia[1], Jie Han[2], Ruoxi Yuan[3], Jun Sun[4], Ren Xu[2], Jean X. Jiang[5], Matthew B. Greenblatt[1], Baohong Zhao[1]. [1]Weill Cornell Medical College and Hospital for special surgery, United States. [2]The first Affiliated Hospital of Xiamen University, China. [3]Hospital for special surgery, United States. [4]Weill Cornell Medical College , United States. [5]University of Texas Health Science Center, United States

M-CSF, encoded by Csf1, is a critical growth factor for myeloid lineage cells, including monocytes, macrophages, and osteoclasts. Tissue-resident macrophages in most organs rely on local M-CSF. However, it is unclear what specific cells in the bone marrow produce M-CSF to maintain myeloid homeostasis. We performed an integrative scRNAseq analysis based on five published bone marrow scRNAseq datasets and human bone marrow scRNA-seq datasets. Although the current paradigm indicates osteoblasts as the main cellular source of M-CSF in bone marrow, we surprisingly found that the osteoblasts do not express Csf1 in vivo. In contrast, we identified that Adipoq-lineage (Adipoq+) bone marrow progenitor cells possess the predominant and highest Csf1 expression level in bone marrow. The Adipoq-lineage progenitors with high CSF1 expression also exist in human bone marrow. We further generated Csf1 conditional knock out (cKO) mice, in which Csf1 is specifically deleted in Adipoq+ cells by crossing Csf1flox/flox mice with Adipoq-cre mice (hereafter referred to as Csf1?Adipoq). Csf1 deficiency in Adipoq+ cells lead to a drastic decrease in bone marrow macrophages and a severe osteopetrotic phenotype in mice with significantly reduced osteoclast numbers and enhanced bone mass. Without exogenous M-CSF, RANKL is able to induce osteoclastogenesis in bone marrow harvested from the control mice, but not from Csf1?Adipoq bone marrow. These results further support an essential role for M-CSF secreted from Adipoq+ bone marrow cells in osteoclastogenesis in vivo. Interestingly, Csf1 is undetectable in other Adipoq highly expressed cells, including peripheral mature adipocytes or mature bone marrow adipocytes. Tissue macrophages in other organs appear normal in Csf1?Adipoq mice. Furthermore, the lack of the Adipoq+ cell-produced M-CSF prevented the estrogen-deficiency induced excessive osteoclast formation and osteoporosis, indicating a potential novel therapeutic strategy for postmenopausal bone loss by targeting M-CSF produced by Adipoq+ cells. Collectively, our data reveal a specifically high Csf1 expression feature of the Adipoq+ bone marrow progenitor cells. These cells constitute approximately only 0.05% of bone marrow cells, but are the major cellular source of M-CSF in bone marrow. These findings challenge the current paradigm and have profound implications for our understanding of bone marrow macrophage development, osteoclastogenesis, bone homeostasis, and pathological bone loss.

In Vivo Tracking of Human Fetal Skeletal Stem Cell Lineage Dynamics at the Single Cell Level *Thomas Ambrosi[1], Rahul Sinha[2], Charles Chan[2]. [1]UC Davis, United States. [2]Stanford University, United States

With the increasing socioeconomic impact of skeletal disorders and the absence of reliable treatments, innovative approaches are required to prevent bone loss and restore skeletal tissues. Skeletal stem cells (SSCs) show great potential as a new therapeutic option; however, progress has been hindered by a lack of understanding regarding the identity and function of these cells in humans. Here, we utilized a combination of prospective flow cytometric isolation and SmartSeq2 single cell RNA-sequencing (scRNAseq) to interrogate the diversity of over 4,000 human SSCs from ten distinct skeletal sites at 20 weeks gestational age. In vivo tracing of lentivirally barcoded fetal human SSCs was combined with scRNA-seq readouts to assess unique clonal dynamics of human growth plate and periosteal SSCs. RNAscope was employed to map SSC subsets in situ. A xenograft model of fetal skeletal elements together with scRNAseq was used to further deconstruct the human SSC lineage tree in fetal long bones. Transcriptomic analysis of single fetal SSCs from distinct skeletal sites revealed diversity of SSCs tied to specialized features correlating with anatomical localization. Intriguingly, gene expression in specific types of SSCs residing in different bone regions was linked to skeletal phenotypes caused by genetic mutations. For example, XYLT1, a gene that if mutated leads to dwarfism, was highly expressed in growth plate SSCs but not cranial, periosteal, pelvic or vertebra SSCs, while SEC24D, a gene associated with craniosynostosis, was highly expressed in suture SSCs. Overall, we identified two major types of SSCs - an osteochondral SSC and a stromal SSC. We also found that growth plate and periosteal SSCs of long bones, representing examples of the two specialized SSC subtypes, presented with distinct clonal dynamics thereby differentially contributing to skeletal development. Functional and bioinformatic approaches highlighted that neither of the two SSC types were dispensable and that they tightly interacted to facilitate proper bone growth and maintenance. Lastly, index-sort analysis of prospectively isolated SSC lineage subsets was able to reconstruct stem cell dynamics and identify additional new subsets of specified, more committed skeletal lineage cell populations. In summary, our research provides novel insights into human skeletal stem cell biology and offers experimental vantage points to study skeletal development and disease at an unprecedented resolution.

Mitochondrial Metabolism Determines Mesenchymal Stem Cell Fate *CHEN YU[3], RUBENS SAUTCHUK JR[2], Roman Eliseev[3]. [3]University of Rochester, , [2], , [3]University of Rochester, United States

Aging-related changes in bone marrow stromal (a.k.a. mesenchymal stem) cells (BMSCs) shift cell fate away from osteogenesis and towards adipogenesis. The mechanism(s) underlying such changes are not completely understood. Mitochondria are important cell organelles that not only produce energy but also determine cell behavior by regulating metabolism, signaling, calcium homeostasis, apoptosis, and other cellular processes. We have previously shown that mitochondrial activation is important during osteogenesis of BMSCs. In aged bone tissue, we observed pathological opening of the mitochondrial permeability transition pore (mPTP) which leads to mitochondrial dysfunction, oxidative phosphorylation uncoupling, and cell death. Cyclophilin D (CypD) is a mitochondrial protein that facilitates opening of the mPTP. We found that CypD is downregulated during osteogenesis of BMSCs leading to lower mPTP activity and, thus, protecting mitochondria from dysfunction. On the other hand, we observed that during adipogenesis, BMSC alternative fate, cells significantly upregulate glycolysis and increase CypD expression and mPTP activity. Confocal imaging shows that mitochondrial morphology remains rounded and fragmented during this process (Figure). CypD gene, Ppif, promoter analysis reveals multiple binding sites for adipogenic C/EBP and inflammatory NF-?B transcription factors. Luciferase assay and ChIP-PCR analysis confirm C/EBP? as a transcriptional activator of CypD. NF-?B p65 translocates to the nucleus during adipogenesis and shows synergistic effect with C/EBP? in inducing Ppif expression, suggesting a potential link between ‘inflammaging’ and altered BMSC fate. In vitro CypD overexpression enhances, whereas CypD knockdown impairs adipogenesis. Pharmacological inhibition of CypD by NIM811 also impairs adipogenesis in vitro. Prx-1Cre-mediated deletion of CypD in Ppiff/f mice decreases bone marrow fat in 13-month-old mice. Currently we are pursuing the effect of Prx1Cre-mediated CypD overexpression in mice. In summary, BMSCs maintain or upregulate CypD expression during adipogenesis leading to increased mPTP activity, activated glycolysis and low mitochondrial function, thus establishing a metabolic profile that appears to be favorable for adipogenic lineage. The overall goal of this study is to define the potential role of CypD/mPTP during BMSC adipogenesis, facilitating the understanding of stem cell fate determination and molecular mechanism of age-related bone loss.

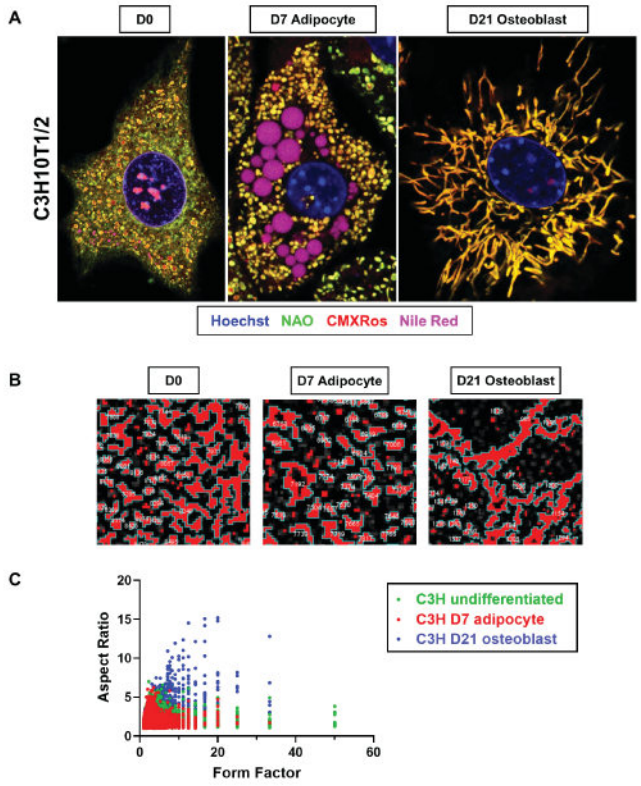

Figure. Mitochondrial network during osteogenesis and adipogenesis in C3H10T1/2.
A) Representative images of mitochondrial morphology in C3H/10T1/2 cells. Cells were cultured in adipogenic media for 7 days or osteogenic media for 21 days. After staining, images were taken by confocal microscopy at 63x magnification. B) Representative images of mitochondrial morphology analysis in C3H10T1/2. Analysis was performed with CMXRos staining using ImageJ. C) Quantification of mitochondrial morphology. For each group, three cells were randomly selected for analysis.

Effect of Protein Supplementation during Weight Loss on Trabecular and Cortical Bone Mineral Density of the Hip in Older Adults with Obesity: a Randomized Controlled Trial *Ashley Weaver[1], Katelyn Greene[2], Joshua Stapleton[3], Xiaoyan Leng[4], Leon Lenchik[4], Mary Lyles[4], Barbara Nicklas[4], Sue Shapses[5], Denise Houston[4]. [1]Wake Forest University, United States; [2]Wake Forest School of Medicine, , [3], , [4]Wake Forest University School of Medicine, United States; [5]Rutgers University/ Rutgers RWJ Medical School, United States

Weight loss (WL) to treat obesity is controversial in older age as it can exacerbate bone loss. We conducted a double-blind, randomized controlled trial in 187 low-functioning older adults with obesity (mean+/-SD: 71.0+/-4.3 yrs; BMI 34.2+/-4.1 kg/m2; 34% men) to assess the effect of protein supplementation during WL on hip volumetric bone mineral density (vBMD). Participants were enrolled in a 6-month WL intervention (caloric restriction and moderate-intensity treadmill walking 3d/wk) followed by 12 months of follow-up and randomized to one of 3 groups: 50 g/d of supplemental protein (PRO; n=62) or carbohydrate (CHO; n=62) for the 6-month WL period, or 50 g/d of supplemental PRO for the 18-month WL plus follow-up period (n=63). Computed tomography (CT) scans at baseline and 18 months were analyzed to assess trabecular and cortical vBMD of the total hip, femoral neck, and intertrochanter and differences in change were examined using analysis of covariance adjusted for age, sex, race, baseline weight, and baseline bone measure. Spearman's correlations of WL vs bone changes adjusted for age, race, and sex were also examined. Protein intake at 18 months was higher in the 18-m PRO group compared to the 6-m PRO and 6-m CHO groups (mean+/-SD: 1.0+/-0.4 vs 0.8+/-0.3 and 0.8+/-0.3 g/kg/d, respectively; p<0.01). 18-month WL did not differ by group (-5.2+/-5.6, -4.9+/-5.4, -4.3+/-5.3 kg for 18-m PRO, 6-m PRO and 6-m CHO, respectively). Total hip cortical vBMD improved over 18 months (Fig A) but did not differ by group (adjusted mean+/-SE: 12.8+/-4.3, 13.4+/-4.2, 11.6+/-3.9 mg/cm3 for 18-m PRO, 6-m PRO and 6-m CHO, respectively; all p<0.05). Similar trends were observed in cortical vBMD changes of the femoral neck and intertrochanter. Trabecular vBMD losses (mg/cm3) did not differ by group (Fig B), but there was more preservation in the 18-m PRO group at the total hip (0.0+/-1.4 vs -1.7+/-1.4 and -1.0+/-1.4 for 6-m PRO and 6-m CHO, respectively), femoral neck (0.9+/-2.2 vs -1.8+/-2.1 and -0.7+/-2.1) and intertrochanter (-0.7+/-1.8 vs -2.4+/-1.7 and -2.3+/-1.7). Greater weight loss was associated with more trabecular vBMD loss at the total hip (?=0.22, p=0.03) and intertrochanter (?=0.29, p<0.01). In low-functioning older adults with obesity in a weight loss trial, hip cortical vBMD increased (possibly due to more physical activity) and trabecular vBMD declined; trends suggest protein supplementation for 18 months better preserved trabecular bone compared to protein or carbohydrate supplementation for 6 months.

Exploring a Network of Pathways and Proteins: A Proteomic Analysis of ENPP1 Deficiency *Juancarlos Torres[1], Shira Ziegler[2], Carlos Ferreira[3]. [1]NHGRI, NIH, United States; [2]Johns Hopkins University School of Medicine, United States; [3]National Institutes of Health,

Ectonucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1) deficiency leads to a slew of symptoms, including arterial calcification, hypophosphatemic rickets, cervical vertebral fusions, retinal involvement and auditory impairment. The molecular mechanisms leading to these protean manifestations remain largely unknown. To try to better understand the pathogenesis of this rare disease, we performed proteomic analysis from patients' plasma and calvarial osteoblasts from mutant mice. Specifically, we compared protein levels from 18 ENPP1-deficient patients v. 22 controls, and cell lysates from calvarial osteoblasts obtained from 5 Enpp1asj/asj mice v. 5 littermate controls. Proteomic analysis was performed by the SomaScan® Assay, which uses Slow Off-Rate Modified Aptamers to quantify 7,322 different proteins. Proteomics data visualization and analysis were performed with ProViz, and the results filtered based on Fold Change and adjusted p-value. These results were uploaded to QIAGEN Ingenuity Pathway Analysis (IPA), which uses a built-in library to group the proteins into pathways to find overrepresentation of biological functions. The enriched pathways were sorted by adjusted p-value and Z-score into eight groups: Cardiac, FGF Signaling, Insulin, MAPK, mTOR/PTEN, Rho (including RHOGDI), G-proteins, P2Y Purinergic Receptor Signaling, and Miscellaneous Signaling Pathways. All pathways in these groups, except for RHOGDI and PTEN Signaling, were upregulated in patients and mutant mice. The proteins identified by ProViz were further analyzed, and four (SRC, SMAD5, PAK6, and RAC1) were selected based on their fold changes and p-values (PAK6 was prominent in plasma results, RAC1 was prominent in lysate results, while SRC and SMAD5 were prominent in both), for independent confirmation of results via ELISA assays, which are currently underway. Finally, upstream analysis performed through IPA predicted that the activation of regulators including TGFB1 and FGFR1 heavily influenced the change in expression of the target proteins. In summary, we performed proteomic analysis in patients' plasma and calvarial osteoblasts obtained from a mouse model of ENPP1 deficiency and found overrepresentation of several proteins and pathways that are shared between ENPP1-deficient patients and mutant mice. Our work increases understanding of the pathomechanisms of ENPP1 deficiency and opens new avenues for research into this rare disease.

Hip fractures are associated with significant disability and mortality. Early identification of patients at high risk of hip fracture is important to inform efficient intervention strategies. Published genetic risk scores (GRS) improve hip fracture prediction modestly. The present study aimed to develop and validate a protein-based risk score (PrRS) for hip fracture prediction.In the Cardiovascular Health Study (CHS) and the HUNT study, we performed a comprehensive circulating protein association study on incident hip fractures using the aptamer-based 5K SomaScan assay, including 4,979 aptamers. A PrRS was developed in CHS (3,171 subjects, mean 74.4 yrs, 39% men, 456 hip fractures) using two different strategies. In the first strategy, univariate associations between protein levels and hip fractures were calculated using age and sex-adjusted Cox regression models. A weighted PrRS (W-PrRS) was developed, including the 18 proteins passing the significance level after adjustment for multiple testing. In the second strategy, using machine learning (ML), LASSO with repeated splits of training (70%) and testing data sets (30%) was carried out to develop a PrRS including 6 proteins (ML-PrRS) with optimal improvement of c-index.The performances of the two PrRSs to predict incident hip fractures were determined in the independent HUNT validation cohort (3,259 subjects, mean 64.5 yrs, 61% men, 187 hip fractures). Age and sex-adjusted Cox regression models revealed that both the W-PrRS (Hazard ratio (HR) 1.51, 95% confidence interval 1.25-1.81 per standard deviation increase in risk score) and the ML-PrRS (HR 1.42, 1.19-1.69) improved fracture prediction more than GRSs previously developed using 47 genome-wide significant markers for femoral-neck BMD (FN-BMD-GRS; HR 1.14, 0.98-1.32) or using ML (21,716 genetic markers) of ultrasound-derived speed of sound in the heel (gSOS-GRS; HR 1.09, 0.94-1.26). Hip fracture prediction for the two PrRSs were only marginally attenuated after adjustment for clinical risk factor based FRAX score (W-PrRS, HR 1.45, 1.19-1.75; ML-PrRS, HR 1.37, 1.14-1.64). Discriminative analyses revealed that both the W-PrRS and the ML-PrRS ($p<0.05$), but not the FN-BMD-GRS or the gSOS-GRS, improved the c-index for hip fractures compared with an age and sex-adjusted base model.In conclusion, our developed PrRSs improve hip fracture prediction more than available GRS and may add clinically useful information for hip fracture prediction.

Rare Coding Variant in SERT is Associated with Improved Bone Mass in Mice and Humans *Emily Larson[1], Hillary Larson[1], Eric Orwoll[2], Robert Klein[1]. [1]Veterans Affairs Portland Health Care System, United States. [2]Oregon Health & Science University, United States

Common susceptibility loci thus far identified by genome-wide association studies (GWAS) account for a small proportion of the estimated genetic heritability of bone mineral density (BMD). One explanation for the missing heritability is the existence of less common variants with larger biological effects that are poorly detected by GWAS. We hypothesized that genes contributing to biological pathways that regulate BMD could be identified by studying subjects at the phenotypic extremes for BMD. Subjects from the Osteoporotic Fractures in Men Study (MrOS) with the lowest total hip BMD (N =?98) and highest BMD (N =?110) were selected for exome sequencing. We observed an amino-terminal-localized Gly56Ala substitution (rs6355) in the serotonin transporter (SERT or SLC6A4) with a minor allele frequency 4-fold higher in the high BMD pool (4.1%) compared to the low BMD pool (1%). In the entire MrOS European-American population (n=5,008) associations between rs6355 and total hip BMD (maf 1.8%; ? = 0.31; p = 5x10-5) and femoral neck BMD (maf 1.8%, ?= 0.29; p = 1x10-4) were again confirmed. Inspection of the GEFOS Femoral Neck BMD 2012 Data Release provided concordant support for this variant (maf 2.4%; ? = 0.06; p = 0.014). To further explore this novel association, we examined SERT Ala56 mouse knock-in mice (provided by R. Blakely, Florida Atlantic University). Compared to wild-type Gly56Gly littermates, male SERT Ala56Ala knock-in mice demonstrated increased whole body (3.3%; $p < 0.01$) and femoral (3.3%; $p < 0.01$) BMD and greater resistance to 3-point bending (12%; $p < 0.001$). In contrast, no genotype-dependent effect on any skeletal parameter was observed in female SERT Ala56Ala knock-in mice. The rs6355 variant has been demonstrated to exhibit tonic elevation of serotonin (5-HT) transport activity in transfected cells and human lymphoblasts in vitro and when examined in a SERT Ala56 knock-in mouse model leads to an increased 5-HT clearance rate in vivo, along with altered sensitivity to SERT regulatory signaling pathways. The mechanisms whereby this variant results in the acquisition and/or maintenance of increased bone mass are unclear, but our results in both mice and humans suggest that serotonin signaling is involved in skeletal physiology and manipulating this pathway is a potential target for the treatment of osteoporosis.

A comprehensive single cell transcriptomic atlas of adult human bone marrow *Michael Duffy[3], Shovik Bandyopadhyay[2], Kyung Jin Ahn[2], Kai Tan[2], Ling Qin[3]. [3]University of Pennsylvania, . [2]Children's Hospital of Philadelphia, United States. [3]University of Pennsylvania, United States

Bone marrow (BM) is primarily made of mesenchymal and hematopoietic lineage cells to provide mechanical support and produce blood. While mouse BM has been characterized at the single cell level, the rareness of mesenchymal cells in human BM aspirate has led to a lack of heterogeneity in scRNA-seq datasets and hindered human studies. Here, we developed a robust protocol to enzymatically isolate cells from fresh femoral head BM acquired after total hip arthroplasty. We separately enriched non-hematopoietic (CD45 depletion) and hematopoietic progenitor (CD34 selection) cells and then mixed them with RBC-depleted BM cells at 10:3:3 ratio for scRNA-seq using 10x genomics. From 12 samples (age 52-74, median 65+/-8), we profiled 53,417 hematopoietic and 29,325 non-hematopoietic cells at 3117 genes/cell and identified 35 cell clusters (Fig 1) of hematopoietic (25), mesenchymal (7), endothelial (2), and smooth muscle cells (1). Further analyzing 6 groups of mesenchymal cells, Fibro-mesenchymal stromal cells (MSCs), Osteofibro-MSCs, Osteo-MSCs, Osteoblasts, Adipo-MSCs, and THY1+ MSCs, with distinct markers, only Fibro-MSCs, marked by HAS1, DPT, and PDPN, expressed canonical mesenchymal stem markers and were identified as the most primitive population by CytoTRACE. Contributing a variable proportion of mesenchymal cells (52% +/- 31%, mean +/- SD), THY1+ and Adipo-MSCs highly expressed adipogenic markers. However, THY1+ MSCs had a unique expression profile including THY1 and LBP, and a high CytoTRACE score. We designed a flow panel to sort Fibro-, Thy1+-, Osteo-, and Adipo-MSCs. Fibro-MSCs showed the highest CFU-F forming ability and maintained the highest proliferative status over the long term culture, followed by THY1-MSCs, while Osteo- and Adipo-MSCs grew poorly. Fibro-MSCs also differentiated into osteogenic and adiopogenic cells efficiently in culture, confirming their stem and progenitor properties. CellChat analysis revealed that Adipo- and Thy1+-MSCs produce the highest amount of CXCL12 and KITL to regulate HSPCs and specifically express IL7 to regluate lymphopoiesis. Csf1, a major melopoiesis cytokine, was expressed in Adipo-MSCs, and Notch ligands, which are also important for lymphopoiesis, were mainly produced by arteriol endothelial cells. Together, our work presents a first comphrehensive cellular atlas of adult human bone marrow, identifies a new primitive MSC population, and reveals the importance of adipoprecursors in supporting hematopoeitic function.

Spatial Proteomics via Mass Spectrometry Imaging of Human Tibial Plateaus Reveals Alterations to Subchondral Bone Precede Cartilage Loss in Medial Osteoarthritis *Charles Schurman[6], Jonathan Woo[2], Nannan Tao[3], Tamara Alliston[4], Peggi Angel[5], Birgit Schilling[6]. [6]Buck Institute for Research on Aging, , [2]University of California - San Francisco, United States, [3]Bruker Scientific, United States, [4]University of California, San Francisco, United States, [5]Medical University of South Carolina, United States, [6]Buck Institute for Research on Aging, United States

Osteoarthritis (OA) of the knee is a degenerative condition of the skeletal extracellular matrix (ECM) marked by the loss of articular cartilage and changes in the underlying bone. OA commonly displays spatial discrimination preferring either the lateral or medial joint, while evidence of early degenerative changes may be found across the entire joint and even in 'healthy' joints of aged individuals. Matrix-assisted laser desorption/ionization (MALDI) mass spectrometry imaging (MSI) offers the ability to spatially investigate the proteomic landscape of OA progression in bone and cartilage to elucidate mechanisms of joint degeneration.Human tibial plateaus from BMI matched male donors aged 60-75 with and without diagnosed medial OA (N=5 patients each) were formalin fixed and decalcified to prepare for paraffin embedding and sectioning. Mounted tissue sections were prepared for MSI with a collagenase treatment to target ECM components and imaged utilizing the Bruker timsTOF fleX mass spectrometer. Untargeted and guided statistical comparisons of collected MS1 mass spectra were processed using the Bruker SCiLS Lab software package.We demonstrate the first simultaneous collection of spatial ECM proteomic spectra from human bone and cartilage from tibial plateaus of healthy and OA patients. Visualization of detected ions revealed striking separation in the abundance of features assignable to human cartilage and bone via principal component analysis (PCA). Unsupervised spatial clustering of the top 500 MS1 precursor ions from diseased joint tissue revealed progressive subchondral bone sclerosis from the medial joint where cartilage loss was the greatest into the lateral joint despite a thick identifiable cartilage layer. Statistical comparison via SCiLS found 35 ions specific to the most severe OA regions that were confirmed as derived from bone and cartilage collagen chains ?-1(I) and ?-1(II) while new unannotated peptides were identified by MS/MS as belonging to other 10 other collagen sub-types and 37 additional ECM proteins including aggrecan, biglycan, and others. Some of these signature markers were identified at lower abundance in the transitional region between cartilage and bone in aged-control joint samples, offering possible novel markers of early OA with age. The spatial up-regulation of certain collagens and ECM-derived peptides in OA and their unexpected appearance in aged-healthy joints reveal new molecular details about the development of OA.

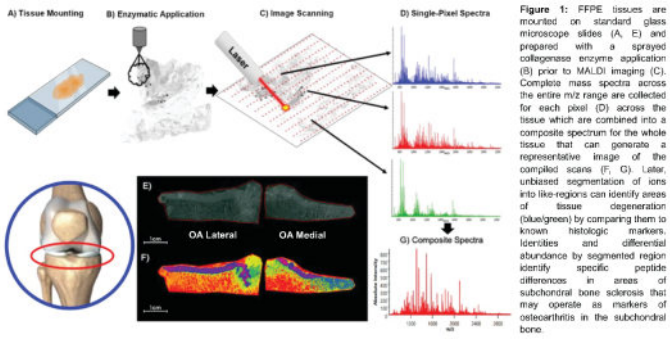

Figure 1: FFPE tissues are mounted on standard glass microscope slides (A, E) and prepared with a sprayed collagenase enzyme application (B) prior to MALDI imaging (C). Complete mass spectra across the entire m/z range are collected for each pixel (D) across the tissue which are combined into a composite spectrum for the whole tissue that can generate a representative image of the compiled scans (F, G). Later, unbiased segmentation of ions into like-regions can identify areas of tissue degeneration (blue/green) by comparing them to known histologic markers. Identities and differential abundance by segmented region identify specific peptide differences in areas of subchondral bone sclerosis that may operate as markers of osteoarthritis in the subchondral bone.

Large-Scale Integration of Human Bone Proteomics, Circulating Proteomics and Genetics to Discover Molecular Pathways and Risk Factors of Osteoporotic Fractures *Yi-Hsiang Hsu[1], Sjur Reppe[2], Fangtang Yu[3], Xue Zeng[4], Ming-Ju Tsai[3], Ronald Kwon[5], Kaare Gautvik[2]. [1]HSL Institute for Aging Research, Harvard Medical School, United States, [2]Oslo Univ. Hosp., Oslo, Norway, Norway, [3]HSL Marcus Institute for Aging Research , United States, [4]Amgen, United States, [5]University of Washington, United States

Despite significant progress being made in mapping the basic blueprints (DNA variants) of human diseases, we have yet to comprehensively decipher the myriad end products (proteins) contributing towards these diseases. Thus, proteomics is an emerging tool and a deeper view of proteome alterations in bone tissues from fractures will advance our understanding of molecular pathways and enhance new drug target discovery. In addition, identifying circulating protein biomarkers allows us to identify high risk subjects of fractures. Two proteomics studies were conducted. (1) Bone proteomics was measured by mass spectrometry on human hip bone biopsies from 180 hospitalized adults due to hip replacement surgeries. The whole genome seq was done and DXA FNBMD was measured at non-fracture hip. (2) Serum (circulating) proteomics was measured by OLINK immunoassays in 48,000 UK Biobank subjects. Incident osteoporotic fractures were assessed via eHR. Among them, 237 had osteoporotic fractures and 5,217 had DXA BMD. In both studies, differential protein expression analyses were performed w/wo adjusting for BMD to identify proteins contributing to fractures independently from BMD. Mendelian randomization (MR) analyses were performed to inference causally relations. We observed 6,154 proteins from hip bone biopsies. 198 (88 higher and 110 lower expressed) proteins significantly differentially expressed ($p < 1.7x10-5$) in fracture subjects comparing to controls. These proteins are enriched in terpenoids biosynthesis, ECM-receptors, cytokine-ligand-receptor interactions and TGF-beta, NFKB, PPAR signaling pathways. For example, SOST, VKDPs and EFEMP1 are associated with increased fracture risks. COL6A1, osteoadherin and osteopontin are associated with decreased risks. MR analyses adjusted for BMD identified proteins (e.g. CA2, EIF3I, EFEMP1) associated with fractures independently from BMD. For circulating proteomics, 2,941 proteins were measured. 81 (69 higher and 12 lower expressed) proteins significantly associated with incident osteoporotic fracture (e.g. SOST, GDF15, IL6). In conclusion, we identified novel proteins causally associated with osteoporotic fracture from hip bone biopsies. Not all the fracture-associated proteins observed in bone biopsies could be observed in circulating (plasma); thus, our finding provided tissue-specific molecular insights underlying osteoporotic fractures. We also identified novel circulating proteins predicating risks of incident fractures.

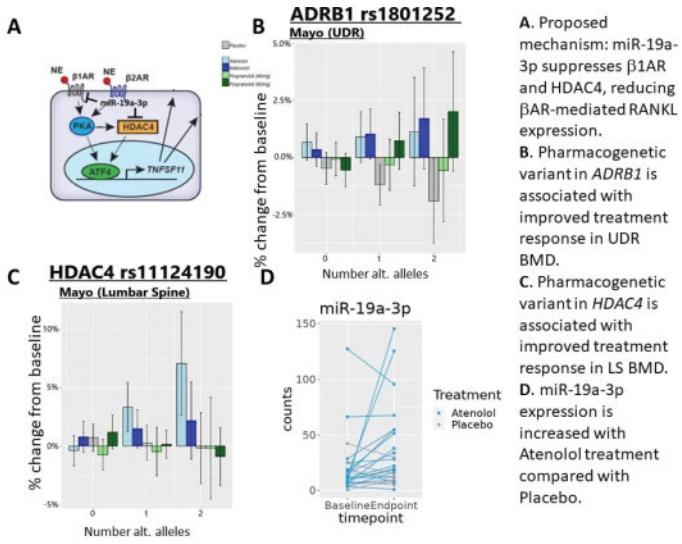
Pharmacogenetic and microRNA mechanisms of beta blocker treatment response in bone *Christine Lary[2], Griffin Scott[2], Hongyu Chen[2], Archana Nagarajan[3], Elizabeth Atkinson[4], David Monroe[5], Aaron Brown[6], Katherine Motyl[7], Sundeep Khosla[8]. [2]Northeastern University, , [2]Northeastern University, United States, [3]Tufts University School of Biomedical Sciences, , [4]Mayo Clinic, United States, [5]Mayo Foundation, United States, [6]MaineHealth Institute for Research, United States, [7]MaineHealth, United States, [8]Mayo Clinic College of Medicine, United States

Atenolol, a beta-1 selective beta blocker (BB), is being evaluated to prevent postmenopausal bone loss in the randomized clinical trial, "Atenolol for the Prevention of Osteoporosis". Atenolol inhibits norepinephrine binding of the beta-1 and beta-2 adrenergic receptors (b1-AR and b2-AR) on osteoblasts and osteoclasts (Figure A). Previous pharmacogenetic effects have been found in b1-AR (ADRB1) and in HDAC4, a histone deacetylase that stabilizes ATF4-mediated upregulation of TNFSF11 (RANK Ligand) in osteoblasts. We have also shown that miR-19a-3p, which is associated with BB treatment response for hypertension, and which targets both b1-AR and HDAC4, is positively associated with BB use, bone mineral density (BMD), and reduced fracture risk. However, these associations have not been studied longitudinally with BB treatment. We analyzed pharmacogenetic data using variants from ADRB1, ADRB2, and HDAC4 in a pilot clinical trial performed at the Mayo Clinic in 155 postmenopausal women randomized to placebo, propranolol (40 mg or 80 mg), atenolol (50 mg), or nebivolol (5 mg) daily for 20 weeks. We also collected miRNA-seq data at baseline and endpoint from 24 participants, 9 each from the atenolol group with high response (HR) or low response (LR) based on changes in C-terminal telopeptide (CTX), and 6 from the placebo group. We modeled the change in BMD at the femoral neck (FN), lumbar spine (LS), or ultradistal radius (UDR) or in serum CTX as a function of baseline values, SNP dosage, treatment group, and their interaction. Longitudinal miRNA-seq data was analyzed using negative binomial regression with generalized linear mixed models. An increase in UDR BMD for the propranolol 80 mg group was found compared to placebo for each additional copy of the ADRB1 rs1801252 G allele (Figure B), and an increase in LS BMD and decrease in CTX was found for the atenolol group for each additional copy of the HDAC4 rs11124190 G allele (LS BMD in Figure C). miR-19a-3p was associated with a significant increase in the low responder group over time compared with placebo (OR = 2.8, p= 0.028) and with a trend towards significance in the combined atenolol groups (OR = 2.2, p=0.06, Figure D). Taken together these results are consistent with a mechanism in which genetic variation or miR-19a-3p-induced suppression of b1-AR and HDAC4 is associated

with improved treatment response. These results will be validated in an ongoing ancillary study for the APO clinical trial.



A. Proposed mechanism: miR-19a-3p suppresses β1AR and HDAC4, reducing βAR-mediated RANKL expression.
B. Pharmacogenetic variant in *ADRB1* is associated with improved treatment response in UDR BMD.
C. Pharmacogenetic variant in *HDAC4* is associated with improved treatment response in LS BMD.
D. miR-19a-3p expression is increased with Atenolol treatment compared with Placebo.

Augmentation of BMP signaling leads to ectopic cartilages through changes in chromatin structures *YUJI MISHINA[1,] Hiroki Ueharu[1.] [1]University of Michigan,

Dysregulation of proliferation, migration, and differentiation of cranial neural crest cells (NCCs) develop craniofacial anomalies. We have reported that enhanced BMP signaling in NCCs (caAcvr1; P0-Cre mice, mutant mice hereafter) developed ectopic cartilages in the midfacial region at embryonic day 14.5 (E14.5). Pharmacologic rescue experiments using an inhibitor for BMP signaling revealed that a time window for suppression of ectopic cartilage formation is at E11.5, which is a stage before the initiation of the ectopic cartilage formation. We hypothesize that augmentation of BMP signaling directs the multipotency of cranial NCCs towards chondrogenesis. This study aims to reveal the mechanism for cell fate specification of cranial NCCs by BMP signaling. We compared gene expression profiles in cranial NCCs between control and mutant mice at E10.5 by single cell RNA sequence. In the mutant embryos, cranial NCCs formed the ectopic cartilages, but trunk NCCs did not, thus we speculated that genes changed only in cranial NCCs of mutant mice but not in trunk NCCs involve in the formation of ectopic cartilage. Through these 2 way comparisons, we identified 11 genes of which expressions are specifically changed in mutant cranial NCCs. Among these genes, we found that Xist, a main player for X chromosome inactivation, is significantly increased in cranial NCCs of mutant mice. We further observed that cranial NCCs in mutant female embryos have ectopic X chromosome inactivation: one cell has two inactive X chromosomes that are entirely coated with Xist RNA. Surprisingly, ectopic X chromosome inactivation was also found in cranial NCCs of mutant male mice, which should not have X chromosome inactivation. This finding may explain the fact that both male and female mutant mice develop ectopic cartilage in a comparable manner. We demonstrated that silencing of Xist in cranial NCCs decreases chondrogenic differentiation capacity in vitro, and genetic reduction of Xist in mutant mice by deletion of Kdm5C, a known factor positively regulates Xist expression, significantly reduced formation of ectopic cartilages. These results suggested that enhanced BMP signaling develops the ectopic cartilages through induction of ectopic X chromosome inactivation. This is for the first time to demonstrate BMP-Xist axis contributes cell fate specification of cranial NCCs in both sexes.

Differential transcriptional responses to intracellular infection by S. aureus in osteoclasts and their precursors. *Luke O'Connor[1,] Deborah Veis[2.] [1], [2]Washington University in St. Louis School of Medicine, United States

S. aureus is an opportunistic pathogen that causes 30-50% of all osteomyelitis (OM) cases. During OM, S. aureus survive in colonies, as well as within osteocytes, osteoblasts, and osteoclasts (OCs). We have recently shown that OCs, unlike their bone marrow macrophage (BMM) precursors, allow bacteria to replicate intracellularly and the magnitude of growth increases with OC differentiation . We hypothesized that OC differentiation alters host-pathogen interactions by changing nutrient availability and host defense pathways to favor intracellular S. aureus growth. To test this, we conducted dual RNA-seq to analyze host and S. aureus gene expression at 4 critical infection timepoints: prior to infection, after bacterial internalization (2h), during bacterial metabolic transition (6h), and after bacterial expansion in OCs or killing in BMMs (21h). Bone marrow was cultured from 6-7 week-old male B6/alb mice, and BMMs (MCSF only) or OCs (3 days RANKL) generated prior to infection with USA300 MRSA strain TI3. To ensure data robustness we sequenced 3 batches of pooled samples per cell type, with each pool representing 3 mice and 3 separate infections (total: 18 mice, 10 infections). S. aureus transcripts were aligned to S. aureus USA300_FPR3757 and DESeq2 used to analyze genes differentially expressed by cell type (BMM vs OC) over the time course. In parallel, we used PyModulon to analyze modules of co-regulated genes in bacteria. These analyses show that bacteria in OCs have lower expression of Fur regulated iron scavenging genes as well as genes related to CodY, PerR, PurR, and CymR, which regulate amino acid metabolism. Thus, S. aureus in OCs may be less stressed for iron and amino acids than bacteria in BMMs. Murine host transcripts were aligned to Mm39 and analyzed in DESeq2, followed by supplemental analysis with Gene Ontology (GO) enrichment and using weighted coregulated gene network analysis (WGCNA). GO analysis highlights that OC and BMM responses largely differ in host defense and bacterial response pathways. WGCA of all differentially expressed genes and a subset of genes from the top 10 GO identify Pi3kr1, Id2, and ZO-2 as genes highly interconnected with differential host response and indicate a potential roles for PI3K, TGF-?, and Hippo signaling pathways. Collectively these results suggest OCs have an altered response to infection and provide greater access to nutrients than their BMM precursors, allowing S. aureus expansion in OCs but not BMMs.

In vivo stimulation of Tfeb, a master regulator of autophagy and lysosomal biogenesis, via in vivo CRISPR activation increases bone mass and strength *Alicen James[2,] James Hendrixson[2.] Ilham Kadhim[2.] Jacob Laster[2.] AMY SATO[3,] Stuart Berryhill[2.] Julie Crawford[2.] Melda Onal[2.] [2]University of Arkansas for Medical Sciences, [2]University of Arkansas for Medical Sciences, United States, [3]UAMS, United States

Autophagy is a recycling pathway in which cellular components, including damaged or dysfunctional proteins, protein aggregates, and organelles are delivered to lysosomes for degradation. Reduction or insufficiency of autophagy is thought to contribute to a number of skeletal diseases such as skeletal aging. Accordingly, elimination of autophagy from the entire osteoblast lineage or only from osteocytes reduces osteoblast number, decreases bone formation, and causes low bone mass. However, whether increasing autophagy in osteoblast lineage cells is beneficial for bone health under physiological or pathological conditions is unknown. To address this, we generated a novel model to increase endogenous Tfeb expression in the osteoblast lineage. Transcription factor EB (Tfeb) is a master transcriptional regulator of autophagy and lysosomal biogenesis. Consistent with this, Tfeb overexpression (OE) induces autophagy in cultured osteoblasts. We stimulated expression of the endogenous Tfeb gene in osteoblast lineage cells of mice via in vivo CRISPR activation. Specifically, we expressed a sgRNA targeting the Tfeb transcription start site from the Rosa26 locus and activated a dCas9::SPH transgene using the Osx1-Cre transgene. This maneuver increased Tfeb expression 2.5-fold in RNA isolated from whole bones. At 8 weeks of age, the skeletal phenotype of mice overexpressing Tfeb was similar to littermate controls. However, at 4 months of age, Tfeb overexpressing male mice displayed increased femoral and vertebral cortical thickness. Histological analysis revealed that the increase in femoral cortical thickness was due to increased bone formation. Tfeb OE was also anabolic for femoral and vertebral cancellous bone. Analysis of osteoblast and osteoclast marker gene expression in lumbar vertebrae revealed that the anabolic impact of Tfeb OE was associated with high bone turnover. Moreover, the anabolic actions of Tfeb OE were sufficient to elevate bone strength as determined by femoral three-point bending analysis. Similar to males, serial BMD measurements of female mice showed that Tfeb OE in the osteoblast lineage also increases bone mass of female mice. Moreover, the high bone mass of female mice became more pronounced between 3 to 8 months of age. In conclusion, Tfeb overexpression in osteoblast lineage cells is anabolic and results in mechanically stronger bones and may represent an effective approach to combat age-associated bone loss.

Wnt10b is required for the bone anabolic effect of a natural antibody that blocks oxidized phospholipids. *Michela Palmieri[1,] Intawat Nookaev[2,] Maria Jose Almeida[3,] Ha-Neui Kim[4,] Teenamol E Joseph[1,] Stavros Manolagas[3,] Charles O'Brien[5,] Elena Ambrogini[3.] [1]Division of Endocrinology and Metabolism, Center for Musculoskeletal Disease Research, University of Arkansas for Medical Sciences and the Central Arkansas Veterans Healthcare System, United States, [2]2Department of Biomedical Informatics, University of Arkansas for Medical Sciences, United States, [3]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, United States, [4]Univ. Arkansas for Medical Sciences, Central Arkansas VA Healthcare System, United States, [5]Univ of Arkansas for Medical Sciences, United States

Oxidized phospholipids containing phosphatidylcholine (PC-OxPLs), present on oxidized low-density lipoproteins (OxLDL) and apoptotic cells, are pathogenic in many dis-

eases, including osteoporosis, atherosclerosis, and non-alcoholic steatohepatitis. OxPLs decrease Wnt and BMP2 signaling, induce ferroptosis and stimulate pro-inflammatory cytokine production. The natural antibody IgM E06 binds PC-OxPLs and blocks their deleterious effects. Transgenic expression of the antigen-binding domain of E06 (E06-scFv) increases bone mass in 6-month-old mice and attenuates high fat diet- and age-induced bone loss by increasing osteoblast number and function. It was shown earlier that E06-scFv upregulates the expression of Wnt10b and Wnt signaling in vivo, but not other Wnt ligands. We investigated the mechanism(s) mediating the anabolic effect of E06-scFv. Single cell RNA-sequencing (scRNA-seq) of mesenchymal cells, isolated from long bones of 7-month-old female mice, revealed a 3-fold increase in Wnt10b expression (adj-P=3.04E-11) in pre-osteoblasts and osteoblasts obtained from E06-scFv transgenic mice compared to cells from WT mice. Wnt target genes were also upregulated. An integrated analysis of 9 published scRNA-seq datasets from bone resident mesenchymal and hematopoietic cell types revealed that the bulk of Wnt10b in the bone microenvironment originates from cells of the osteoblast lineage. Consistent with this evidence, OxLDL decreased Wnt10b and Wnt target genes in calvaria- and bone marrow-derived osteoblastic cell cultures but had no impact on ferroptosis of osteoblastic cells. Moreover, gene expression markers of ferroptosis, as well as BMP2 signaling pathways, were similar in the mesenchymal cells from E06-scFv and WT mice as determined by scRNA-seq. Expression of inflammatory cytokine genes was also similar in vertebral bone by bulk-RNA-seq, and in myeloid cells by scRNA-seq, of WT and E06-scFv mice. To examine the requirement of Wnt10b in the anabolic activity of E06-scFv, we next determined the effect of Wnt10b deletion on the bone phenotype in WT vs E06-scFv transgenic male mice at 6 months of age. We found that both the increase in BMD by DXA and BV/TV of vertebral and femoral cancellous bone by micro-CT were prevented in E06-scFv transgenic mice lacking Wnt10b. Collectively, these findings indicate that the bone anabolic effect of E06-scFv is due to increased Wnt10b expression that results from removal of the suppressive effects of PC-OxPL.

Inactivation of the Polycomb Repressive Complex 2 in Osteoblasts Increases Trabecular Bone Mass and Results in Mechanically Stronger Bones *Amel Dudakovic[1,] Sofia Jerez[1,] Christopher Paradise[1,] M. Lizeth Galvan[1,] Oksana Pichurin[1,] Padmini Deosthale[2,] Roman Thaler[1,] Lilian Plotkin[2,] Andre van Wijnen[3,] [1]Mayo Clinic, United States, [2]Indiana University School of Medicine, United States, [3]University of Vermont, United States

Epigenetics, including post-translational modifications of histones, control osteoblast activity and bone formation. The Polycomb Repressive Complex 2 (PRC2) methylates H3 at lysine 27 (H3K27me3), a heterochromatin mark that suppresses gene expression. PRC2 is made of two main structural proteins, Eed and Suz12, and one of two methyltransferases, Ezh1 or Ezh2. We and others showed that Ezh2 inhibition stimulates osteoblast differentiation in vitro and bone formation in vivo. However, Ezh2 loss in osteoblasts (Osx-Cre) is not bone stimulatory in vivo. Thus, the mechanistic understanding of the divergency between Ezh2 inhibition and Ezh2 loss on bone formation remains elusive. These studies build on our findings that Ezh2 is expressed in progenitors while Ezh1 is expressed in committed osteoblasts. We reasoned that loss of the entire PRC2 function will stimulate bone formation. We generated mice in which Ezh1 is depleted globally and Ezh2 is lost in osteoblasts (control = Osx-Cre; Ezh1 KO = Ezh1-/-: Osx-Cre; Ezh2 cKO = Ezh2f/f: Osx-Cre; dKO = Ezh1-/-: Ezh2f/f: Osx-Cre). Ezh1 and Ezh2 dKOs male and female mice exhibited significantly increased trabecular bone (μCT) and bone strength (3-point bending) when compared to controls, Ezh1 KOs, and Ezh2 cKOs (8 weeks). While doxycycline (Cre suppression) prevented this phenotype in dKOs (8 weeks), its removal (8 weeks) to inactivate Ezh2 in osteoblasts (on a Ezh1 null background) lead to a significantly higher trabecular bone mass (14 weeks). We next assessed the effects of targeting PRC2 scaffolding proteins. Eed inhibitors A395 and EED226 enhanced osteogenic differentiation of MC3T3 pre-osteoblasts as assessed by RNA expression (e.g., Bglap and Ibsp) and alizarin red staining (mineral deposition). Similarly, siRNA mediated Eed or Suz12 loss stimulated MC3T3 differentiation. Because Eed can be targeted by small molecules, our initial in vivo studies focused on Eed over Suz12. μCT analysis revealed a significant enhancement of trabecular bone and bio-mechanical bone properties in male and female Eed cKOs (8 weeks). Together, these studies reveal that loss of PRC2 functionality in osteoblasts, through dual Ezh1 and Ezh2 or Eed inactivation, results in high bone mass and mechanically stronger bones. Our findings may enhance the development of novel therapeutic strategies focused on the inactivation of PRC2 to stimulate short-term or sustained bone formation.

WNT16 Regulates Mitochondrial Function and Smooth Muscle Cell Phenotype Via Yap /Taz Signals To Restrain Vascular Remodeling and Mitigate Cardiovascular Risk *Abraham Behrmann[1,] Dalian Zhong[1,] Li Li[1,] Shangkui Xie[1,] Megan Mead[1,] Parastoo Sabaeifard[1,] Mohammad Goodarzi[1,] Andrew Lemoff[1,] Julia Kozlitina[1,] Dwight Towler[1,] [1]UT Southwestern Medical Center, United States

Deterioration in bone and vascular health are frequent concomitants with aging, highlighted by the surgeon-pathologist Jean Lobstein who first coined the terms “osteoporosis” and “arteriosclerosis” as he described this relationship. Wnt16 is selectively expressed in bone and arterial vascular smooth muscle (VSM), and hypomorphic WNT16 alleles convey fracture risk. We show that these same WNT16 cSNPs also convey risk for composite cardiovascular (CV) events in the Dallas Heart Study (OR = 1.25, p = 0.02; adjusted for age, systolic blood pressure / SBP, body mass index, sex & ancestry)/ To better understand Wnt16’s role in vascular medicine, we generated Wnt16-deficency in LDLR-/- mice, a validated background for studying CV disease. SBP & vessel stiffness were reduced in Wnt16-/-;LDLR-/- mice vs. LDLR-/- controls. Ascending aorta (AscAo) aneurysm following angiotensin-II (AngII) infusion was worsened with Wnt16 deficiency. VSM contractile markers such as Acta2 - known to convey AscAo aneurysm risk & reduce SBP with genetic deficiency - were down-regulated in Wnt16-/- VSM, with reduction in TGFbeta-induced contraction. Mitochondrial spare respiratory capacity was significantly impaired with Wnt16 deficiency and restored by exogenous Wnt16 treatment. LC-MS/MS revealed Acta2 protein was reduced in Wnt16-/-;LDLR-/- VSM as was aortic Ankrd1- a target of Yap and Taz(Wwtr1) activation via nuclear TEAD-directed transcription. Wnt16-/- VSM exhibited reduced nuclear Yap+Taz protein. RNAi targeting either Wnt16 or Taz phenocopied Wnt16 deficiency, inhibited Wnt16 up-regulation of the mature contractile VSM phenotype & reversed C3 (dedifferentiation biomarker) suppression. By contrast,Yap1 mediated cytokine suppression. RNAi targeting Yap/Taz inhibitory kinases Lats1/2 or Ccm2 -- but not Ccm3 or Stk3/Stk4 -- elicited responses reciprocal to Wnt16 deficiency. Biotin proximity labeling following Taz-BioID2 expression identified TEAD1, IQGAP3, & GPR180 as functionally important Wnt16 signaling mediators. TEAD cognates in the Acta2 promoter conveyed transcriptional responses to Wnt16 and Taz+Tead1, and Wnt16 treatment increased Taz association with the Acta2 promoter in aortic VSM. Thus, in addition to known roles in bone, Wnt16 also promotes the VSM contractile phenotype and mitochondrial function in the vasculature ro regulate arterial remodeling. Strategies that augment Wnt16 signaling relays may help preserve both cardiovascular and skeletal health with aging.

C-Jun N-terminal Kinase (JNK) Isoform 2 Augments Human Osteoblast Differentiation by Integrating Bone Morphogenetic Protein Signaling and Canonical Notch Signaling *Yadav Wagley[1,] Benjamin Graham[2,] Kurt Hankenson[2,1], [2]University of Michigan, United States

The c-Jun N-terminal kinases (JNK) are evolutionary conserved regulators of proliferation, differentiation, and cell death responses. In vivo studies have shown that Jnk1-/- and Jnk2-/- mice display varying degrees of osteopenia due to impaired bone formation. However, JNK1 and JNK2 isoform specific contribution to human osteoblast differentiation is lesser known. Here, we used small interfering RNA-mediated knockdown of JNK1 and JNK2 in bone-marrow derived human mesenchymal stem cells (hMSC) to evaluate their role in BMP-mediated osteoblast differentiation. Histochemical staining for alkaline phosphatase (ALP) expression and extracellular matrix mineralization using Alizarin red S showed that JNK2 activity is essential for hMSC osteoblastic differentiation, whereas JNK1 activity was dispensable. Gene expression analysis revealed a minimal effect on BMP-dependent RUNX2 and SP7 expression after JNK2 knock-down, but their levels were enhanced in JNK1 silenced cells. Since, BMP signaling requires canonical Notch signaling to promote human osteoblastogenesis, we evaluated JNK-isoform specific effects on Notch signaling components. The expression of Notch ligand JAG1 and downstream Notch target genes HES1 and NOTCH3 was reduced in response to BMP stimulation of JNK2 silenced cells, while the effects were modest after JNK1 knock-down. Consequently, the absolute requirement of JAG1 for BMP-mediated hMSC osteoblastogenesis was established as JAG1 silenced hMSC failed to enhance ALP expression and extracellular matrix mineralization. Finally, we generated JNK2-deficient immortalized hMSC using CRISPR-Cas9 genome editing and subjected these cells to BMP2 stimulation. Corresponding to the results with siRNA, JNK2 knock-out cells failed to produce extracellular matrix mineralization in response to BMP2. Collectively, these results establish a regulatory role of JNK2 in human osteoblast differentiation and suggest that it functions by integrating canonical BMP/SMAD signaling and Notch signaling in human cells.

ClC-3 and ClC-5 are essential to drive normal bone mineralization. *Quitterie Larrouture[2], Irina Tourkova[2], Deborah Nelson[3], Paul Schlesinger[4], Harry Blair[2]. [2]University of Pittsburgh, , [2]University of Pittsburgh, United States, [3]University of Chicago, United States, [4]Washington University , United States

Osteoblasts form an epithelial-like layer that separates the extracellular fluid (ECF) that contains the essential components to bone formation from the bone matrix. The production of hydroxyapatite in bone matrix produces a massive number of protons and their removal is essential to avoid stopping the mineralization process. Previously we established that Na/H exchangers 1 and 6 are highly expressed at secretory osteoblast basolateral surfaces and neutralize massive acid loads. We hypothesized that high-capacity proton transport from matrix into osteoblast cytosol must exist to support acid transcytosis for mineral deposition. Gene screening of cultured mineralizing osteoblasts showed dramatic expression of chloride-proton antiporters ClC3 and ClC5. Localization of ClC3 and ClC5 proteins at the apical secretory surface facing the bone matrix was confirmed by antibody labeling, at the EM level, of plasma membrane ClC3, and ClC5, in ClC3 knockout mice (Figure). To study the importance of ClC3 and ClC5 in bone mineralization in vivo and in vitro we used ClC-5 KO mice as well as ClC-3 KO mice. The whole exome sequencing confirmed the deletion of the whole exon 7 in ClC-3 KO mice and the deletion of part of the exon 6 in ClC-5 KO mice. No additional deletions were detected. The ClC-3 KO mice sowed a mildly disordered mineralization (microCT) and serum level of ALP and TRAP compared to WT. Surprisingly, at 3-5 months, body weights of ClC-5 KO females were significantly higher than control mice and 3D morphometry of the lumbar vertebrae showed a significant increase in bone surface/volume ratio in CLC-5 KO mice compared to control. Mass spectrometry-based proteomics confirmed that both KO mice have the presence of modified dysfunctional protein not seen in WT mice). In CLC-3 KO mice the normal CLC-5 protein was increased confirming what we showed previously that cultured ClC-3 KO osteoblasts have an increase in ClC-5 protein expression. After isolation from the bone marrow, CLC-3 KO and CLC-5 KO stromal stem cells were differentiated on PET membrane showing a lower alkaline phosphatase activity, a weak staining with Von Kossa as well as a decrease in collagen production, suggesting a decreased bone turnover. We conclude that regulated acid export, mediated by chloride-proton exchange, is essential to drive normal bone mineralization, and that CLC transporters also regulate fine patterning of bone.Figure: Transmission electron microscopy of mouse vertebrae showing the presence of CLC-5 (immunogold labeling, 12nm) at the apical secretory surface (red arrows) of an osteoblast facing the bone matrix (blue stars).

Nuclear factor I A (NFIA) regulates osteoblast differentiation of skeletal progenitor cells in bone growth and fracture healing in mice *Hiroaki Manabe[1], Noriaki Ono[2]. [1]The University of Texas Health Science Center at Houston, United States, [2]University of Texas Health Science Center at Houston School of Dentistry, United States

NFIA is a transcription factor belonging to the nuclear factor I family and has key roles in the development of multiple organs. NFIA is known to interact with other transcription factors such as SOX9 during glial cell differentiation; however, the function of NFIA in skeletal development remains unknown. We evaluated the skeletal phenotype of mice in which NFIA was conditionally deleted in a cell type-specific manner. For this purpose, Nfia-floxed mice were crossed with Col2a1-cre (chondrocytes), Osx-creER (osteoblasts, pulsed at postnatal day (P) 3) or Prrx1-cre (skeletal progenitor cells) drivers. Deletion of NFIA in chondrocytes or osteoblasts did not cause any apparent bone phenotype. In contrast, NFIA deletion in skeletal progenitor cells using Prrx1-cre (Prrx1-NFIA cKO) resulted in a significant decrease in trabecular bone mass at P21 and 8 weeks of age (W), associated with an increased cortical thickness at 8W. Bone histomorphometry revealed a reduction in osteoblast numbers and an unchanged osteoclast number per bone perimeter in Prrx1-NFIA cKO mice, associated with decreased trabecular but increased cortical bone formation rates as determined by calcein double labeling, accompanied by the significant reduction of the serum bone formation marker PINP level. In contrast, the growth plate of Prrx1-NFIA cKO mice showed only modest structural changes, associated with no overt change in the expression level of chondrocyte marker genes as determined by qPCR. In addition, upon the complete fracture of the mid-shaft, Prrx1-NFIA cKO femurs showed normal callus formation but delayed calcification of the healing site. In primary cell culture, bone marrow stromal cells (BMSCs) isolated from Prrx1-NFIA cKO mice showed reduced alkaline phosphatase and alizarin red staining, indicating impaired osteogenic potential of skeletal progenitor cells. Bulk RNA-seq analyses of NFIA-deficient BMSCs identified 53 differentially expressed genes including downregulation of Ibsp (encoding bone sialoprotein, BSP), Igfbp2, and Camk4, which are known to play important roles in osteoblast differentiation. Interestingly, inspection of the genome-wide association study (GWAS) catalog database revealed 6 SNPs statistically significantly associated with heel bone mineral density, implicating a role of NFIA in human bone metabolism. Our study demonstrates that NFIA plays an important role in osteoblast differentiation of skeletal progenitor cells in bone growth and fracture healing.

Mitochondrial dysfunction and integrated stress response in G610C mouse osteoblasts *Elena Makareeva[1], Megan Sousa[1], Laura Gorrell[1], Shakib Omari[1], Satoru Otsuru[2], Sergey Leikin[1]. [1]National Institutes of Health, United States, [2]University of Maryland, United States

Osteoblast cell stress caused by the misfolding of procollagen has been shown to be an important factor in bone pathology resulting from Gly substitutions in osteogenesis imperfecta (OI). Our previously published studies of G610C mice with a Gly610Cys substitution in the triple helical region of the ?2(I) chain of type I collagen revealed increased EIF2? phosphorylation and ensuing integrated stress response (ISR) in osteoblasts without upstream unfolded protein response (UPR). Instead, upregulated expression of Hspa9 and Atf5 encoding mitochondrial paralogues of BIP and ATF4 suggested mitochondrial involvement in the ISR activation, probably via disruption of ER-mitochondria contacts. In the present study, we tested this hypothesis in primary osteoblast cultures by investigating which of the four EIF2? kinases activate the ISR and by imaging mitochondrial dynamics, ATP, and reactive oxygen species (ROS). We observed altered mitochondrial fission, increased ROS production in differentiating osteoblasts, reduced ATP synthesis in mature cells, and EIF2? phosphorylation by GCN2 rather than PERK in response to the G610C mutation. Taken together with our published studies of G610C procollagen trafficking in osteoblasts, these observations suggest the following ISR activation mechanism. Like all secretory proteins, the procollagen precursor of collagen is folded in the ER and exported through ER exit sites (ERESs). Its triple helix misfolding, however, is detected at ERESs rather than in the ER lumen. Blockage and depletion of functional ERESs due to the retention of misfolded procollagen by ERESs disrupts the exit of all secretory proteins and causes their accumulation in the ER. The resulting ER dilation disrupts ER-mitochondria contacts, leading to mitochondrial dysfunction and activation of the mitochondrial, not ER, arm of the ISR, in which EIF2? is phosphorylated by GCN2 rather than PERK. This novel pathway of ISR activation by secretory protein misfolding in the ER may present new opportunities for therapeutic targeting of osteoblast malfunction in classical OI.

Extrachromosomal circular DNA is produced by bone cells and may regulate physiological and pathological bone remodeling in mice and humans *Alongkorn Kurilung[1], Pratomporn Krangvichian[1], Manish Adhikari[2], Michela Palmieri[3], Lowry CL Barnes[4], Simon C Mears[4], Jeffrey B Stambough[4], Benjamin Stronach[4], Elena Ambrogini[3], Jesus Delgado-Calle[2], Intawat Nookaew[1]. [1]Department of Biomedical Informatics, University of Arkansas for Medical Sciences, United States. [2]Department of Physiology and Cell Biology, University of Arkansas for Medical Sciences, United States. [3]Division of Endocrinology, University of Arkansas for Medical Sciences, United States. [4]Department of Orthopaedic Surgery, University of Arkansas for Medical Sciences, United States

Extrachromosomal circular DNAs (eccDNAs) are nuclear, closed-circular DNAs derived from chromosomes. eccDNAs have been implicated in oncogene amplification and gene expression regulation in cancer cells. A population of eccDNAs encodes full-length transcripts, leading to high-copy number and transcription levels. eccDNAs also carry enhancers and genes encoding for miRNAs, which regulate chromatin accessibility and gene expression. Recent breakthroughs in eccDNA detection and functional analysis revealed that these molecules play important roles in cancer progression. However, current knowledge about eccDNA production and function in normal bone cells or destructed bone by cancers is limited. We have, therefore, searched for eccDNA circulomes in bone cell lines and tissue specimens from mice and humans, using a novel eccDNA enrichment method and our high-accuracy bioinformatic tool, CReSIL. Using third-generation sequencing, we detected eccDNA molecules (per 5?g of genomic DNA) in murine osteocyte-like MLOY4 cells (~12,000), primary murine osteoblasts (~20,000). eccDNAs were also detected in murine cortical bone (~4,000) and human trabecular bone obtained from femoral heads resected during hip replacement surgery (~4,000). Approximately 10% of the eccDNAs harbored full/truncated genes and miRNAs, including genes directly involved in bone homeostasis, in both MLO-Y4 (Apod, Adm2, Ecm1, Ilk, Mat2a, Sosc1, miR-200a, miR-429) and primary Obs (Bglap2, Elf3, miR-101, miR-137). Wee next performed functional GO term analysis of the genes carried by the identified eccDNAs from whole murine cortical bone. We found enrichment in terms associated with RNA transcription, Wnt signaling, mesenchymal differentiation and bone growth. It has been shown earlier that apoptosis and the consequent DNA fragmentation stimulate eccDNA formation and its production. Consistent with this evidence,we detected a 3-fold increase in eccDNA molecules in the cortical bone of mice bearing human multiple myeloma tumors, in which osteoblast and osteocytes undergo premature apoptosis, compared to naïve mice. This observation suggests that apoptotic osteoblastic cells are a source of regulatory eccDNA molecules in the multiple myeloma tumor niche. Taken all together, these findings provide compelling evidence for the existence of eccDNAs in bone and suggesta role in the regulation of cellular and molecular events influencing physiological and pathological bone remodeling.

Targeted Expression of Claudin (Cldn)-11 in Osteoblasts Increases Trabecular Bone Mass by Stimulating Bone Formation and Reducing Marrow Adiposity in Mice *Weirong Xing[1], Sheila Pourteymoor[2], William Tambunan[2], Subburaman Mohan[3]. [1]Musculoskeletal Disease Center, Jerry L. Pettis Memorial Veteran s Admin., United States. [2]VA Loma Linda Healthcare System, United States. [3]Jerry L. Pettis Memorial VA Medical Center, United States

The claudin (CLDN) family comprises 24 members of 20-34 kDa tetraspan transmembrane proteins of tight junctions. In addition to their established canonical role as barriers controlling the flow of molecules in the intercellular space between cells, a distinct non-canonical role for CLDNs is now emerging in which they serve as mediators of cell signaling. In previous studies, we showed that mice with global deletion of Cldn-11 gene exhibited reduced trabecular bone mass. However, the impact of Cldn11 expression osteoblast lineage cells in vivo remains undefined. Here, we generated osteoblast-specific transgenic lines expressing Cldn11 transgene driven by the ColCAT2.3 promoter and characterized their skeletal phenotype. Micro-CT analysis of distal femoral metaphysis showed that trabecular bone mass was increased by 50% and 38% (both $P<0.01$, n=8-10 per gender), respectively, in the transgenic male and female mice compared to littermate control mice that was caused by a significant increase in trabecular number and reduction in trabecular separation. Trabecular bone mass was also increased by 43% ($P<0.01$) in the proximal tibial metaphysis of transgenic mice of both genders. Histology and serum biomarker studies revealed that increased bone formation, and not reduced bone resorption, is the cause for increased trabecular bone mass in the Cldn11 Tg mice. Accordingly, expression levels of bone formation (Alp, Bsp) but not bone resorption (Ctsk) markers were increased in the bones of Cldn11 transgenic mice. Since bone marrow stromal cells are common precursors for osteoblasts and adipocytes and marrow adipose tissue (MAT) is known to correlate with trabecular bone mass inversely, we measured MAT by micro-CT of osmium tetroxide labeled bones. MAT was reduced by 86% ($P<0.05$) in the proximal tibia of transgenic male mice compared to control mice. Accordingly, the expression levels of the adipogenic markers (adiponectin and Asc1) and regulators of MAT (adipsin and leptin), were significantly reduced by 45-53% ($P<0.05$) in the bones of transgenic male mice. Our data are consistent with the possibility that CLDN11 exerts anabolic effects in osteoblasts by promoting the differentiation of mesenchymal stem cells towards osteoblasts at the expense of adipocytes.

Phospholipase C beta 4 regulates RNAKL-mediated osteoclastogenesis via its interaction with MKK3 and p38 *Dong-Kyo Lee[1], Xian Jin[1], Xiangguo Che[1], Poo-Reum Choi[1], Ying Cui[1], Sihoon Lee[2], Hyun-Ju Kim[1], Je-Yong Choi[1]. [1]School of Medicine, Kyungpook National University, Republic of Korea. [2]Gachon University College of Medicine, Republic of Korea

Phospholipase C beta (PLC?) exerts diverse biological functions including inflammatory response, tumorigenesis and neurogenesis, but its role in bone cell function is largely unknown. Among the PLC? isoforms (?1-?4), we found that PLC?4 was highly upregulated during osteoclastogenesis. Here, using global and osteoclast lineage-specific PLC?4 conditional knockout mice (LysM;PLC?4fl/fl), we show that PLC?4 is a key regulator of osteoclast differentiation induced by RANKL. Both global and osteoclast lineage-specific deletion of PLC?4 in mice led to a significant reduction in osteoclast formation in vitro and decreased osteoclast marker gene expression. Importantly, compared to WT littermates, LysM;PLC?4fl/fl male mice had higher bone mass and lower osteoclast numbers in vivo without altering osteoblast histomorphometric indices. Mechanistically, PLC?4 formed a complex with mitogen-activated protein kinase kinase (MKK) 3 and p38 MAPK and modulated p38 activation after RANKL stimulation. Subsequently, RANKL-induced phosphorylation of p65, a downstream target of p38, was blocked in LysM;PLC?4fl/fl cells. Overall, our findings reveal that PLC?4 controls osteoclastogenesis via RANKL-dependent MKK3-p38-p65 pathway, and that PLC?4 may be a potential therapeutic candidate for bone diseases such as osteoporosis.

Short-term RAGE inhibition enhances osteoclast activity in a mouse model of type 2 diabetes *KAITLYN BROZ[1], Remy Walk[2], Simon Tang[3, 1]. [2]Washington University in St. Louis, . [3]Washington University in St Louis, United States

Patients with type 2 diabetes experience more fractures in spite of increased bone mineral density. One likely contributor is the accumulation of advanced glycation endproducts (AGEs) and activation of the receptor of AGEs (RAGE). We previously showed that the systemic genetic ablation of RAGE from 6-8 month-old type 2 diabetic mice protected against the decline of osteocyte density and increased AGEs in the vertebrae. To translate these findings, we sought to determine the effects of short-term RAGE inhibition on the vertebrae of db/db mice.Female leptin receptor deficient (db/db) mice and littermates at 5 months-old were injected daily with 1mg/kg/ml of FPS-ZM1, a small molecular inhibitor of RAGE, in 0.05% DMSO or with vehicle (n=4-5/group) for 60 days. Body weight was monitored biweekly. L4 vertebra were scanned by microCT (Scanco vivaCT 40, 10um, 70 keV, 170uA, 300ms integration) before treatment and then again immediately prior to sacrifice. The L3 vertebra were stained with TRAP / H&E to measure osteoclast activity (osteoclast surface per bone surface, Oc.S/BS) and osteocyte density. Mice were injected with calcine 2 days prior to sacrifice to measure osteoblast activity (mineralizing surface per bone surface, MS/BS). L5 vertebra were scanned by microCT and tested in compression and an AGE fluorometric assay was performed.Body weight for all groups was unchanged throughout. BV/TV was unchanged in wt mice with and without treatment, and BV/TV was increased in the untreated db/db mice. The changes in BV/TV were concomitant with an increase in Oc.S/BS in the db/db treatment group, with a trending effect of treatment on MS/BS. Diabetes reduced osteocyte density, increased vertebral AGEs, and impaired mechanical properties, and these were unaffected by RAGE inhibition.Inhibiting RAGE for 60 days in db/db mice enhances osteoclast action and prevents the bone accumulation. RAGE inhibition did not affect bone matrix AGEs, osteocyte lacunae density, though osteoblast mineral apposition was modestly increased. Our previous study revealed that systemic, constitutive RAGE ablation in 6-8 month-old db/db mice rescued osteocyte lacunar density, enhanced bone mineralizing surface, but not osteoclast function. Taken together, short-term RAGE inhibition may stimulate the actions of osteoclasts to stimulate bone removal, but prolonged treatment may be required to stimulate the sustained actions of the osteoblast and the osteocyte to restore bone matrix quality.

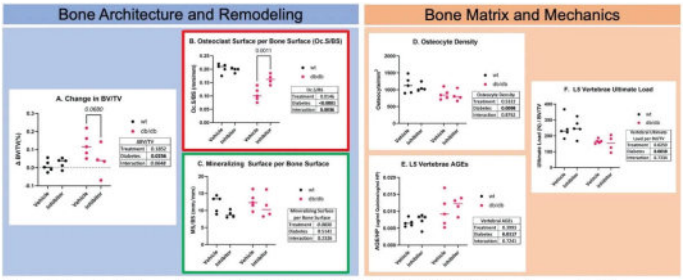

Figure 1. Bone Architecture and Remodeling: [A] The administration of a RAGE inhibitor nearly prevented the accumulation of bone in the db/db (p = 0.068). [B] The inhibition of RAGE also restored the Oc. S/BS in the db/db animals, suggesting that the osteoclast function is enhanced. [C] Inhibiting RAGE did not appear to affect osteoblast function. Bone matrix and mechanics: [D] Osteocyte density is reduced in db/db animals and not affected by RAGE inhibition. [E] AGEs also accumulated in vertebrae of db/db animals with no effect of treatment. [F] Finally, the fragility observed in the db/db animals was not affected by the treatment.

Docosahexaenoic acid inhibits TNF-?-induced osteoclast formation and bone resorption through GPR120 *Jinghan Ma[2,] Hideki Kitaura[2,] Fumitoshi Ohori[3,] Takahiro Noguchi[2,] Aseel Marahleh[2,] Ria Kinjo[4,] Kayoko Kanou[4,] Itaru Mizoguchi[2,] [2]Tohoku University, , [2]Tohoku University, Japan, [3]Tohoku University Graduate School of Dentistry, Japan, [4]Tohoku University Tohoku University Graduate School of Dentistry, Japan

Objectives: Docosahexaenoic acid (DHA), an omega-3 fatty acid which exerts its function via G protein-coupled receptor 120 (GPR120). DHA possesses anti-inflammatory effects and inhibits osteoclastogenesis. Orthodontic force induces the expression of tumor necrosis factor-? (TNF-?) which supports osteoclastogenesis by increasing RANKL expression. In our studies, we investigated the effect of DHA on TNF-?-induced osteoclastogenesis in vivo and in vitro. We also observed the effect of DHA on TNF-?-induced NF-?B pathway activation through GPR120. Furthermore, we also aim at the inhibitory effect of DHA on osteoclast formation and bone resorption in bone marrow chimeric mouse by using WT and GPR120 deficient mouse.Materials and methods: WT and GPR120-KO mice were administered supracalvarial injections with either PBS; TNF-?; DHA and TNF-?; or DHA. Calvaria were analyzed for bone resorption and osteoclastogenesis. We also analyzed RANKL mRNA expression in both kinds of mice osteoblasts treated as above. Then measured osteoclastogenesis in co-cultures of GPR120-KO osteoclast precursors and osteoblasts from WT or GPR120-KO mice. To observe how DHA influence proinflammatory signaling pathway, we stimulated osteoblast of both kinds of mice by TNF-? then analyzed by immunofluorescence. Finaly, we generated chimeric mice by transplanting the bone marrow cells from donor into the irradiated recipient mice, which resulting chimeric mice have stromal cells derived from the recipient and macrophages derived from the donor. Then, these mice were also received DHA and TNF-? injection and were used for histological examination. Results and Discussion: Calvaria of WT but not GPR120-KO mice injected with DHA and TNF-? had less bone resorption and osteoclastogenesis than mice injected with TNF-? alone. TNF-?-induced RANKL mRNA expression was reduced in WT mice but not GPR120-KO osteoblasts treated with DHA. DHA also inhibited TNF-?-enhanced osteoclast formation in co-culture of osteoblasts obtained from WT mice but not GPR 120-KO mice. Moreover, DHA exerted inhibitory effects on the NF-?B pathway activated by TNF-? in osteoblasts of WT mice but not GPR120-KO mice. Osteoclast number and bone resorption were increased in the chimeric mice which have GPR120-KO stromal cells compared to those owns WT stromal cells.Conclusion: DHA suppresses osteoclast formation and bone resorption induced by TNF-? in vivo and in vitro, and inhibits osteoclastogenesis and bone resorption via GPR120. Moreover, stromal cells contribute more to osteoclast formation than macrophages during this process. Additionally, DHA directly inhibits RANKL expression in osteoblasts in vitro via GPR120.

Identification of glutamine metabolism as a metabolic vulnerability in osteoclasts *GUOLI HU[1,] Yilin Yu[3,] Robert Tower[3,] Guo-fang Zhang[4,] Courtney Karner[3,] [1]UT Southwestern Medical Center, , [3]University of Texas Southwestern Medical Center, United States, [3]University of Texas Southwestern Medical Center, , [4]Duke University, United States

Osteoclasts are bone resorbing cells that are essential to maintain skeletal integrity and function. Excessive osteoclast activity causes both age-related and pathological bone loss associated with several diseases including osteoporosis. While many of the growth factors and molecular signals that govern osteoclastogenesis are well studied, a large gap in our knowledge exists about the role and regulation of cellular metabolism during osteoclastogenesis. Advances in our understanding of differentiation associated metabolic changes will aid in identifying metabolic vulnerabilities that can be exploited therapeutically to reduce bone resorption and pathological bone loss. Here, we used a multifaceted approach to define the metabolomic signature of osteoclasts. When compared to bone marrow monocyte and macrophage cultures, mature osteoclasts (mOC) have significantly increased abundance of amino acids and purine and pyrimidine nucleotides. Osteoclasts must increase the consumption and metabolism of glutamine which provides carbon and nitrogen for amino acid and nucleotide biosynthesis. Importantly, inhibiting glutamine metabolism in mOC resulted in a complete loss of the metabolomic signature and prevented osteoclast differentiation in vitro. Deletion of a floxed Gls allele (Glsfl) in myeloid progenitor cells using LysmCre resulted in significantly higher bone mass at 4- and 6-months of age in male and female mice. The LysmCre;Glsfl/fl bone phenotypes were attributed to a reduction in osteoclast numbers and bone resorption with no change osteoblast parameters. Conversely, expressing a doxycycline inducible Gls allele (tetoGls) using LysmCre (LysmCre;R26rtTA;tetoGls) increased osteoclastogenesis, enhanced bone resorption and rapidly reduced bone mass. Highlighting the therapeutic implications of these findings, genetically inhibiting glutamine metabolism prevented ovariectomy induced bone loss in mice. Collectively, our data provide genetic evidence that glutamine metabolism is essential to regulate osteoclast metabolism, osteoclastogenesis and bone resorption in mice. Moreover, our study demonstrates osteoclasts are reliant on glutamine metabolism like cancer cells. Targeting glutamine dependency using Telaglenastat is being developed as a potential cancer treatment. Our findings indicate it may be possible to repurpose this strategy to prevent excessive bone resorption.

A Novel Fluorogenic Probe for Intravital Microscopic Imaging of Enzymatically Active Cathepsin K in Functional Osteoclasts *Eun Jung Lee[1,] Seyoung Koo[2,] Da Hyeon Yoon[1,] Jong Seung Kim[2,] SERK IN PARK[1,] [1]Korea University College of Medicine, Republic of Korea, [2]Department of Chemistry, Korea University, Republic of Korea

Cathepsin K (CTSK) is a lysosomal cysteine protease that is essential to the osteolytic activity of functional osteoclasts. Several fluorescence-based probes for CTSK have been developed for preclinical studies on osteoclast inhibitors but the sensitivity and signal intensity are insufficient for real-time live imaging in mice. To overcome this limitation, we synthesized a novel fluorescence resonance energy transfer (FRET)-based fluorogenic CTSK probe and tested its efficacy in vitro using a confocal microscope and in vivo using an intravital microscope. A peptide substrate specific to CTSK was conjugated with a TAMRA fluorophore and a BHQ-2 quencher. Upon addition of a nano-molar range of recombinant CTSK, the TAMRA fluorophore was cleaved from the quencher, resulting in a strong fluorescence signal, which was fully suppressed by odanacatib, a CTSK inhibitor. Notably, our probe exhibited over 60-fold higher sensitivity than previously reported probes. For in vitro imaging, osteoclasts were formed by treating murine bone marrow monocytes with RANKL and M-CSF on collagen-coated plates or dentin discs, followed by fixation, permeabilization and staining with the probe, phalloidin and DAPI. Confocal microscopy demonstrated the subcellular localization of CTSK in osteoclasts (Figure Panel A). A strong fluorescence signal was localized in the ruffled border, indicating that the probe is sensitive and specific to functional CTSK in bone-resorbing osteoclasts. For intravital imaging, we used three different mouse models: an ovariectomy-induced osteoporosis model, a RANKL injection bone loss model, and a bone metastasis model using intra-tibial injection of breast tumor cells. The CTSK probe was administered by tail-vein injection (50?mol), and live real-time images were captured in the proximal tibia with a small skin incision under anesthesia. No significant toxicities were noted in multiple injection groups of mice. Two-photon intravital microscopy showed clear real-time images of osteoclasts on the endosteal surface or trabecular bone of live animals (Figure Panel B). The fluorescence signal was not detectable in negative control mice, and the signal was significantly reduced in mice treated with zoledronic acid or odanacatib. In conclusion, we developed a novel probe for sensitive and specific visualization of functional CTSK in real-time live mice that can be useful in bone biology research and in the development of therapeutics for CTSK or osteoclasts.

Interactome of Galectin-8 Isoforms to Dissect their Impact on Human Osteoclasts *Leopold Mbous Nguimbus[1], Michèle Roy[1], Marie A. Brunet[2], Sophie Roux[1]. [1]Rheumatology, Department of Medicine, Sherbrooke University, Canada. [2]Department of Biochemistry and Functional Genomics, Sherbrooke university, Canada

Using a screening strategy, we previously showed an alternative splicing (AS) event in LGALS8 encoding galectin-8 (gal-8) in overactive pagetic osteoclasts (OCs), with a decrease in long spliced isoform while total gal-8 was upregulated compared to controls (Klinck et al. 2014). LGALS8 AS leads to the formation of distinct splice variants that only differ in their linker region whose length and structure could influence its biological functions. The best-characterized functions of gal-8 are performed extra-cellularly, where it binds glycans to modulate cell-matrix interactions. The functions of intracellular gal-8 are less well known, but cytosolic gal-8 has been shown to act as a danger recognition receptor. Our objective was to evaluate the impact of gal-8 isoforms on OC phenotype, and to identify interacting partners for each isoform to better understand their role in OCs. We used fetal monocytes to generate OCs, adding isoform-specific knockdown (siRNA) at the end of long-term cultures. Inhibiting gal-8 expression decreased OC nuclearity and bone resorption, mainly attributable to the short isoform as its targeting significantly decreased the number of multinucleated cells and the resorbed surface area compared to control siRNA. Targeting gal-8 long isoform did not induce any phenotypic changes. The two isoforms may interact with distinct proteins and pathways, which led us to analyze the interactome of gal-8 isoforms by liquid chromatography mass spectrometry in HEK293T cells transfected with either isoform. Results were scored using SAINTexpress which identified 31 gal8-interacting proteins, including 22 proteins shared by both isoforms, as well as 9 specific to the short isoform. Proteins specific to the short isoform of gal-8 included proteins involved in cell adhesion (ITGA4, ITGA5, TPBG), lysosomal proteins (LAMP1, SCL17A5, GLMP) or membrane receptors (M6PR, PTGFRN). The tertiary structure of each isoform was generated with AlphaFold2 and could also suggest spatial interference of the long isoform with some binding sites. GO enrichment analyses confirmed specificity in some cell adhesion or lysosomal pathways for the short isoform. Finally, 3 protein-protein interactions with gal-8 were confirmed by double immunofluorescence staining in resorbing OCs. Our proteomics approach of the interaction partners allowed to identify some molecules or pathways associated with the short isoform that drive gal-8 pro-OC activity in humans.

Osteoclast-specific Deletion of ?2-Adrenergic Receptor Limits Trabecular Bone Acquisition in Male, but not Female Mice *Rebecca Peters[3], Ryan Neilson[2], Hannah Feliciano[3], Katherine Motyl[4]. [3]MaineHealth Institute for Research, . [2]MMCRI, United States. [3]MaineHealth Institute for Research, United States. [4]MaineHealth, United States

The sympathetic nervous system (SNS) is important for maintenance of bone homeostasis through ?-adrenergic signaling. Our lab and others found that osteoclasts are direct targets of the SNS, and that ?-blockers limit osteoclast differentiation. Osteoclasts express both ?1- and ?2-adrenergic receptor (?2AR), but ?2AR is more highly expressed. To directly examine the effects of ?2AR on osteoclasts, we developed an osteoclast-specific ?2AR knockout mouse model. Adrb2fl/fl mice were crossed with the myeloid lineage specific Lyz2Cre/Cre (a.k.a. LysM-Cre) mice. We tested the efficiency of deletion with Adrb2fl/fl-Lyz2Cre/+ (Cre/+) and Adrb2fl/flLyz2Cre/Cre (Cre/Cre) mice and found deletion of Adrb2 was comparable in both using gene expression and in situ hybridization in the distal femur. Using µCT, we measured the bone microarchitecture of wildtype (+/+) and Cre/+ male and female mice at 8 and 26 weeks of age (N=7-10). In male mice with the deletion, L5 vertebrae trabecular bone parameters (BV/TV, BMD, Tb.Th) were significantly lower. Distal femur trabecular BMD was reduced by 10% and SMI was elevated by 35% in Cre/+ compared to +/+ ($p<0.05$). Cortical bone (Ct.Ar/Tt.Ar, Ct.TMD) tended to be lower in Cre/+ mice ($p<0.09$). Both osteoclast and osteoblast marker genes were reduced in tibia, including Acp5, Alpl, Col1a1 and Tnfsf11 (Rankl). Although no changes in serum CTX-1 or P1NP were observed in untreated mice, ?2AR deletion in osteoclasts attenuated the elevated CTX-1 caused by the ?2AR agonist salbutamol (N=3, $p=0.031$). The low bone mass phenotype subsided by 26 weeks, suggesting age-related bone loss is unaffected by Adrb2 deletion in osteoclasts in male mice. Female mice had no significant changes in bone microarchitecture or serum bone remodeling markers at 8 or 26 weeks of age. Although global deletion of Adrb2 has been reported to cause a high bone mass phenotype, our work indicates that ?2AR function in bone is sex, age, cell-type, and stress dependent. We have also found that ?2AR deletion in osteoclasts may have indirect effects on osteoblast function, indicated by lower osteoblast marker gene expression. Future studies will examine this using osteoblast culture and co-culture studies with osteoclasts. These studies will aid in our understanding of mechanisms through which stress and ?-blockers influence bone density, which may inform osteoporosis prevention and treatment strategies.

Pim1 contributes to maintenance of bone homeostasis via regulation of osteoclast function *Soo Young Lee[1], Ryeojin Ko[1], Jeongin Seo[1]. [1]Ewha Womans University, Republic of Korea

ObjectiveThe proviral integration site for Moloney murine leukemia virus 1 (Pim1) protein is a highly conserved serine/threonine kinase that is involved in a variety of cellular processes including cell survival, proliferation, and apoptosis. In addition, Pim1 has been shown to regulate the differentiation of osteoclasts. Mature osteoclasts absorb bone matrix by forming an actin ring between themselves and the bone surface. However, the role of Pim1 in the bone-resorbing function of osteoclasts is largely unknown.MethodsIn this study, we generated Pim1-/- mice to investigate the role of Pim1 in the regulation of bone metabolism. We conducted immunofluorescence staining of actin and acetylated tubulin in osteoclast on dentin slices and coverslips in wild-type and Pim1-/- mice. To identify whether Pim1 deletion affects bone growth in vivo, we examined the microstructure of the distal femur from 8 weeks old male mice wild-type and Pim1-/- mice using micro-computed tomography (micro-CT) analysis.ResultsWe demonstrated that Pim1 deletion does not affect the differentiation of osteoclasts. However, a significant reduction in resorption area was observed in Pim1-/- mice. In addition, Pim1-deficient osteoclasts were unable to form normal actin rings, and the acetylation pattern of microtubules was abnormal. Furthermore, an increase in distal femoral bone mass was observed in Pim1-/- mice compared to wild-type mice.Conclusions-These results indicate that Pim1 plays an important role in the bone-resorbing function of osteoclasts. Therefore, the control of osteoclast activity via targeting Pim-1 will provide a novel therapeutic option for the treatment of bone diseases.

Transcriptional Reprograming during Human Osteoclastogenesis Identifies Targets for Predicting and Modulating Osteoclast Differentiation and Activity *Morten S. Hansen[1], Kaja Madsen[2], Maria Price[3], Kent Søe[1], Caroline M. Gorvin[3], Morten Frost[1], Alexander Rauch[2]. [1]Odense University Hospital, Denmark. [2]University of Southern Denmark, Denmark. [3]University of Birmingham, United Kingdom

Background: Increased osteoclastogenesis and osteoclast activity are important causes of postmenopausal osteoporosis. Understanding the transcriptional reprogramming during osteoclastogenesis has the power to identify targets for novel anti-osteoporotic drugs.Purpose: Define gene expression dynamics during human osteoclast differentiation for the alignment with bone mineral density related expression and GWAS data, the construction of

transcriptional networks and the identification of G-protein-coupled receptors and surface molecules that allow interference with osteoclast activity and the prediction of subject-specific resorptive potential.Methods: Human osteoclasts were differentiated (t=10 days) in vitro from CD14+-monocytes from eight female donors aged 18-49 years. RNA-sequencing was performed at four time points (day 0 prior to and 2-, 5-, and 9-days post-differentiation). GPCRs were targeted with agonist and/or antagonists and FACS based surface molecule expression was determined in relation to bone resorbing activity.Results: We identified 8446 differentially expressed genes with high reproducibility across donors that were grouped into eight temporal patterns which based on network analysis are linked by mutual and temporal dependencies. These patterns were enriched for distinct molecular functions, metabolic pathways, and genes that are flanked by bone mineral density associated SNPs. Compared to normal, osteoporotic bones exemplified gene signatures of mature osteoclasts and absence of precursor related genes. Using pharmacological interference with differentially expressed GPCRs, we found activation of somatostatin receptor 2 (SSTR2) to decrease osteoclast resorption, activation of free fatty acid receptor 4 (FFAR4/GPR120) to decrease both osteoclast numbers and activity, and activation of complement C5a receptor 1 (C5AR1) to increase osteoclast numbers. FACS analysis affirms expression of oxidised LDL receptor 1 (LOX1) and activated CDC42 kinase 1 (ACK1) on precursors to be correlating with activity of the mature cells. Conclusions: We provide a consecutive map of the transcriptional reprogramming during human osteoclastogenesis that highlights the strong implication of osteoclast genes in the aetiology and genetics of human bone loss. Targeting stage specifically expressed GPCRs as well as the quantifying resorption-associated surface molecules highlights the identification of targets and monitors for anti-resorptive treatment options.

The endosomal RANKL-LGR4 signaling during osteoclast differentiation *Wonbong Lim[1], Beomchang Kim[1], Young Jong Ko[1], Yuria Jang[1]. [1]Department of Premedical Science, College of Medicine, Chosun University, Republic of Korea

LGR4 (Leucine-rich repeat-containing G-protein coupled receptor 4, also known as GPR48) is a membrane receptor and known as a negative regulator of RANK signaling cascade during osteoclast differentiation. Although cell signaling and endocytic membrane trafficking from membrane receptor have traditionally been viewed as distinct processes, it is now recognized that these processes are intimately and bidirectionally linked. In this study, we investigated the difference between membrane-bound LGR4 signaling and internalized LGR4, and whether the LGR4 signaling cascade gives RANKL signal in internalized endosomes as an potential regulator during RANKL-induced osteoclastogenesis. Herein, we showed that LGR4 is endocytosed to endosome after binding to RANKL in osteoclast precursor cells RAW 264.7s. The internalized LGR4 activates LGR4-RANKL signaling in the early endosome. When RANKL is bound to LGR4, it is endocytosed and located in the Rab5 positive ealry endosome. In LGR4-down regulated RAW 264.7 cells, it was analyzed that the early endosome signal increased and the inhibitory phosphorylation of GSK-3beta decreased. Raw 264.7 cells treated with Dynasore (Dynamin inhibitor) confirmed the same reduction in inhibitory P-GSK3B as LGR4 CKO(Conditional Knock-out) cells. With similar results, it was confirmed that the reduced inhibitory P-GSK3B was recovered when DRG2 KO mice were treated with Dynasore, which is similar to the results of DRG2 WT mice. As a result of confirming NFATC1 nuclear translocation by RANKL treatment in LGR4 CKO Raw 264.7 cells and DRG2 KO mouse, nuclear translocation of NFATC1 increased in both groups. In addition, decreased bone density and increaesd TRAP activity in DRG2 KO mice which is known to be increased the early endosome duration were investigated. Taken together, our result showed that the internalized LGR4 could be a potential regulator for the modulation of osteoclast differentiation via RANKL-LGR4 signaling in endosomes.

Proteomics Analyses Unveil Leucine Repeat Rich Kinase 1 (LRRK1) Signaling Targets Proteins Critical for Endosome/Lysosome Sorting and Trafficking in Osteoclasts *Subburaman Mohan[1], Weirong Xing[2]. [1]Jerry L. Pettis Memorial VA Medical Center, United States. [2]Musculoskeletal Disease Center, Jerry L. Pettis Memorial Veteran s Admin., United States

LRRK1 plays a pivotal role in regulating osteoclast activity and bone resorption. Global knockout (KO) of Lrrk1 gene in mice caused severe osteopetrosis due to failure of osteoclast to resorb bone. The molecular mechanism of LRRK1 regulation of osteoclast function is not fully understood. Since LRRK1 is a serine/threonine kinase and most aspects of cellular biology and protein function are regulated by protein phosphorylation, we performed a 2D DIGE phosphor-proteomics analysis to identify potential LRRK1 target proteins in osteoclasts. Osteoclasts derived from Lrrk1 KO, and control WT mice were differentiated for 5 days, starved in M-CSF and RANKL-free media for 1 hour, followed by 1 hour M-CSF and RANKL stimulation. The cells were then lysed, and total cellular proteins were extracted. For phosphoprotein profiling, same amounts of lysate from Lrrk1 KO and WT osteoclasts were labeled with Cy3-dye and run on 2D SDS PAGE. The gels were then stained using Pro-Q® Diamond Phosphoprotein Gel Stain. For the protein profiling, lysates from Lrrk1 KO and control WT cells were labelled with Cy3- and Cy5-dye, respectively. Labelled proteins were mixed and analyzed on the same 2D SDS PAGE. The fluorescent intensities of overlapped spots on the gels were scanned using Typhoon TRIO and analyses using DeCyder software. Phosphor-ratio of two samples (WT/KO) were calculated by adjusting phosphor-ratios with protein ratios in LRRK1 deficient vs. control WT cells. Differentially phosphorylated spots between the two types of cells were picked up by Ettan Spot Picker, digested with modified porcine trypsin in the gel, and identified by MALDI-TOF MS and TOF/TOF tandem MS/MS. Twenty-four phosphoproteins were identified, six of which involved in endosome/lysosome sorting, vacuolar protection, and trafficking SNX2, VPS35, VTA1, CFL1, and CTSA proteins were significantly hypo-phosphorylated while SNX3 was hyper-phosphorylated in LRRK1-deficient osteoclasts. Phosphorylated VPS35 was reduced by 80% while phosphorylated SNX3 was elevated by 4-fold in LRRK1 deficient osteoclasts. Since both VPS35 and SNX3 are critical retromer complex components responsible for membrane trafficking, and the phosphorylation of SNX3 at serine 72 is known to block its phosphoinositide binding to control release of endosomal SNX3 to the cytosol, our results suggest that LRRK1 signaling target proteins critical for endosome/lysosome sorting and trafficking in osteoclasts.

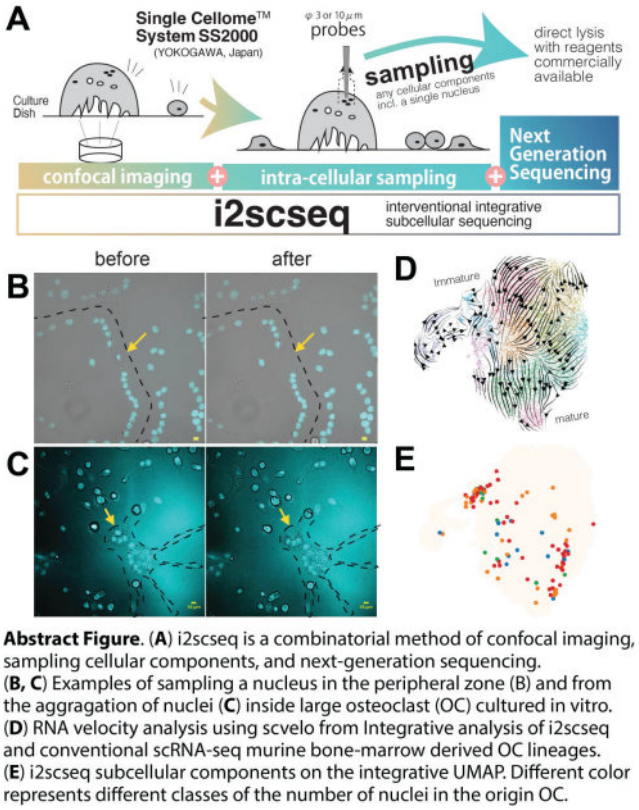
The transcriptome at single-cell resolution clarifies the diversity of cell populations. Single-cell RNA-seq (scRNA-seq) has already been adopted for giant cells such as osteoclasts (OCs) (Omata, Okada, JBMR plus 2022). Although large OCs could not pass through a fluid-based cell dissociation device because of their diameter, acid-producing mature OCs were captured using conventional scRNA-seq.At ASBMR 2022, we presented intra-single cell sequencing (iSCseq) (Okada, bioRxiv 2022). iSCseq is a combinatorial method of high-resolution confocal imaging, picking of intracellular components, including a single nucleus, using the Single CellomeTM System SS2000 (Yokogawa, Japan), and next-generation sequencing at high resolution for mRNA. Our previous results showed that individual nuclei within the same cell are heterogeneous in terms of gene expression.The next version of iSCseq called i2scseq (interventional and integrative subcellular sequencing) can also collect cytoplasm in a small ordinary cell with a 3um probe and capture the living subcellular transcriptome. The average number of genes per cell detected by a 10um probe is much higher, and one by a 3um is equivalent to traditional fluid-based sequencing.i2scseq was used for the in vitro lineage of cells differentiating into OCs. i2scseq clarified that some small cells, which were not morphologically regarded as OCs, were classified into the final cluster of lineages, and vice versa, that giant OC contain immature nuclei in terms of gene expression. With integrative analysis of i2scseq and fluid-based sequencing datasets using a deep machine learning method, large OCs have embedded components at many stages of differentiation.i2scseq clarified the subcellular heterogeneity of mature OCs at a higher resolution than previous iSCseq. We partially solved the question of why conventional scRNA-seq has captured so-called mature OCs. i2scseq is expected to be a core method in cell biology.



Abstract Figure. (**A**) i2scseq is a combinatorial method of confocal imaging, sampling cellular components, and next-generation sequencing. (**B, C**) Examples of sampling a nucleus in the peripheral zone (B) and from the aggragation of nuclei (**C**) inside large osteoclast (OC) cultured in vitro. (**D**) RNA velocity analysis using scvelo from Integrative analysis of i2scseq and conventional scRNA-seq murine bone-marrow derived OC lineages. (**E**) i2scseq subcellular components on the integrative UMAP. Different color represents different classes of the number of nuclei in the origin OC.

La, a repurposed RNA-binding protein, regulates osteoclast multinucleation and function. *Jarred M. Whitlock[1], Evgenia Leikina[1], Kamran Melikov[1], Luis Fernandez De Castro Diaz[2], Sandy Mattijssen[1], Richard Maraia[1], Michael Collins[2], Leonid Chernomordik[1]. [1]NICHD, United States. [2]NIDCR, United States

Multinucleated osteoclasts, essential for skeletal remodeling in health and disease, are formed by the fusion of osteoclast precursors, where each fusion event raises their bone-resorbing activity. Here we show that the nuclear RNA chaperone, La protein has an additional function as an osteoclast fusion regulator. Monocyte-to-osteoclast differentiation starts with a drastic decrease in La levels. As fusion begins, La reappears as a low molecular weight species at the osteoclast surface, where it promotes fusion. La's role in promoting osteoclast fusion is independent of canonical La-RNA interactions and involves direct interactions between La and Annexin A5, which anchors La to transiently exposed phosphatidylserine at the surface of fusing osteoclasts. Disappearance of cell-surface La, and the return of full length La to the nuclei of mature, multinucleated osteoclasts, acts as an off switch of their fusion activity. Targeting surface La in a novel explant model of fibrous dysplasia inhibits excessive osteoclast formation characteristic of this disease, highlighting La's potential as a therapeutic target.

The PDE4 inhibitors Roflumilast and Rolipram Rescue ADO2 Osteoclast Resorption Dysfunction *Jung Hong[1], Angela Bruzzaniti[1], Rita O'Riley[2], Dena Acton[2], Imranul Alam[2], Michael Econs[2]. [1]Indiana University School of Dentistry, United States. [2]Indiana University School of Medicine, United States

Autosomal Dominant Osteopetrosis type II (ADO2) is a rare bone disease of impaired osteoclastic bone resorption caused by heterozygous missense mutations in the chloride channel 7 (CLCN7). Previous reports have shown that ADO2 knock-in mouse models containing the CLCN7 mutation exhibit elevated bone mass. A CLCN7 mutation is thought to affect not only Clcn7 chloride exchange activity but also affect endosomal-lysosomal trafficking which is critical for formation of the resorption lacunae of active osteoclasts. It is well known that adenylate cyclase is critical for lysosomal acidification in osteoclasts and other cells. Adenylate cyclase catalyze the formation of cyclic adenosine monophosphate (cAMP), an important small second messenger that activates key cellular target proteins. Intracellular cAMP concentration is tightly regulated at the level of its synthesis by adenylate cyclase and hydrolysis by specific phosphodiesterase (PDEs). We investigated the cellular mechanism involved in ADO2 OC dysfunction and found that both immature and mature ADO2 osteoclasts exhibit reduced cAMP levels, compared to wild-type OCs, implicating the signaling pathways that regulate cAMP synthesis or hydrolysis. QPCR analysis revealed higher expression levels of the three PDE4 subtypes (4a, 4b, 4d) in ADO2 osteoclasts compared in WT. Next, we examined the effects of two cAMP specific PDE4 inhibitors, roflumilast and rolipram, on ADO2 osteoclast formation and resorption activity in vitro. Non adherent bone marrow macrophages from ADO2 and WT mice were cultured with RANKL and MCSF in the presence of roflumilast or rolipram (0-250 nM). Roflumilast and rolipram increased osteoclast formation in a dose-dependent manner in both ADO2 and WT osteoclasts. Importantly, the PDE4 inhibitors also displayed a concentration-dependent increase in osteoclast resorption activity which was greater in ADO2 osteoclasts than WT osteoclasts. The key findings from our studies demonstrate that ADO2 mice exhibit reduced cAMP levels and that PDE4 inhibition by rolipram and roflumilast rescue ADO2 osteoclast activity dysfunction in vitro. Further understanding of this mechanism will potentially lead to the development of new approaches for the treatment of clinically affected ADO2 patients.

Proton-Activated Chloride Channel Enhances Endplate Porous Osteoclast Resorption to Induce Spinal Pain *Weixin Zhang[1], Peng Xue[2], Shenyu Wang[2], Jiachen Chu[2], Janet Crane[2], Mei Wan[2], Zhaozhu Qiu[2], Xu Cao[2]. [1]Johns Hopkins university, . [2]Johns Hopkins University, United States

Proton-activated chloride (PAC) channel is responsive to pathological acidic pH in ischemic brain injury in mice and acid-induced neuronal cell death as a completely new ion channel family. Our PAC structure study revealed that the protein exists in two states: namely, a high-pH resting closed state and a low-pH proton-bound non-conducting state. PAC channel undergoes striking conformational changes when the pH drops from 8 to 4, leading to an opening of the channel and the conduction of anions across cellular membranes, thereby inducing diseases associated with tissue acidosis (acid-induced cell death). Skeletal pain in bone disorders is often associated with aberrant osteoclast-mediated resorption due to very low pH environments. But the role of PAC in pathological osteoclast resorption and spinal pain is still unexplored. Chronic low back pain (LBP) can severely affect daily physical activity and is one of the leading risk factors for the development of immobility and frailty. Aberrant osteoclast-mediated resorption during spinal degeneration leads to the development of a porous endplate that in turn allows for the sensory innervation of the spinal unit, leading to LBP. But the mechanism by which aberrant osteoclast activity occurs during spinal degeneration is unclear. Here, we report that the expression of proton-activated chloride channel (PAC) is induced specifically in the apical membrane of osteoclasts in the porous endplates via a RANKL-NFATc1 signaling pathway. Extracellular acidosis evokes the ICl, H current in the cell membrane of osteoclasts by activating the PAC-encoded Cl? channel. Thus, a combination of an acidic environment of porous endplates and elevated PAC expression results in enhanced osteoclast fusion and resorption that, in turn, provokes LBP. Further, we find that genetic knockout of PAC significantly reduces endplate porosity and spinal pain in a mouse model of spine degeneration, but it does not affect bone development or homeostasis of bone mass in adult mice. Aberrant osteoclast-mediated resorption is found in most skeletal disorders, including osteoarthritis, ankylosing spondylitis, rheumatoid arthritis, heterotopic ossification, enthesopathy, and Paget disease, in addition to spine degeneration. Thus, elevated PAC expression and PAC activity could be a common mechanism for various bone pathologies and thus a potential therapeutic target.

The Effect of Osteocyte-Derived RANKL on Bone Graft Remodeling *Balazs Feher[1], Carina Kampleitner[2], Patrick Heimel[2], Stefan Tangl[2], Jill Helms[3], Ulrike Kuchler[2], Reinhard Gruber[2]. [1]Harvard School of Dental Medicine, United States. [2]Medical University of Vienna, Austria. [3]Stanford University School of Medicine, United States

Autologous bone is considered the gold standard for grafting, yet it suffers from a tendency to undergo resorption over time. While the exact mechanisms of this resorption remain elusive, osteocytes have been shown to play an important role in stimulating osteoclastic activity through their expression of receptor activator of NF-?B (RANK) ligand (RANKL). During physiological remodeling, this activity is also necessary for bone formation. We hypothesized that osteocyte-derived RANKL plays an important role in the remodeling of bone grafts by suppressing resorption and thus potentially preventing new bone formation.In 8-week-old Tnfsf11fl/fl;Dmp1-Cre osteocyte-specific RANKL knockout and Dmp1-Cre control mice, we harvested a 2.6 mm bone disk from the left parietal bone and transplanted it either into a subcutaneous pouch above or as a subperiosteal onlay graft onto the right parietal bone, creating 4 groups in total. We performed histology and micro-computed tomography of the grafts as well as the donor regions 28 days after grafting.Histology revealed marked resorption of subcutaneous control Dmp1-Cre grafts (Fig. 1A) and new bone formation around subperiosteal Dmp1-Cre grafts (Fig. 1C). In contrast, Tnfsf11fl/fl;Dmp1-Cre grafts showed effectively no signs of either bone resorption or formation (Fig. 1B, D). Quantitative micro-computed tomography of the bone disks (Fig. 1E-H) revealed a significant difference in residual graft area between subcutaneous and subperiosteal Dmp1-

Cre grafts ($p < 0.01$, Fig. 1I). This difference was not observed between subcutaneous and subperiosteal Tnfsf11fl/fl;Dmp1-Cre grafts ($p = 0.17$). Residual graft volume ($p = 0.08$, Fig. 1J) and thickness ($p = 0.13$, Fig. 1K) did not differ significantly among the groups. Regeneration of the donor areas was comparable between Tnfsf11fl/fl;Dmp1-Cre and Dmp1-Cre mice and restricted to the defect margins.Without osteocyte-derived RANKL, bone grafts remained virtually unreactive, showing neglectable signs of either resorption or new bone formation. Bone grafts with undisturbed osteocytic expression of RANKL showed substantial resorption when placed subcutaneously, and resorption as well as visible new bone formation when placed subperiosteally. Within the limitations of our study, the results suggest an active function of osteocyte-derived RANKL within the bone graft remodeling cascade.

Live Cell, Confocal and Tissue Clearing/3D Imaging in Mice Expressing a Membrane-GFP targeted to Osteocytes, Odontoblasts and Cementocytes
*Yixia Xie[1], David Moore[1], Eleanor Ray[1], Lisa Le[1], Sarah Dallas[1]. [1]University of Missouri - Kansas City, United States

High resolution 3D imaging of cells in hard tissues is challenging due to the light scattering properties of mineralized matrix. Resolving fine detail of osteocyte, cementocyte & odontoblast dendritic processes requires cell-specific staining methods targeting the membrane or specific substructures in the dendrites. Using transgenic mice expressing a membrane-bound GFP driven by the 10kb Dmp1 promoter (Dmp1-mGFP mice) or mice co-expressing Dmp1-mGFP & a LysM-Cre/tdTomato reporter to target osteoclasts, we have used 3D confocal imaging & tissue clearing/3D imaging to define tissue localization of the mGFP reporter and fine cellular detail of osteocytes, odontoblasts & cementocytes in the lower jaw. Samples were counterstained with alexa555-phalloidin to visualize F-actin and DAPI to label nuclei. Dmp1-mGFP mice were also used for confocal live cell imaging to examine osteocyte embedding dynamics. 3D confocal imaging on 50?m cryosections in 7d mandibles showed Dmp1-mGFP expression in osteocytes, odontoblasts, pulpal cells adjacent to odontoblasts and a subset of mature osteoblasts. Membrane-targeting of GFP enabled resolution of branching & fine detail of odontoblast processes (Fig.1) and osteocyte dendrites. Dmp1-mGFP was also expressed in cementocytes in 2mo mice. Dmp1-mGFP also labeled 80-500nm extracellular vesicle-like particles, at the dentin-enamel junction adjacent to odontoblast processes (Fig 1, arrows) and throughout the mineralized bone & cementum matrix, which likely represent matrix vesicles that initiate mineralization. PEGASOS clearing enabled deep tissue imaging and lightsheet imaging enabled 3D reconstruction of Dmp1-mGFP & LysM-Cre/td tomato expression in the intact mandible and virtual sectioning in any plane. This also revealed Dmp1-GFP expression in a subset of cells in blood vessels supplying the cervical loop region of the incisor. Long term live cell imaging of osteocyte embedding in calvarial explant cultures revealed Dmp1-mGFP first switching on in post mitotic polygonal cells that extended and retracted dendrites during embedding/positioning. Live imaging of osteoclasts & osteocytes revealed that the majority (95%) of osteocytes die during the process of bone resorption. We conclude that the Dmp1-mGFP mouse is a valuable tool for studying differentiation of mineralizing cell types and imaging their fine structure and is compatible with high resolution confocal imaging, tissue clearing/3D lightsheet imaging & live cell imaging.

FRI-360

The role of NFATc1 in 1,25 dihydroxyvitamin D mediated regulation of osteocyte lacuno-canalicular remodeling *Supriya Jagga[1], Niusha Manoochehri Arash[2], Melissa Sorsby[2], Eva Liu[1]. [1]1 Division of Endocrinology, Diabetes, and Hypertension, Brigham and Women's Hospital, Boston, Massachusetts 02115 2 Harvard Medical School, Boston, Massachusetts 02115, United States. [2]Division of Endocrinology, Diabetes, and Hypertension, Brigham and Women's Hospital, Boston, Massachusetts 02115, United States

Osteocytes are multifunctional bone cells that act as modulators of mineralized matrix resorption. They reside in small cavities of bone called lacunae and form an extensive canalicular network of dendrites (lacuno-canalicular network, LCN) for cell-cell interaction. Bones from mice with X-linked hypophosphatemia (Hyp), which have impaired production of 1,25 dihydroxyvitamin D (1,25D), demonstrate abnormal LCN organization, with enlarged lacunae, impaired canalicular structure, and enhanced osteocyte expression of bone resorption genes compared to WT. Administration of 1,25D or an anti-FGF23 targeting antibody to Hyp mice improves LCN organization, supporting a role for 1,25D in regulating LCN remodeling. In support of this, bones from mice lacking the vitamin D receptor (VDR) in osteocytes (VDRf/f;DMP1Cre+) have impaired LCN organization compared to control, demonstrating that osteocyte-specific actions of 1,25D regulate LCN remodeling. In osteoclasts, the transcription factor nuclear factor of activated T cells cytoplasmic 1 (NFATc1) induces the expression of matrix resorption genes to acidify the extracellular environment and enhance bone resorption. Since osteocytes also acidify their microenvironment and resorb matrix, we hypothesize that NFATc1 plays a role in 1,25D-mediated LCN remodeling. Consistent with this hypothesis, 1,25D suppresses Nfatc1 mRNA expression in IDG-SW3 osteocytes, and knockdown of Nfatc1 expression by lentivirus carrying anti-Nfatc1 shRNA in IDG-SW3 cells attenuates the 1,25D-mediated suppression of matrix resorption gene expression and blocks the 1,25D-mediated suppression of RANKL-induced acidification of the osteocyte microenvironment. These data show that NFATc1 is required for 1,25D-mediated regulation of perilacunar remodeling in vitro. Corresponding with the in vitro data, VDRf/f;DMP1Cre+ osteocytes have enhanced Nfatc1 and matrix resorption gene

expression. To determine the role of NFATc1 in 1,25D mediated LCN remodeling, histomorphometric analyses of tibiae from mice lacking osteocyte-specific NFATc1 (NFATc1f/f;-VDRf/f;DMP1Cre+) were performed, demonstrating that bones from these mice have decreased lacunar size, decreased immunoreactivity for matrix resorption marker cathepsin K, and improved canalicular structure compared to VDRf/f;DMP1Cre+ control. Taken together, the current study demonstrates that NFATc1 is necessary for 1,25D-mediated regulation of osteocyte LCN remodeling.

Bone formation by osteoid-osteocytes and osteocytes in C57Bl/6 mice *Sarah Ford[1], Svetlana Komarova[2], Katharina Jähn-Rickert[3], Kerstin Tiedemann[2], Elizabeth Zimmermann[2, 1], [2]McGill University, Canada, [3]University Medical Center Hamburg-Eppendorf, Germany

Purpose: Bone formation is described as occurring on bone surfaces by osteoblasts. However, as bone forming osteoblasts become entrapped in the bone matrix, these so-called osteoid-osteocytes may continue to produce bone matrix while differentiating into osteocytes [1]. Mature osteocytes deeply embedded in the bone have also been observed to remodel their surrounding bone matrix in lactation and hibernation: a process termed perilacunar remodeling [2]. The contribution of osteocyte-driven bone remodeling in the regulation of healthy bone tissue is currently unknown.Methods: Skeletally mature female C57Bl/6 mice received two calcein injections. MMA-embedded undecalcified L3-L5 vertebrae sections were prepared. A region of interest (ROI) of trabecular bone was identified and the bone area of the ROI was measured on brightfield images. Osteocyte lacunae with calcein labels were identified on z-stacks imaged with confocal microscopy. Lacunae were classified (Fig. 1) as osteoid-osteocytes (in or adjacent to the line of osteoblast bone formation) or mature osteocytes (> 3 µm from osteoblast bone formation labels). Bone formation rate (BFR) due to osteoblast activity on bone surfaces followed ASBMR guidelines. BFR of mature osteocytes was measured as follows:BFRosteocyte=(L.Th)/(Ir.L.t) ((sLSocy)/(Ocy.S)) L.Th is label thickness, Ir.L.t is time between calcein injections, and sLSocy is lacunar label length. Ocy.S is total osteocyte surface calculated as the product of lacunar density, bone area and average lacunar perimeter.Results: Active bone formation was observed in 206 +/- 64 lacunae/mm2. Around 80-90% of labeled lacunae were associated with bone forming osteoid-osteocytes (173 +/- 50 lacunae/mm2) and 16% mature osteocytes (33 +/- 6 lacunae/mm2). The osteoblast BFR was 3.17 µm/day and the osteocyte BFR was 0.078 nm/day (not including osteoid osteocytes).Conclusion: Here, we observed that a majority of bone formation at lacunae occurs at osteoid-osteocytes, which should be distinguished from mature osteocytes. BFR due to osteocyte activity may seem small, but perilacunar remodeling is an emerging phenomenon for which the implications on bone quality and bone fragility are not fully understood.References:1. Hypoxia Inducible Factor-2? Predominantly Contributes to Cortical Microarchitecture of Vhl cKO mice *Sarah Mendoza[5], Benjamin Osipov[2], Deepa Murugesh[3], Blaine Christiansen[4], Gabriela Loots[5], Damian Genetos[6], Clare Yelllowley[5, 5]University of California, Davis, , [2]UC Davis Health, , [3]Lawrence Lvermore National Lab, United States, [4]University of California Davis Health, United States, [5]University of California, Davis, United States, [6]University of California, Room 1020 VM3B, United States

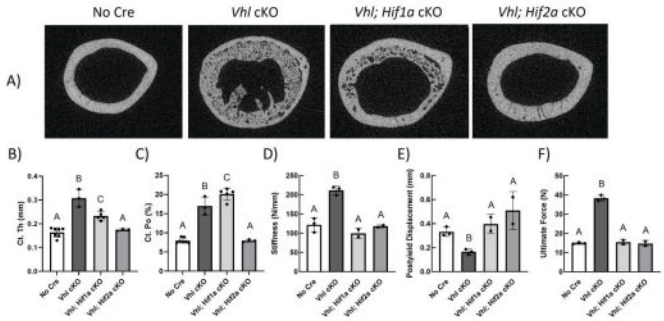
Osteoporosis causes more than 8.9 million bone fractures every year, predominantly affecting the increasingly aging population. Current osteoporotic therapies are undeniably suboptimal due to their adverse side effects and attenuated efficacy. Thus, identification of novel therapeutic targets that provide lifelong improvements in bone mass and quality are necessary. Hypoxia inducible factor (HIF) signaling is required for skeletal health and maintenance. HIFs are transcription factors composed of an oxygen-dependent HIF-? subunit (transcriptionally active isoforms: HIF-1?, HIF-2?) and a constitutively stable nuclear HIF-? subunit. Under normoxic conditions, HIF-? subunits are hydroxylated and targeted for degradation by an E3 ligase complex Von Hippel-Lindau (VHL). Under hypoxic conditions, HIF-? subunits escape VHL-mediated degradation, complex with HIF-?, and induce osteoanabolic gene expression. We've shown that deletion of osteocytic (OCY) Vhl generates a strikingly high bone mass (HBM) phenotype, and deletion of OCY Hif1a or Hif2a showed no effect on skeletal microarchitecture. However, expressing a degradation-resistant OCY HIF-2?, not HIF-1?, generated a HBM phenotype. To determine the requirement of HIF-2? in generating the Vhl cKO HBM phenotype, we utilized 16-week-old mice with dual OCY Vhl and Hif1a (Vhl;Hif1a cKO) or Hif2a (Vhl;Hif2a cKO) deletion. Micro-computed tomography revealed that deletion of Vhl with Hif1a (n=5) or Hif2a (n=3) partially mitigated the trabecular phenotype, whereas dual deletion of Hif2a and Vhl fully mitigated the cortical phenotype. To determine effects on biomechanical integrity, we conducted three-point bending tests on contralateral femora from Vhl;Hif1a cKO (n=2), Vhl;Hif2a cKO (n=2), Vhl cKO (n=3) and cre-negative control (n=3) mice. We found that dual deletion of Vhl and Hif1a or Hif2a fully mitigated cortical stiffness, postyield displacement (PYD), and ultimate force to cre-negative levels, while the Vhl cKO showed increased stiffness and ultimate force with decreased PYD. Although HIF-2? appears to predominantly determine cortical microarchitecture in the Vhl cKO, HIF-? isoform-specific contributions to biomechanical integrity are less clear. Future studies will evaluate HIF-? isoform-specific effects on tissue mechanical properties and collagen orientation that contribute to the mitigated biomechanical phenotype we observe. DKM and GGL conducted work under the auspices of the USDOE by LLNL (DE-AC52-07NA27344).



Hypoxia inducible factor-2α predominantly contributes to cortical microarchitecture of *Vhl* cKO mice. Representative microCT mid-sagittal images of left femora from (A) *cre*-negative, *Vhl* cKO, *Hif1a*; *Vhl* cKO, and *Hif2a*; *Vhl* cKO mice. Investigating Osteocyte Morphology in Crtap -/- Mouse Model of Recessive Osteogenesis Imperfecta *Carolina Leynes[1], Ellen Busschers[1], Mary Adeyeye[1], Iwen Song[1], Yangjin Bae[1], Brendan Lee[1, 1]Baylor College of Medicine, United States

Osteogenesis Imperfecta (OI) is characterized by short stature and brittle bones. OI type VII has been associated with the loss of CRTAP (Cartilage-associated protein) which is responsible for post-translational modifications of type I collagen via 3-hydroxylation of Pro986 of chain alpha1(I) and Pro707 of chain alpha2(I). Currently, Crtap-/- mice are used as a model for recessive OI as mice present with a decrease in body size, osteo-chondrodysplasia, kyphosis, and severe osteopenia. Furthermore, our lab and others have shown Crtap-/- mice have upregulated transforming growth factor-? (TGF-?) resulting in decreased bone volume to total bone volume (BV/TV), maximum load, and ultimate strength. In addition, an increase in osteoclast, osteoblast, and osteocyte was observed in Crtap-/- mice. Previous studies in children with OI type I and V have also shown an increase in osteocyte number in cortical and trabecular bone compared to age match controls. Given osteocytes' mechanosensory and bone regulatory role via sclerostin and RANKL secretion, we studied

morphological changes in osteocytes of Crtap-/- mice. In this study, we collected femurs from Crtap-/- and WT mice of 4 months of age (n=6) and performed phalloidin staining on 30 ?m sections. Using Imaris analysis software, we processed the images and analyzed osteocyte dendrite length, branch depth, branch level, and area. Our analysis showed an increase osteocyte number, consistent with our and others' previous report, and a decrease in dendrite branch length, depth, level, and area in Crtap-/- mice compared to WT control mice. Our data suggest Crtap-/- mice have decrease osteocyte branching complexity which might be correlated to the decrease in bone mass, maximum load, and ultimate strength previously published by our group. Future studies will further determine the changes in dendrite network after 1D11, an anti-TGF-? treatment, in Crtap-/- mice and investigate the underlying molecular changes in osteocytes of OI models such as Crtap-/- mice and additional OI mouse models.

Poloxamer-188 treatment rescues osteocytes with an impaired ability to repair plasma membrane disruptions caused by mechanical loading *Anik Tuladhar[2], Joseph Shaver[2], Wesley McGee[2], KANGLUN YU[3], Wendy B. Bollag[2], Mark W. Hamrick[2], Meghan McGee-Lawrence[4]. [2]Augusta University, , [2]Augusta University, United States. [3], , [4]Medical College of Georgia, Augusta University, United States

We and others have seen that osteocytes sense high-impact osteogenic mechanical loading via transient plasma membrane disruptions (PMDs) which initiate downstream mechanotransduction. However, a PMD must be repaired for the cell to survive this wounding event. The protein Prkd1 (PKC-?) was suggested to play a crucial role in PMD repair via vesicular exocytosis, and our previous studies implicated it as an important mediator of bone adaptation to mechanical loading, where inhibition or deletion of Prkd1 in osteocytes delayed PMD repair rate, decreased cell viability, and blunted the bone's response to in vivo mechanical loading. To determine if impaired osteocyte PMD repair rate can be rescued, the current study investigated whether the FDA-approved synthetic copolymer Poloxamer 188 (P188) can mediate membrane repair and stability in Prkd1-targeted osteocytes. We generated an osteocyte-targeted Prkd1 conditional knockout (CKO) mouse from which primary osteocytes were isolated, and used MLO-Y4 cells and Prkd1 inhibitors to test the effects of P188 on PMD repair rate. MLO-Y4 cells were treated with P188 (2%) for 24hrs followed by Prkd1 inhibitors (kbNB 142-70, 10 ?M; staurosporine, 100 nM) or vehicle for 30 minutes and subjected to laser wounding using a 2-photon microscope (Zeiss) in the presence of membrane impermeant FM1-43 fluorescent dye. Prkd1 inhibitors significantly delayed PMD repair rate (p=0.017), and this effect was rescued by P100 treatment (p=0.001). Similar beneficial effects of P188 treatment on PMD repair rate were seen in Prkd1 CKO primary osteocytes (p=0.010). MLO- Y4 cells were seeded into flow chamber slides, treated with P188 followed by Prkd1 inhibitors as described above, and exposed to fluid flow shear stress (50 dynes/cm^2; 5 minutes; Harvard Apparatus). Viability was assessed 10 minutes after flow exposure ceased via PI staining. Prkd1 inhibition impaired post-wounding cell survival in osteocytes (p=0.0005) subjected to flow, but treatment with P188 significantly (p=0.00006) improved post-wounding viability. To test the efficacy of P188 treatment in vivo, we injected the Prkd1 CKO mice with P188 (460mg/kg) 30mins before osteogenic tibial loading bouts (alternating days for 2 weeks) and saw a significant improvement in the bone mineral density in the loaded tibia (p=0.0006) as compared to the controls. Our findings suggest a potential therapeutic application of P188 in improving osteocyte membrane repair and promoting bone health.

Irisin modulates murine osteocytic osteolysis in a sex and age-specific manner *Anika Shimonty[1], Fabrizio Pin[1], Matt Prideaux[1], Gang Peng[1], Lynda Bonewald[1]. [1]Indiana University School of Medicine, United States

Irisin, a hormone generated by the proteolytic cleavage of Fibronectin type III Domain Containing protein 5 (FNDC5) has been described to have beneficial effects on the brain and fat, but effects on bone are contradictory [1], as some studies have found positive effects but our studies have shown that irisin deletion protects against bone loss due to ovariectomy [3]. Recently we have shown that irisin deletion also protects against bone loss with lactation and a low calcium (Ca) diet in females but exacerbates male mice bone loss due to a low Ca diet. To determine if irisin plays a role in bone loss with aging, 5 and 20-month (mo)-old mice were compared. No differences were observed between WT and FNDC5 global KO female mice (BV/TV; 57.5% WT:58.5% KO), however, male KO mice, 5 and 20 mo, had higher BV/TV (60.8% KO:57.6% WT) but less biomechanical strength compared to WT males (ultimate force; 18.5N KO:22.1N WT, stiffness;78.6Nmm KO:94.3Nmm WT). With a low Ca diet, both 5 and 18 mo female KO were partially protected against bone loss and weakness: (BV/TV;43.2% KO:40.4% WT), ultimate force (17.8N KO:15.7N WT) and stiffness (59.8Nmm KO:43.4 Nmm WT). In contrast, both 5 and 18-mo male KO mice lost more bone and had lower bone volume (BV/TV; 48.6% KO:55.4% WT) on a low Ca diet and lower ultimate force (14.9N KO:18.4N WT). To begin to identify responsible molecular mechanisms, RNAseq was performed on osteocyte-enriched bone from 5 mo old animals as two major functions of the osteocyte are to remove their perilacunar matrix to provide calcium and to produce RANKL to activate osteoclasts. Sex differences showed that the female WT osteocyte transcriptome had higher expression of genes responsible for osteocytic osteolysis including Acp5, Ocstamp, Dcstamp, Ctsk, Tnfsf11, and Mmp13 compared to WT males. This difference was not evident in KO females compared to KO males. On a low Ca diet, KO females had lower expression of osteocytic osteolysis genes such as Tnsfs11 and Ocstamp compared to WT females. Analysis of the osteocyte transcriptome is ongoing. In summary, in young females irisin aids or primes the osteocyte to release Ca under Ca-demanding conditions to possibly aid in offspring survival, however in the aging female, this effect of irisin on osteocyte function becomes detrimental with sex hormone and/or Ca deficiency. In contrast, irisin appears beneficial for males at any age, but especially with aging.1.Maak et al, Endocr Rev, 20212. Kim et al, Cell, 2018

Deletion of Osteocyte-Intrinsic MMP13 is Protective from Temporal Mandibular Joint Osteoarthritis *Cristal Yee[1], Marianne Demirdji[1], Karsyn Bailey[1], Alena Larios[1], Christoforos Meliadis[1], Clarissa Aguirre Luna[1], Sunil Kapila[2], Tamara Alliston[1]. [1]University of California, San Francisco, United States. [2]University of California, Los Angeles, United States

Osteocytes support the crosstalk between cartilage and subchondal bone that maintains joint homeostasis. In human knee osteoarthritis (OA), osteocyte perilacunar-canalicular remodeling (PLR) and MMP13 expression are suppressed. Using mice with an osteocyte-intrinsic deficiency in MMP13 (MMP13ocy-/-), we showed that suppression of MMP13-dependent PLR is sufficient to cause early OA in the knee. However, whether these mechanisms are conserved in the fibrocartilaginous temporomandibular joint (TMJ), which differs from the knee in its anatomy, cell types, and OA progression, remains unclear. We aim to determine the cellular and molecular mechanisms that distinguish progression of knee and TMJ osteoarthritis (TMJOA) and if osteocytic MMP13 plays a causal role in the TMJ degeneration as it does in the knee. Given the importance of osteocytic MMP13 in knee joint homeostasis, we hypothesize that osteocytic-ablation of MMP13 will compromise PLR and exacerbate degeneration of the TMJ.Male MMP13ocy-/- mice and littermate controls (Ctrl, n=6 mice/group) at 12 weeks of age, were injected with saline or 0.10 mg of monosodium iodoacetate (MIA) in the intra-articular joint of the TMJ, a model of TMJOA. After 28 days post injection, TMJs were assessed for cartilage degeneration and lacunar canalicular network (LCN) integrity. Unlike the knee, genotype-dependent differences in the TMJ cartilage were not apparent in a modified Mankin score among the uninjured controls or saline-treated Ctrl and MMP13ocy-/- mice. As expected, MIA significantly increased the TMJ Mankin score in Ctrl mice, with excessive Safranin-O staining of the chondrocyte pericellular matrix, disorganization of TMJ chondrocytes, and changes in the histological boundary between cartilage and bone. However, MMP13ocy-/- mice were protected from MIA-induced TMJOA. MIA-injected MMP13ocy-/- TMJs showed no change in Mankin scores compared to the MMP13ocy-/- saline-injected group. Further, silver nitrate staining of the LCN showed an MIA-dependent increase in subchondral bone osteocyte number in the Ctrl mice that was absent in the MMP13ocy-/- TMJ. Therefore, we find that ablation of MMP13 in TMJ osteocytes plays a protective role in the TMJ, preventing MIA-induced OA and osteocytic deregulation. Thus, osteocyte-intrinsic MMP13 plays a distinct role in knee and TM joint homeostasis, providing new insight into the differential susceptibility of these joints to OA.

Sex Differences in in vivo Osteocyte Ca2+ Signaling and Gap Junction Inhibition *JAMES BOORMAN-PADGETT[1], Randy Valcourt[2], Bridget Saw[3], Jelena Basta-Pljakic[2], Mia Thi[4], David Spray[3], Mitchell Schaffler[5]. [1], United States. [2]City College of New York, United States. [3]Albert Einstein College of Medicine, United States. [4]ALBERT EINSTEIN COLLEGE OF MEDICINE, United States. [5]The City College of New York, United States

INTRODUCTION: Osteocytes (Ot) in vivo exhibit a highly coordinated Ca2+ signaling response to mechanical loading, in which number of responding Ot increases in proportion to increasing applied strain [1,2]. Earlier studies established this signaling pattern in female mice. Whether Ot in males respond similarly to loading is unknown. Here, we compared Ot Ca2+ signaling responses to loading in male vs female mice and further tested whether signaling in both sexes responded similarly to gap junction inhibition.METHODS: Osteocyte Ca2+ signaling responses to mechanical loading were examined in tamoxifen inducible GCaMP6f Ca2+ indicator mice (4 mo, n=22F/30M). Studies used urethane anesthesia, which unlike isoflurane does not interfere with gap junctions [3]. This allowed us to test gap junction function using the inhibitor carbenoxolone (CBX). 3rd metatarsals (MT3s) were cyclically loaded to test strains of 250-3000 ??; 2-photon microscopy was used to image Ca2+ fluorescence in diaphyseal Ot during loading [1,2]. CBX was given after the first (baseline) loading bout and 20 minutes were allowed for diffusion into the bone; loading and imaging studies were then repeated. Cumulative in vivo fluorescent signal intensity as a function of time was calculated for each osteocyte in the region of interest (>1000 cells/group). Ot Cx43 gene and protein expression were determined.RESULTS: Ot in male mice showed ~40% greater cumulative fluorescent signal intensity with loading than Ot in female mice [Fig 1A] and occurred at all strain levels. Blocking gap junctions slightly reduced cumulative signal

intensity in males. In contrast, blocking gap junctions in females dramatically attenuated Ca2+ signal intensity. Cx43 mRNA and protein levels were significantly higher in male than female Ot [Fig 1B, 1C - mRNA: 1.4-fold; Protein: ~2.5-fold].DISCUSSION: Our studies reveal unexpected differences in loading-induced osteocyte Ca2+ signaling in male and female mice. The reasons underlying this sex difference in Ot response to loading remain obscure, but may include sex hormones effects and/or intrinsic biological differences between males and female cells [4,5]. Indeed, the more profound Ot response to gap junction inhibition in female mice may reflect such a biological difference, as female Ot express comparatively less Cx43 at both gene and protein levels.REFERENCES:1)Lewis+ PNAS 2017 2)Lewis+ JoVE 2023 3)Burt+ Cir Res 1989 4)Lewis+ Bone 2021 5)McNamara+ Curr Ost Rep 2021

Disparate impact of osteocyte oxygen-sensing mechanisms on bone quality *Kristina Wells[1], Sarah Mendoza[4], Alice Wong[1], Deepa Murugesh[3], Gabriela Loots[4], Clare Yellowley[5], Damian Genetos[6]. [1]UC Davis, United States. [4]University of California, Davis, . [3]Lawrence Lvermore National Lab, United States. [4]University of California, Davis, United States. [5]University of California School of Veterinary Medicine, United States. [6]University of California Davis, United States

Bone strength involves bone quantity and quality, with bone quantity receiving greater engagement and investigation than bone quality. Ideal osteoanabolic therapies will involve both the quantity and the quality of bone matrix. We have recently demonstrated that constitutive osteocytic oxygen sensing (degradation resistant HIF2a, HIF2cDR) or a regulatory protein upstream of oxygen sensing (Vhl cKO) produce unique high bone mass phenotypes. While both disruptions increase cortical and trabecular bone, HIF2cDR does not phenocopy Vhl KO either in quantity of bone produced or apparent bone organization. Understanding overlapping and unique contributions to bone quality in Vhl cKO vs. HIF2cDR will identify ideal targets for osteoanabolic therapies. We developed mice with osteocyte-enriched (10kb-Dmp1-cre) deletion of Vhl, Hif1a, or Hif2a or degradation-resistant HIF1A or HIF2A and established distinct impact of these deletions on bone strength, which was increased in Vhl cKO and reduced in HIF2cDR mice compared to wild-type controls. We next used ?CT to evaluate total mineral density distribution of knockout and transgenic femora. Both Vhl cKO and HIF2cDR mice had reduced mid-cortical peak mineral and mean mineral density, indicating impaired tissue material properties despite distinct impact on bone strength. Collagen alignment, analyzed by second-harmonic generation, was altered in each genotype relative to wild-type controls. Finally, we sought a potential mechanism for the differences in bone quality. SPARC - a matrix mineralization protein involved in collagen fibrillogenesis- is regulated by both hypoxia and Vhl in myriad cell types; absence of SPARC causes osteopenia and impairs both the organic and mineral content of bone. IHC staining revealed higher Sparc levels in both HIF2acDR and Vhl cKO compared to wild-type bones, with greater staining in Vhl cKO compared to Hif2cDR. In summary, manipulating oxygen-sensing pathways in osteocytes elicits high bone mass phenotypes with diverse outcomes on bone quality.DKM and GGL conducted work under the auspices of the USDOE by LLNL (DE-AC52-07NA27344)

Previous Fracture and Subsequent Fracture Risk: A Meta-analysis to Update FRAX *Eugene McCloskey[5], Helena Johansson[2], Nicholas Harvey[3], Enwu Liu[4], Marian Schini[5], Liesbeth Vandenput[4], Mattias Lorentzon[6], William Leslie[7], John Kanis[4], and the FRAX Meta-analysis Cohort Group. [8]. [5]University of Sheffield, United Kingdom. [2]University of Gothenburg, Sweden. [3]University of Southampton, . [4]Australian Catholic University, Australia. [5]University of Sheffield, . [6]Sahlgrenska Academy, University of Gothenburg, Sweden. [7]University of Manitoba, Canada. [8]Sheffield, United Kingdom

The aim of this study was to quantify the fracture risk associated with a prior fracture on an international basis and to explore the relationship of this risk with age, sex, time since baseline and bone mineral density (BMD).We studied 665,971 men and 1,438,535 women from 64 cohorts in 32 countries followed for a total of 19.5 million person-years. The effect of a prior history of fracture on the risk of any clinical fracture, any osteoporotic fracture, major osteoporotic fracture and hip fracture alone was examined using an extended Poisson model in each cohort. Covariates examined were age, sex, BMD and duration of follow up. The results of the different studies were merged by using the weighted ?-coefficients.A previous fracture history, compared with individuals without a prior fracture, was associated with a significantly increased risk of any fracture (Hazard ratio, HR = 1.88; 95% CI = 1.72-2.07). The risk ratio was similar for the outcome of osteoporotic fracture (HR = 1.87; 95% CI = 1.69-2.07), major osteoporotic fracture (HR = 1.83; 95% CI = 1.63-2.06) or for hip fracture (HR = 1.82; 95% CI = 1.62-2.06). There was no significant difference in risk ratio between men and women. Subsequent fracture risk was marginally downward adjusted when account was taken of BMD. Low BMD explained a minority of the risk for any fracture (14%), osteoporotic fracture (17%), and for hip fracture (33%). The risk ratio for all fracture outcomes related to prior fracture decreased significantly with adjustment for age and time since baseline examination.A previous history of fracture confers an increased risk of fracture of substantial importance beyond that explained by BMD. Its quantitation on an international basis permits the more accurate use of this risk factor in case finding strategies.

Development of Artificial Intelligence System for Predicting Areal Bone Mineral Density from Plain Radiographs *Huy Nguyen[1], Dinh Tan Nguyen[2], Thach Tran[3], Lan Ho-Pham[4], Tuan Nguyen[5]. [1]The University of Technology Sydney, . [2]University of Technology Sydney, . [3]Garvan Institute of Medical Research, Australia. [4]Saigon Precision Medicine Research Center, Viet Nam. [5]University of Technology Sydney , Australia

Background and Aim: Currently, dual-energy X-ray absorptiometry (DXA) is the gold standard for measuring bone mineral density (BMD) and diagnosing osteoporosis, but DXA is not widely available in low-resource settings. In this study, we developed an Artificial Intelligence (AI) system to estimate BMD from plain radiographs for osteoporosis screening. Methods: The development of AI algorithms was based on 5134 plain X-rays, and the testing was based on 1926 plain X-rays from the Vietnam Osteoporosis Study. Anteroposterior and oblige digital X-ray hip and spine were taken by FCR Capsula XLII (Fujifilm Corp., Tokyo, Japan). We used seven backbone models, including VGG16, VGG19, ResNet34, ResNet50, ViTB16, ConvNextB, and RegNetY16F, to extract 1000 features from each radiograph. From the features, we developed models to estimate areal BMD at the lumbar spine, total hip, and femoral neck. We termed the estimated BMD as 'xBMD'. We then compared xBMD with DXA-based areal BMD (aBMD) measured at the lumbar spine, total hip, and femoral neck (Hologic Horizon, Hologic Corp., Bedford, MA, USA). The concordance between xBMD and aBMD was assessed by the coefficient of correlation and the Bland-Altman approach. Results: The correlation between xBMD and aBMD was 0.87, 0.91, and 0.90 for the lumbar spine, total hip, and femoral neck, respectively. The correlation was greater in women than men, but the difference was not statistically significant (p-overall = 0.568). When aBMD was used to classify into osteoporosis vs non-osteoporosis, the discrimination of xBMD was high, with area under the ROC curve (AUC) being 0.92 for lumbar spine, 0.95 for total hip and 0.94 for femoral neck.Conclusion: These results suggest that it is possible to accurately predict areal BMD from plain radiographs, and that the AI system developed here can be used as an effective tool for opportunistic screening osteoporosis in high-volume settings.

Automated Deep Learning-based CT-Scout View Assessment of Prevalent Vertebral Fractures *Eren Bora Yilmaz[1], Till Yannik Fricke[2], Claus-C Glueer[3], Carsten Meyer[2]. [1]Christian-Albrechts-Universität Kiel , . [2]Ostfalia University of Applied Sciences, Germany. [3]Christian Albrechts Universitaet zu Kiel, Germany

Automated detection and grading of vertebral fracture status on computed tomography (CT) scout scans using artificial intelligence (AI) may be useful for both diagnosis and opportunistic prognostic evaluation of fracture risk (no added radiation dose). 2D localizer images (scout scans) taken as part of a CT protocol to select the scan range usually cover a larger area of the spine than the final 3D CT volume and thus may provide more comprehensive information on prevalent vertebral fractures, a key risk factor for future fracture. Aim: To develop and test an AI tool for classification and grading of fractures on CT scout scans. Method: "fNet" is a deep CNN that was previously applied to 3D CT volumes (Yilmaz et al., 2023) and was modified to work with 2D scout scans. It was used to classify the fracture status of individual vertebrae based on 2D image patches centered on vertebral bodies (47 × 47 mm at 1 mm/px) that were extracted using ground truth vertebral body center coordinates. The model was trained on scout scans from the Diagnostik Bilanz dataset (147 scout scans from 7 centers, 1798 vertebrae, 127 fractured, 101 with fracture grade>=2, 32 with grade 3). Ground truth (vertebral body center coordinates and per-vertebra fracture status) for T4-L4 was previously annotated by a trained radiologist using slices of 3D CT volumes. Experiments were conducted in a 4-fold cross-validation setting also used to compute mean confidence intervals (noted +/- in the following). Results: For classifying osteoporotic fractures (positive class; Genant SQ grades 1 - 3) versus normal vertebrae (negative class; Genant SQ grade 0 and deformities), the model achieved 90.6%+/-1.5% ROC-AUC. At a classification threshold of ?=0.05 the sensitivity was 81%+/-4%, the specificity 86%+/-1.3%. When regarding Genant SQ grades 2 and 3 as positive class, ROC-AUC, sensitivity and specificity (?=0.05) were 91.5%+/-0.8%, 85%+/-2% and 85%+/-1.0%, respectively. Finally, with only SQ grade 3 as positive class, we obtained 95.9% 0.8%, 87%+/-7% and 90.6%+/-0.8%, respectively. Discussion: In previous experiments on 3D CT volumes instead of scout scans we reported AUC=98.4%+/-0.4%for the classification of "0-1 vs 2-3". 2D vs 3D differences and image quality of the scout scans could be reasons for lower AUC. Conclusion: To our knowledge this is the first automatic vertebral fracture assessment method on CT scout scans. We demonstrated robust classification performance across three fracture classification tasks.

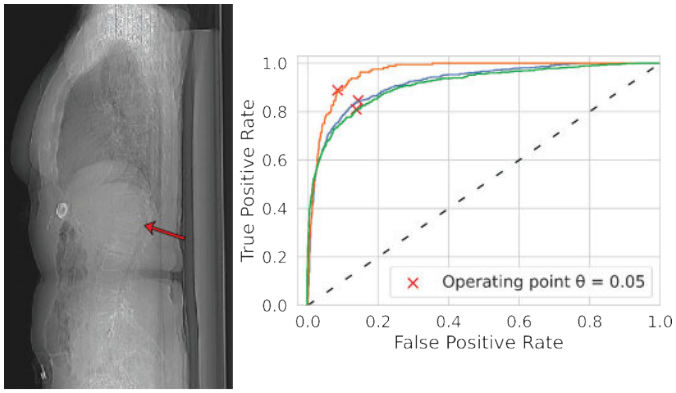

Figure: Vertebral fracture detection on CT scout scans. Left: Arrow indicates indicates Genant SQ grade 3 fracture fracture that was correctly detected by the model. Right: ROC-Curves for binary classifications of fracture grades "0 vs 1-3" (green line), "0-1 vs 2-3" (blue line), and "0-2 vs 3" (orange).

Joint Prediction Incident Fractures by Prevalent Vertebral Fracture & Abdominal Aortic Calcification Ascertained by Automated Algorithms in Clinical Practice *John Schousboe[1], Joshua Lewis[5], Barret Monchka[3], Siobhan Reid[3], Michael Davidson[3], Doug Kimelman[3], Mohamed Jafari Jozani[3], Cassandra Smith[4], Marc Sim[5], Zulqarnain Gilani[5], David Suter[5], William Leslie[3]. [1]Park Nicollet Clinic HealthPartners Institute University of Minnesota, . [5]Edith Cowan University, Australia. [3]University of Manitoba, Canada. [4]Victoria University, . [5]Edith Cowan University,

Background: Prevalent vertebral fracture (PVFx) and abdominal aortic calcification (AAC) jointly are associated with incident fractures. The need for trained interpreters of lateral spine bone mineral density (BMD) images remains a barrier to widespread ascertainment of PVFx and AAC in older adults. Our aim was to estimate the joint associations of PVFx and AAC ascertained by automated algorithms in clinical practice with incident major osteoporotic (MOF), hip, and any clinical fracture.Methods: Separate convolutional neural networks (CNNs) were used to develop automated algorithms to identify fractured thoracolumbar vertebrae and score AAC using the Framingham scale on lateral spine bone density images obtained in the province of Manitoba at the time of bone densitometry between 2010 and 2017. In a separate test set of 6,371 individuals (mean [SD] age 75.8 [6.9], 93% female), automated vertebral fracture status was determined and AAC scored and categorized as low (score 0-1), moderate (2-5) or high (6-24). Cox models were used to estimate associations of PVFx and AAC with incident fractures, adjusted for other covariates and each other. Cumulative incidence of fractures over 5 years in subsets defined by AAC level and PVFx status were calculated accounting for competing mortality. The importance of predictor variables relative to each other for prediction of all three fracture types was compared using Wald chi-square statistic of the full model with each single predictor variable left out vs included.Results: 15% had PVFx, 41% had low AAC, 33% had moderate AAC, and 27% had high AAC. PVFx had higher importance than any other predictor for MOF, second most important for any clinical fracture prediction after age (Figure), and third most important for hip fracture prediction after age and BMD. AAC was of moderate importance for predicting all fracture types. Compared to low AAC, those with high AAC had a fully-adjusted HR 1.32 (95% CI 1.05-1.66) for MOF and HR 1.42 (95% C.I. 0.95-2.11) for hip fracture. The 5-year cumulative incidence of MOF was 7.1% in those with low AAC and no PVFx, 10.1% in those with high AAC and no PVFx, 12.9% in those with low AAC & PVFx, and 16.7% in those with high AAC and PVFx.Conclusions: Ascertainment of both PVFx and AAC on lateral spine bone density images using automated algorithms can aid fracture risk assessment and stratification amongst older individuals undergoing bone densitometry in clinical practice.

Estimating 'Skeletal Age' by Bone Loss in Elderly Men and Women *Ngoc Huynh[1], Krisel De Dios[1], Thach Tran[1], Tuan Nguyen[2]. [1]University of Technology Sydney, Australia. [2]University of Technology Sydney , Australia

Background and Aim: Skeletal Age is defined as the age of the skeleton as a result of a fracture or exposure to risk factors that elevate the risk of fracture. Higher rates of bone loss are associated with an elevated risk of both fracture and mortality. In this study, we aimed to assess the impact of bone loss on bone fragility by estimating skeletal age using bone loss in elderly men and women. Methods: We analyzed the data from the Study of Osteoporosis Fracture (SOF) and Osteoporotic Fractures in Men (MrOS) that included 9704 women and 5994 men aged 64 years and above. Bone mineral density (BMD) at the femoral neck was measured at baseline and subsequent visits. Mortality was ascertained from death certificates and hospital records. We limited the analysis to those with at least 3 BMD measurements (3848 women and 2925 men). The linear regression model was used to estimate the rate of change in BMD for each individual. The multivariable Cox's proportional hazard model was used to quantify the contribution of the rate of BMD change to mortality, adjusted for age, body mass index, smoking status, alcohol consumption, dietary calcium intake, estrogen and bisphosphonate treatment. The magnitude of the association between bone loss and mortality was then transformed into the number of years of life lost using Gompertz's law of mortality and the US life table. Skeletal age is then determined by the sum of chronological age and years of life lost. Results: In women, the average rate of change in femoral neck bone mineral density (BMD) was found to be -0.61 +/- 1.2% [mean+/-SD] per year, while in men, it was -0.16 +/- 0.9% per year. Throughout the study, 1942 women and 1949 men died. For women, each standard deviation [SD] increase in femoral neck BMD loss was linked to a 1.2-fold (95%CI, 1.1-1.3) increase in total mortality, while for men, the increase was 1.4-fold (95%CI, 1.35-1.5) after adjusting for age, baseline FNBMD, BMI, smoking and drinking status. Additionally, each SD increase in bone loss was associated with a loss of 1.9 years and 3.5 years of life in women and men, respectively. For the same rate of bone loss, men experienced a more substantial loss of years of life than women. Moreover, a 60-year-old woman with a femoral neck BMD loss of more than 2% is estimated to have a skeletal age of 63.5 years. Conclusion: In elderly men and women, excess bone loss is associated with an increased loss of years of life and accelerated bone fragility.

Effect of Race/Ethnicity on United States FRAX Calculations and Treatment Qualification: A Registry-Based Study *William Leslie[1]. [1]University of Manitoba, Canada

Since 2008 the United States has had four race/ethnic FRAX® calculators: White ("Caucasian"), Black, Asian, and Hispanic. The ASBMR Task Force on "Clinical Algorithms for Fracture Risk" has been examining the implications of retaining race/ethnicity in the US FRAX calculators.AIM: To compare treatment qualification based upon existing US FRAX race/ethnicity calculators and a hypothetical US population-based FRAX calculator. METHODS: The study sample consisted of all DXA assessments in Manitoba women aged 50 years or older from 1996-2018, with at least one year of prior coverage to assess FRAX inputs. Race/ethnicity was self-identified (119,243 White, 485 Black, 2,816 Asian, insufficient Hispanic for analysis). We computed FRAX scores according to each US calculator and the proportion exceeding intervention cutoffs (>20% for major osteoporotic fracture, MOF; >3% hip for fracture, and combined with prior fracture and T-score criteria as per the Bone Health and Osteoporosis Foundation, BHOF). We then estimated these measures for a hypothetical population-based FRAX calculator derived as the weighted mean for the US population based upon current US Census Bureau statistics.RESULTS: With identical inputs, the highest FRAX measurements were seen with the White FRAX calculator, lowest measurements with the Black calculator, with intermediate measurements for the Asian and Hispanic calculators. The percentage of women with FRAX scores exceeding the hip fracture treatment threshold was 32.0% for White, 1.9% for Black and 19.7% for Asian women; the MOF treatment threshold was exceeded for 14.9% of White, 0.0% of Black, and 3.5% of Asian women. Disparities in treatment qualification were reduced when additional BHOF criteria including DXA T-score were considered. When fracture risk was recalculated for non-White women using the White FRAX calculator, mean values for Asian women slightly exceeded those for White women but for Black women remained substantially below those for White women. When using a single population-based FRAX calculator for non-White women the mean probability of fracture and treatment qualification increased across the age range, and for Asian women slightly exceeded that for White women.CONCLUSION: Use of a single population-based FRAX calculator, rather than existing US race/ethnic FRAX calculators, will reduce differences in treatment qualification and may ultimately enhance equity and access to osteoporosis treatment.

Proportion of women with high fracture risk according to self-reported race/ethnicity using race/ethnicity-concordant FRAX calculator and population-based FRAX calculator.

Postmenopausal women with normal BMD who have fracture have deteriorated microarchitecture by HRpQCT: a prospective analysis from The OFELY Study *Elisabeth Sornay-Rendu[1], Roland Chapurlat[2], francois duboeuf[2]. [1]INSERM UMR1033, Universit? de Lyon, France. [2]INSERM UMR 1033, France

Alterations of bone microarchitecture (MA) contribute with low areal BMD to skeletal fragility but the contribution of cortical and trabecular (Tb) architecture to the risk of fracture (Fx) has rarely been evaluated prospectively in women with normal areal BMD. The aim of this study was to prospectively investigate the prediction of fragility Fx by bone MA assessed by HR-pQCT in postmenopausal women without low BMD.We measured at the 14th annual follow-up of the OFELY study, bone MA at the distal radius and tibia with HR-pQCT (XTreme CT, Scanco Medical AG, Bassersdorf, Switzerland) in addition to areal BMD with DXA, in 589 postmenopausal women. Among them, 169 (29%) women, mean (SD) age 65 (9) yr, had normal BMD defined as a T score>=-1 at the lumbar spine, femoral neck and total hip. During a median [IQR] 14 [12-15] yr of follow-up, 46 of those women sustained incident fragility Fx, including 19 women with a major osteoporotic Fx (hip, clinical spine, shoulder or wrist). Women who sustained Fx did not differ for age, BMI, tobacco use, prior Fx, FRAX, aBMD and TBS compared with women without incident Fx. In contrast, they had significant impairment of volumetric densities (vBMD) (-0.4 to -0.6 SD), cortical area (Ct.Ar) and cortical thickness (Ct.Th) (-0.7 SD) at the radius, and alterations of stiffness (K) and estimated failure load (FL) (-0.4 to -0.6 SD) at both sites, compared with women without incident Fx .At the radius, each SD decrease of several baseline values of bone MA was significantly associated with an increased MOF risk with hazard ratios [HR(95%CI)] of 2.69 (1.45-4.97) for Tt.vBMD, 2.10 (1.15-3.82) for Tb.vBMD, 1.73 (1.05-2.84) for Ct.vBMD, 1.75 (1.05-2.94) for Ct.Ar, 2.20 (1.30-3.72) for Ct.Th, 2.01 (1.13-3.59) for K and 1.97 (1.10-3.51) for FL. At the tibia, each SD decrease of Tt.vBMD, Ct.Ar, K and FL were also significantly associated with an increased MOF risk (HR from 2.10 to 2.26).We conclude that fragility fractures are associated with deterioration of bone MA even in women with normal areal BMD,that may justify a therapeutic intervention.

Trajectories of Areal Bone Mineral Density Significantly Differ by Patterning of Femoral Neck Area and Bone Mineral Content Across the Menopausal Transition *Aleda Leis[1], Karl Jepsen[1], Kerry Richards-McCullough[2], Tom Richards[2], ERIN BIGELOW[3], Robert Goulet[4], Carrie Karvonen-Gutierrez[5]. [1]University of Michigan, United States. [2]University of Michigan , United States. [3]UNIVERSITY OF MICHIGAN, United States. [4]Michigan Medicine, University of Michigan, United States. [5], United States

Clinical use of areal bone mineral density (aBMD) to identify individuals at risk of fracturing assumes that aBMD change reflects bone mineral content (BMC) change. However, differences in the rate and magnitude of BMC and bone area changes over time may affect the reliability of aBMD. Understanding how different trajectories of BMC and area affect aBMD is thus central to improving our use of DXA measures to monitor bone health. This study examined the differential impact of BMC and area trajectories across the menopausal transition (MT) on aBMD. The Michigan Bone Health and Metabolism Study (MBHMS) is a longitudinal study of women; participants aged 24-50 were recruited in 1992 and followed near-annually through 2010. Femoral neck bone data were assessed using DXA. The sample included 138 women with an observed non-surgical final menstrual period (FMP); a DXA scan 10 years prior to FMP; and at least one post-FMP DXA. Group-based growth trajectory modeling was used to determine trajectory groups of area and BMC. Smoothed loess curves were constructed to examine trajectories of aBMD within each area (lowest, middle, highest) and BMC (slowest decline, moderate decline, and fastest decline) trajectory combination. Cross-tabulations of area and BMC trajectory group showed very few individuals in both the BMC fastest decline trajectory group and the area lowest trajectory group, and in the BMC slowest decline trajectory group and area highest trajectory group. The most common combinations were lowest area/slowest decline BMC (23.2%) and middle area/moderate decline BMC (21.0%). Those in the highest area/fastest decline BMC trajectory groups had the largest decline in aBMD from first to last study visit (mean 13.3% decrease, SD 8.7%; Fig. 1), while those in the highest area trajectory and the slowest BMC decline trajectory had the least decline in aBMD (mean 2.2% decrease, SD 5.9%). Understanding bone health with aging using trajectories of BMC and area change represents a novel approach to examining the significant heterogeneity across the MT, a critical life stage for musculoskeletal health. Notably, our analysis showed women who started at higher aBMD with significant BMC loss may not have been identified earlier as high risk though they show the greatest loss pattern. This information may be highly informative in identifying women at greatest risk for low aBMD and future risk for fracture.

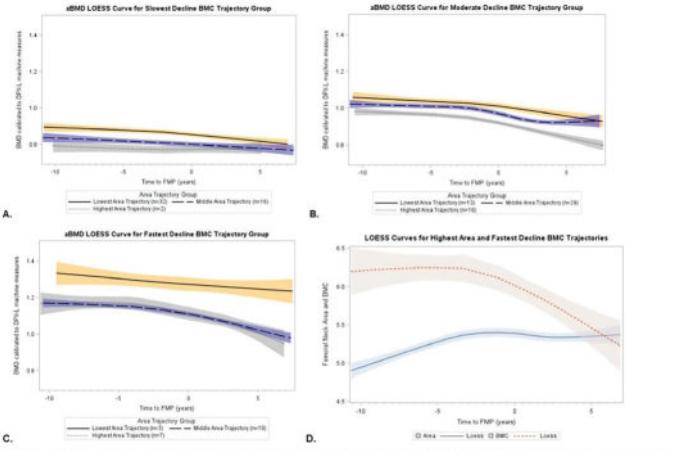

Figure 1. Loess curves for (A) aBMD by area trajectory group for those in the slowest decline BMC trajectory group, (B) aBMD by area trajectory group for those in the moderate decline BMC trajectory group, (C) aBMD by area trajectory group for those in the fastest decline BMC trajectory group, and (D) femoral neck area and BMC for those in the highest area and fastest decline BMC cross-tab trajectory group.

Associations of Cardiorespiratory Fitness with HR-pQCT Bone Parameters in Older Adults: The Study of Muscle, Mobility and Aging (SOMMA) *Nina Heilmann[2], Kerri Freeland[2], Reagan Moffit[2], Nancy Glynn[2], Lauren S. Roe[3], Tong Yu[2], Nicole Sekel[2], Kristen Koltun[2], Katelyn Guerriere[4], Julie Hughes[4], Bradley Nindl[2], Ashley Weaver[5], Paolo Caserotti[6], Peggy Cawthon[7], Anne Newman[2], Jane A. Cauley[8], Elsa Strotmeyer[2]. [2]University of Pittsburgh, . [2]University of Pittsburgh, United States. [3], . [4]US Army Research Institute of Environmental Medicine, United States. [5]Wake Forest University, United States. [6]Department of Sports Science and Clinical Biomechanics and the Center for Active and Healthy Ageing, Denmark. [7]San Francisco Coordinating Center, United States. [8]UNIVERSITY OF PITTSBURGH, United States

Cardiorespiratory fitness and bone mass and strength decline with age, yet few studies have assessed the relationship of cardiorespiratory fitness with bone health in older adults. Physical activity (PA) is related to cardiorespiratory fitness and is recommended for preventing bone loss and osteoporosis. Whether cardiorespiratory fitness is associated with bone health independent of PA is unknown. The Study of Muscle, Mobility and Aging (SOMMA) included baseline assessments of VO2peak from treadmill cardiopulmonary exercise testing using the modified Balke protocol. We investigated associations of absolute VO2peak (mL/min) with bone mineral density (BMD) from dual-energy X-ray absorptiometry (DXA) and bone microarchitecture and strength from high-resolution peripheral quantitative computed tomography (HR-pQCT) collected in the SOMMA Bone Ancillary Study at the year 1 visit. In 124 men (age 76.2+/-4.3 years, 93% White) and 189 women (age 76.2+/-4.2 years, 87% White), relative VO2peak (mL/kg/min) was higher in men (23.8+/-5.5) vs. women (19.6+/-4.6; p<0.001). Bone outcomes differed between men and women (p<0.001) so analyses were stratified with sex-specific z-scores used in linear regression. Models (Table 1) were adjusted for age (years), race (White/non-White), weight (kg), >=1 alcoholic drink/week (y/n), total activity counts from valid wrist-worn accelerometry (>=3 days with >=10 h wear), comorbidity count (0-7), and limb length. In men, higher VO2peak was associated with higher tibial (standardized[std] ?=0.26, p<0.05) and radial (std ?=0.30, p<0.05) failure load, but not with DXA or other HR-pQCT parameters. Higher VO2peak was associated with higher radial trabecular (Tb) BMD (std ?=0.26, p<0.05) and cortical (Ct) area (std ?=0.25, p0.05) after adjusting for total activity. Associations were consistent when adjusting for moderate-to-vigorous PA instead of total activity counts. No significant associations were found between VO2peak and bone outcomes in women. Positive associations of VO2peak with failure load found in older men suggest cardiorespiratory fitness is associated with bone outcomes in a sex-specific manner. Future studies need to explore reasons for sex differences of VO2peak and bone outcomes.

Associations of Muscle Strength and Functional Power to Longitudinal Change in HR-pQCT Bone Parameters: the Osteoporotic Fractures in Men (MrOS) Study *Nina Heilmann[2], Kerri Freeland[2], Tong Yu[2], Paolo Caserotti[3], Andrew Burghardt[4], Mary Winger[5], Nancy Lane[6], Jane A. Cauley[7], Elsa Strotmeyer[2]. [2]University of Pittsburgh, , [2]University of Pittsburgh, United States, [3]University of Southern Denmark, Denmark, [4]University of California, San Francisco, United States, [5]UPMC Insurance Services Division, United States, [6]University of California, Davis Medical Center, United States, [7]UNIVERSITY OF PITTSBURGH, United States

Both bone and muscle function decline with age and are anatomically and functionally related. However, whether and to what extent muscle function (i.e., strength and power) may predict longitudinal changes in bone microarchitecture and strength is unclear. The Osteoporotic Fractures in Men Study (MrOS) included assessments of peak jump muscle power (W) from force plate and grip strength (kg) from dynamometer tests, both normalized to body weight at Visit 4 (2014-2016). We investigated associations of power and grip strength with annual % change in tibial and radial bone parameters of geometry, structure and estimated failure load from high-resolution peripheral quantitative computed tomography (HR-pQCT) between Visit 4 and Visit 5 (2020-2022; 6.2+/-0.6 years follow-up; N=224; age 82.8+/-3.0 years; 88% White). Mean power was 22.9+/-5.6 W/kg and grip strength was 0.49+/-0.1 kg/kg. The largest declines were observed for tibial (-1.0+/-1.3%/year) and radial (-1.1+/-1.8%/year) failure load. Partial correlations of power and grip strength with % change in HR-pQCT outcomes adjusted for age, race, study site, height, and limb length were weak (all r<0.30), though significant associations were largely maintained in multivariable linear regression (Table 1), additionally adjusting for respective HR-pQCT initial values, % absolute weight change, and history of myocardial infarction and congestive heart failure. Higher power was associated with greater %/year increase in tibial Tb.Ar, though greater %/year decrease in tibial Ct.Ar and Ct.Th (all p<0.05). Higher grip strength was significantly associated with greater %/year increase in tibial Tb.Ar (p<0.05) and marginally associated with %/year decrease in tibial Ct.Th (p=0.05). Power and grip strength were not associated with change in failure load or Tb.Th at either site, or with radial Ct.Ar, Tb.Ar, and Ct.Th. Most associations of higher jump power and grip strength in older men were with tibial components of bone geometry and structure. Future analyses will examine changes in tibial and radial BMD. For the tibial site, both power and grip strength predicted changes in Tb.Ar, Ct.Ar, and Ct.Th, suggesting potential mechanisms for bone loss and targets for musculoskeletal interventions.

Table 1. Adjusted linear regression standardized β coefficients of power & grip strength with change in HR-pQCT outcomes

Degree of Trauma in Clinical Fractures with Advancing Age in Older Men *Kristine Ensrud[1], Sheena Patel[2], Lisa Langsetmo[3], Peggy Cawthon[4], Howard Fink[3], John Schousboe[5], Douglas Bauer[6], Jane A. Cauley[7], Eric Orwoll[8]. [1]University of Minnesota and Minneapolis VA Health Care System, United States, [2], , [3]Minneapolis VA Medical Center, United States, [4]San Francisco Coordinating Center, United States, [5]Park Nicollet Clinic HealthPartners Institute University of Minnesota, , [6]University of California, San Francisco, United States, [7]UNIVERSITY OF PITTSBURGH, United States, [8]Oregon Health & Science University, United States

Among community-dwelling older adults, the proportion of fractures (fxs) due to severe trauma is higher in men vs. women. However, the extent to which the degree of trauma in fxs in older men varies with advancing age is unknown.We used data from 1424 MrOS men aged >=65 yrs at baseline who experienced 2351 clinical fxs during a mean (SD) follow-up of 9.9 (5.7) yrs. Participants were contacted every 4 mos until death, termination from study or Feb 2023 to ascertain incident fxs confirmed by radiographic reports. When a fx was reported, staff interviewed the participant about circumstances. Fxs were classified as fall or nonfall related and coded according to degree of trauma. Degree of trauma was considered minimal (fall from <= standing height), moderate (fall on stairs, steps or curb), or severe (fall from > standing height) for fall related fxs, and minimal (coughing), moderate (collisions with objects during normal activity without falling), or severe (motor vehicle accident) for nonfall related fxs.Of the 2351 fxs, 298 (12.7%) occurred in men <75 yrs, 370 (15.7%) in men 75-79 yrs, 613 (26.1%) in men 80-84 yrs and 1070 (45.5%) in men >=85 yrs. 1891 (80.4%) of all fxs were the result of a fall; this proportion was greater with older age at the time of the fx, ranging from 65.8% in men <75 yrs up to 84.7% in men >=85 yrs (p<0.001 across age groups). Six of every 10 (61.5%) of the 1891 fall related fxs were due to minimal trauma, while over half (53.5%) of the 460 nonfall related fxs were due to severe trauma. The proportion of fxs due to severe trauma was lower in a graded manner with advancing age, irrespective of whether the fx was due to a fall or not (Figure). The proportion of fxs due to a fall with severe trauma was 18.5% in men <75 yrs declining to 3.8% in men >=85 yrs (p<0.001 across age groups); the proportion of fxs due to severe trauma without a fall was 19.5% in men <75 yrs declining to 8.4% in men >=85 yrs (p<0.001 across age groups). In contrast, the proportion of fxs due to a fall with minimal trauma was higher in a graded manner with increasing age (p0.98).Among community-dwelling older men, proportions of both fall and nonfall related fxs due to severe trauma decrease with advancing age. Fall-related fxs due to minimal trauma are increasingly common with advancing age and comprise an increasing proportion of all fx events.

Current trends in the risk of subsequent fracture after initial fracture, and post-fracture treatment among commercially insured postmenopausal women in the United States *Min Kim[1], Vanessa Brunetti[9], Felicia Cosman[3], Jeffrey Curtis[4], Mike Lewiecki[5], Matthew Phelan[6], Peter Samai[7], MICHELE MCDERMOTT[8], Tzu-Chieh Lin[9], M Alan Brookhart[10], Kathleen Hurwitz[6, 1], United States. [9]Amgen Inc., United Kingdom. [3]Columbia University College of Physicians and Surgeons, United States. [4]University of Alabama at Birmingham, United States. [5]New Mexico Clinical Research & Osteoporosis Center, United States. [6]Target RWE, Inc, United States. [7]University of North Carolina at Chapel Hill, United States. [8]Amgen, United States. [9]Amgen Inc., United States. [10]Duke University, United States

BackgroundRecent studies suggest that post-fracture pharmacologic management has been declining in the U.S. despite an increase in the burden of osteoporosis (OP). In light of this treatment gap, few studies have reported on the incidence of subsequent fracture risk among commercially insured postmenopausal women with a history of fracture.MethodsWe assembled a retrospective cohort of women aged >=50 years from 2012-2021 using an administrative claims database of privately insured or employer-sponsored Medicare Advantage coverage. Osteoporotic fractures were identified by >=1 insurance claims with a relevant diagnosis and/or procedure code for an open or closed fracture. Treatments for osteoporosis were identified by prescription fills or medical procedure claims. The cumulative incidence of a new, subsequent fracture at the same or a different anatomic site was estimated for any (clinical vertebral, hip, femur, pelvis, tibia, fibula, radius/ulna/distal forearm, humerus, clavicle, rib, sternum), major (any fracture excluding extremities, clavicle, rib, sternum), hip, and clinical vertebral fractures occurring >=90 days of initial index fracture to up to 2 years. Women were followed from the index fracture for up to 2 years to estimate the cumulative incidence of any treatment uptake. All analyses used inverse probability weighting to adjust for differential censoring due to differences in demographics and clinical risk factors. ResultsAmong the 483,564 women with any initial fracture (mean age 74.8), the 1-year cumulative incidence of a subsequent fracture at any site was 11.6%, which increased to 19.1% at 2 years (Figure). The same-site subsequent fracture risk was highest for women with an initial clinical vertebral fracture: 10.1% experienced a subsequent vertebral fracture at year 1 and 15.9% at year 2. Among women with an initial hip fracture, 12.2% and 19.6% experienced a subsequent fracture at any site after 1 and 2 years, respectively, while 8.0% and 12.2% experienced a subsequent hip fracture at 1 year and 2 years, respectively. Most patients did not receive pharmacological treatment one year (91.7%) and two years (89.4%) after their initial fracture.ConclusionAlthough clinical guidelines specify that OP is a lifelong, chronic disease requiring ongoing management, recent data over a 10-year period show that recurrent fracture rates within 2 years are high, while pharmacological treatment remains underutilized in this high-risk population.

Associations of Metabolic Syndrome (MetS) with Fall Rates and Fall Injuries: Results from the Objective Physical Activity and Cardiovascular Health in Older Women (OPACH) *Chen Hu[1], Kerri Freeland[1], Michael LaMonte[2], Marcia Stefanick[3], Kristine Ensrud[4], Jane Cauley[1], Andrea LaCroix[5], Elsa Strotmeyer[1]. [1]University of Pittsburgh, United States. [2]University of Buffalo, United States. [3]Stanford University, United States. [4]University of Minnesota Twin Cities, United States. [5]University of California San Diego, United States

MetS is an increasingly prevalent disorder that consists of a cluster of metabolic conditions. Previous studies found individual MetS components were associated with falls and fall injuries in older adults, though the association of MetS, as a constellation, with these outcomes is unknown. We aimed to evaluate whether MetS was associated with higher fall rates and fall injury risk among older women in a community-based cohort in the OPACH, an ancillary study of the Women's Health Initiative (WHI). Participants were 5,548 women (mean 79.0+/-6.7 years; 63.4% White; 30.8% obese) who had a blood draw and physical measurements during 2012-2013, and >1 month of fall calendars over a 13-month follow-up. MetS (Y/N) was defined as having?>=3 of 5 criteria per NCP/ATP-III guidelines: waist circumference?>88 cm, fasting glucose >=100 mg/dL or hypoglycemic medication use, systolic BP?>=130 or diastolic BP?>=85 mmHg, high-density cholesterol?<50 mg/dL, and triglycerides >=150 mg/dL. Falls and fall injuries were ascertained by monthly fall calendars and telephone interviews. Poisson regression examined MetS associations with fall rates. Weighted logistic regression was used for MetS associations with fall injuries (Y/N), while accounting for sampling strategies for interviews. MetS (N=1,125) was present in 20.3% the cohort and 43.6% (N=2,417) reported >=1 fall. Fall injuries were reported in 35.6% (508/1,428) over mean 11.9+/-2.3 mo. of follow-up. In unadjusted models, MetS was associated with 17% higher fall rates (RR=1.17, 95%CI=1.10-1.24) and 17% higher odds of fall injuries (OR=1.17, 95% CI=1.02-1.34). After adjusting for age, race (White/Black/other), ethnicity (Hispanic/non) and obesity (BMI>=30) the association persisted between MetS and fall rates (RR=1.12, 95%CI=1.04-1.20), but the association between MetS and fall injuries was attenuated to null (OR=1.08, 95%CI=0.93-1.24). In addition to MetS, obesity was an independent risk factor of higher fall rates (RR=1.16, 95%CI=1.08-1.25). Age-stratified adjusted analyses found MetS associated with higher fall injuries (OR=1.18, 95%CI=1.00-1.39) in women aged 65-85 years (N=1,159), but a non-significant inverse association (OR=0.83, 95%CI=0.57-1.10) in women aged >85 years (N=269). MetS was associated with higher fall rates in women >=65 years and injurious falls in women <85 years. Further studies should evaluate potential mechanisms of individual MetS components and how comorbidities may contribute to these associations.

Evaluating Fractures by Race and Ethnicity in a Diverse Sample of Postmenopausal Women - Results from the Women's Health Initiative

*Nicole Wright[1], Steven Ing[2], Joseph Larson[3], Carolyn Crandall[4], Shawna Follis[5], Marcia Stefanick[5], Jane A. Cauley[6]. [1]University of Alabama at Birmingham, United States. [2]The Ohio State University Wexner Medical Center, United States. [3]Fred Hutchinson Cancer Center, United States. [4]University of California, Los Angeles, United States. [5]Stanford Prevention Research Center, Department of Medicine, Stanford University, United States. [6]UNIVERSITY OF PITTSBURGH, United States

Background: The Women's Health Initiative (WHI) recently released more comprehensive race and ethnicity to provide much needed longitudinal fracture data in multiple race and ethnic groups.Methods: The WHI recruited 161,808 postmenopausal women. Women identified as one of the following racial categories: White, Black/African American, American Indian/Alaskan Native, Asian Indian, Chinese, Filipino, Japanese, Korean, Vietnamese, Other Asian, Native Hawaiian, Samoan, Guamanian or Chamorro, or Other Pacific Islander; and one of the following Hispanic ethnic categories: Not Spanish/Hispanic, Cuban, Mexican, Puerto Rican, Other Spanish. Fractures of interest included any clinical fracture, hip, and major osteoporotic fracture (MOF). We computed crude fracture incidence rates per 10,000 woman-years and used Cox proportional hazards model to estimate fracture risk compared to non-Hispanic White women after adjusting for age. For Asian and Hispanic women, we estimated within group fracture risk using the most prevalent subgroup as the reference.Results: Our final analytic sample included 154,948. Over 17.2 years of follow-up 67,213 (43.4%) women experienced any clinical fracture, including 8,677 (5.6%) and 34,545 (22.3%) hip and MOFs, respectively. Women sustaining a fracture were significantly older, White, not Hispanic, highly educated, more physically active, and reported more falls in the past year. Compared to White women, Black, Asian, and Native Hawaiian/Pacific Islander women had significantly lower risk of any clinical fracture and MOF (Table). Black and Asian women had significantly 71% and 52% lower risk of hip fracture compared to White women, respectively (Table). Within Asian women, Filipino women had 23% [0.77 (0.61, 0.99)] lower risk of fracture compared to Japanese women (Table). Hispanic women had 8%, 44%, and 10% lower risk of any clinical, hip, and MOF compared to non-Hispanic women, respectively (Table). Within Hispanic women, Cuban women had 95% [1.95 (1.05, 3.63)] higher risk of hip fracture compared to Mexican women (Table).Discussion: Our study showed significant differences in fracture rates and fracture risk by race, Hispanic ethnicity, and within Asian and Hispanic groups. These data can be used to provide current and more granular information on fractures in communities of color for future research and updates to fracture risk prediction tools that incorporate race and ethnicity.

Medications, Fracture Risk and Oral Bisphosphonate Efficacy - Evidence from a Well-Characterized Prospective Clinical Trial in Older Women

*Andre Tan[1], Eugene McCloskey[7], Zhangan Zheng[3], Nicholas Harvey[4], Mattias Lorentzon[5], John Kanis[6], Marian Schini[7]. [1]National University Health System, Singapore. [7]University of Sheffield, United Kingdom. [3]The Second People's Hospital of Wuhu, China. [4]University of Southampton, . [5]Sahlgrenska Academy, University of Gothenburg, Sweden. [6]Australian Catholic University, Australia. [7]University of Sheffield,

Epidemiological studies have reported several medication classes to be associated with effects on bone mineral density and fracture risk but have largely been unable to adjust for potential confounders. Having observed an interaction between NSAID use and oral bisphosphonate efficacy, we explored the relationship between other baseline medication use and fracture risk in the same cohort.This was a post-hoc analysis of a well-documented, randomized, placebo-controlled study of the oral bisphosphonate, clodronate, in 5212 community dwelling women aged 75 years or more followed for 3-5 years. At baseline, medication classes used by at least 250 women (approximately 5% of the cohort) were identified. Cox regression analysis was used to investigate the hazard ratio (HR) between medication class and osteoporotic fracture risk in univariate and adjusted models. Potential covariates included age, BMI, BMD, other FRAX risk factors excluding alcohol exposure, bone turnover markers, muscle strength and recent falls.In the placebo arm, no association with fracture risk was observed for beta-blockers, angiotensin-converting enzyme inhibitors, loop diuretics, thiazide diuretics, nitrates, digoxin, proton pump inhibitors (PPIs), H2 receptor antagonists, antacids, tricyclic antidepressants, or first-generation antipsychotics. However, compared to non-users of the drug class, the incidence of osteoporotic fractures was higher in users of calcium channel blockers (CCB, n=843, HR 1.49, 1.11-2.01, p = 0.008) and benzodiazepines (BNZ, n=690, HR 1.59, 95% CI 1.15-2.18, p = 0.004) in unadjusted models. When adjusted for significant differences from non-users in risk factors, CCB but not BNZ remained associated with osteoporotic fractures (HR 1.59, 1.13-2.23, p = 0.007). In the clodronate arm, neither BNZ nor CCB were associated with fracture risk. However, PPI use was significantly associated with increased osteoporotic fracture risk in clodronate treated women (HR 1.63, 1.23-2.16, p < 0.001) but not placebo treated women. This association persisted following adjustment for risk factors (HR 1.93, 1.26-2.97, p=0.003).The association of BNZ with fracture risk appears to be largely mediated through co-existing risk factors. The increased risk of osteoporotic fractures with CCB appears independent of measured risk factors but is prevented by bisphosphonate therapy. Concomitant PPI use negated the effect of clodronate in reducing fracture risk.

Impact of Bisphosphonate Use Following Hip Fracture: A Decade-Long Follow-Up of a Cohort Within a Private Healthcare System

*Betiana Perez[1], Maria Eugenia Vera[1], Luisa Carmen Plantalech[1], Maria Diehl[1]. [1]Hospital Italiano de Buenos Aires, Argentina

Bisphosphonate use after hip fracture is useful for secondary prevention and may reduce post-fracture morbidity and mortality. Aims To evaluate the long-term impact of bisphosphonate use after hip fracture in mortality and morbidity. Methods Retrospective cohort study of patients >=50 years from a closed health system hospitalized for a fragility hip fracture between July 2005 and December 2010. Deaths and readmissions were analyzed. Kaplan Meier survival analysis and Cox regressions were performed. Sensitivity analysis with propensity score matching (PSM), considering age, sex, previous fracture and comorbidities was employed to adjust for prescription bias. Results We included 965 patients. The median age was 82.4 years (IQR 77.8-86.6), and 80.7% were female. Secondary prevention with bisphosphonates was administered to 39% of cases within the year after hip fracture. Mortality in the first year was 14.9% and at 10 years 73.2%. Median survival was 5.6 years. The median survival of patients with hip fracture treated with bisphosphonates was 8.33 years, and for those not treated it was 4.06 years (p<0.0001), and remained significantly different after PSM (p= 0.022). Median survival free of readmissions was 2.93 years; 4.02 years for treated with bisphosphonates, and 2.09 years for not treated (p<0.0001), and also remained different after PSM (p= 0.045). Multivariate Cox regression showed that secondary prevention with bisphosphonates remains an independent predictor of survival and survival free of readmissions, even after adjusting for significant covariates (table 1). Conclusions Bisphosphonates positively impacted survival and readmissions in our study after adjusting by demographic variables, comorbidities. However, we could not assess other relevant covariates such as educational level and social support.

	Mortality	Readmissions
Age (each year)	1.08(1.07-1.09) [a]	1.04 (1.03-1.05) [a]
Male sex	1.22(1.01-1.48) [b]	1.12 (0.92-1.37)
Intracapsular fracture	1.46(1.22-1.74) [a]	1.32 (1.10-1.59) [c]
Charlson Index (each point)	1.14(1.08-1.20) [a]	1.17 (1.11-1.23) [a]
Dementia	1.74(1.46-2.07) [a]	1.23 (1.03-1.48) [d]
Congestive heart failure	1.68(1.30-2.17) [a]	1.99 (1.50-2.65) [a]
Secondary prevention with bisphoshonate	0.68 (0.58-0.80) [a]	0.72 (0.61-0.86) [a]

Comparative Effectiveness of Denosumab versus Bisphosphonates among Treatment-Experienced Postmenopausal Women with Osteoporosis in the U.S. Medicare Program *Jeffrey Curtis[1], Tarun Arora[2], Ye Liu[1], Tzu-Chieh Lin[4], Leslie Spangler[4], Vanessa Brunetti[4], Robert Stad[4], MICHELE MCDERMOTT[5], Brian Bradbury[4], Min Kim[4]. [1]University of Alabama at Birmingham, United States. [2]Foundation for Advancing Science, Technology, Education and Research, United States. [4]Amgen Inc., United States. [4]Amgen Inc., Switzerland. [5]Amgen, United States

ObjectivesAlthough clinical trials have shown that transitioning from bisphosphonates (BP) to denosumab (Dmab) increases bone mineral density at key skeletal sites more than remaining on BP, evidence from head-to-head studies evaluating fracture outcomes is lacking. This retrospective observational study compared the effectiveness of Dmab versus BP in reducing fracture risk among treatment-experienced women with postmenopausal osteoporosis (PMO) in the U.S.MethodsFemale Medicare fee-for-service beneficiaries >= 66 years of age with prior history of treatment with an oral BP, who newly initiated Dmab (n~108,000), a different oral BP (alendronate, ibandronate, or risedronate; n=100,649), alendronate (Aln; n=53,165), or zoledronic acid (ZA; n=35,100) between Jan 1, 2012 to Dec 31, 2018 were followed from treatment initiation (index date) until the first instance of a fracture, treatment discontinuation (defined as the end of exposure + 60-day gap) or switch, Medicare disenrollment, death, end of available data (Dec 31, 2019), or 5 years post-index date. A doubly robust inverse-probability of treatment (weights estimated from multivariate logistic regression models) and censoring (weights estimated from multivariate Cox Proportional Hazards regression models) weighted function was used to estimate the relative risk (RR) associated with the use of Dmab compared with oral BP, Aln, and ZA for hip, nonvertebral (NV; includes hip, humerus, pelvis, radius/ulna, other femur), non-hip, nonvertebral (NHNV), hospitalized vertebral (HV), and major osteoporotic (MOP; nonvertebral and hospitalized vertebral) fractures for the overall study period and by year of follow-up. ResultsOver a maximum of 5 years of follow-up, Dmab reduced the risk of hip fracture by 45% (RR=0.55; 95% CI: 0.42-0.68), 37% (0.63; 0.51-0.75), and 38% (0.62; 0.32-0.91), and reduced the risk of MOP fracture by 31% (0.69; 0.61-0.76), 25% (0.75; 0.67-0.82), and 31% (0.69; 0.57-0.82) compared with oral BP, Aln, and ZA respectively (Figure). Similar results were observed for NV, NHNV, and HV fractures, with an increase in the magnitude of fracture risk reduction with increasing duration of exposure across all fracture outcomes. ConclusionIn a large cohort of treatment-experienced women with PMO, we observed robust, clinically meaningful reductions in the risk of hip, NV, NHNV, HV, and MOP fractures for patients on Dmab compared to oral BP, Aln, and ZA; greater reductions in fracture risk were observed with longer duration of exposure.

Romosozumab Increases Modeling-based Bone Formation and Creates a Positive Bone Balance in Remodeling Units at 2 and 12 Months *Erik Eriksen[1], Rogely Boyce[2], Yifei Shi[2], Jacques Brown[3], Donald Betah[2], Cesar Libanati[4], Mary Oates[2], Roland Chapurlat[5], Pascale Chavassieux[5]. [1]Faculty of Odontology, Oslo University, Norway. [2]Amgen Inc., United States. [3]CHU de Québec Research Centre and Laval University, Canada. [4]UCB Pharma, Belgium. [5]INSERM UMR 1033, Université de Lyon, Hospices Civils de Lyon, France

Romosozumab (Romo), a monoclonal antibody against sclerostin, causes an early increase in bone formation that attenuates with treatment and a sustained decrease in bone resorption. Histomorphometric analyses revealed the primary bone-forming effect of Romo is transient early stimulation of modeling-based bone formation (MBBF) on cancellous (Cn) and endocortical (Ec) surfaces. Preclinical studies have demonstrated that Romo may effect changes in the remodeling unit resulting in positive bone balance. Here we compared remodeling bone balance in women treated with Romo vs placebo (Pbo).We analysed bone biopsies from the FRAME clinical trial (NCT01575834) using remodeling site reconstruction to quantify and characterize the changes in bone balance within bone multicellular units (BMU) on Cn/Ec surfaces that may contribute to the progressive improvement in bone mass/structure and reduced fracture risk in women with osteoporosis at high fracture risk. At month (M) 2, the median percentage of MBBF referent to the total bone surface was significantly increased with Romo vs Pbo on Cn (18.0% vs 3.8%; P=0.005) and Ec (36.7% vs 3.0%; P=0.001), but not periosteal (5.0% vs 2.0%; P=0.37) surfaces, with no significant difference in the surface extent of remodeling-based bone formation (RBBF) on all three bone surfaces. Final erosion depth (E.De) at M2 was decreased significantly on the Ec (42.7µm vs 50.7µm; P=0.021) and non-significantly on the Cn surface (38.5µm vs 44.6µm; P=0.11) with Romo vs Pbo. Sector analysis of early Ec formative sites revealed in sector 2 significant increases in osteoid thickness (29.9µm vs 19.2µm; P=0.005) and mineralized wall thickness (W.Th; 18.3µm vs 11.9µm; P=0.004) with Romo vs Pbo. These evolving BMUs may reflect early stimulation of bone formation contributing to the increase in completed W.Th at M12. At M12, there were significant increases in bone balance with Romo vs Pbo on Cn (+6.1µm vs +1.5µm; P=0.012) and Ec (+5.2µm vs ?1.7µm; P=0.02) surfaces; the increase in bone balance was due to a significant decrease in final E.De (40.7µm vs 43.7µm; P=0.05) on Cn surfaces and increased completed W.Th (50.8µm vs 47.5µm; P=0.037) on Ec surfaces.These data suggest that Romo induces a positive bone balance due to effects on bone resorption and formation at the level of the remodeling unit, contributing to the positive effects on bone mass, structure, and fracture risk. This positive balance is further enhanced by significant activation of MBBF.

Antiresorptive Therapy to Reduce Fracture Risk and Effects on Dental Implant Outcomes in Patients with Osteoporosis: A Systematic Review and Consensus Statement *Aliya A. Khan[1], Dalal S. Ali[1], Reza Mirza[2], Archibald Morrison[3], Salvatore Ruggiero[4], Gordon Guyatt[2], Sotirios Tetradis[5]. [1]Division of Endocrinology and Metabolism, McMaster University, Canada. [2]Department of Health Research Methods, Evidence, and Impact at McMaster University, Canada. [3]Citadel Oral and Maxillofacial Surgery, Canada. [4]NYCOMS, United States. [5]University of California, Los Angeles, United States

Background: Placement of a dental implant in a patient on antiresorptive therapy has been hypothesized to increase the risk of Medication-Related Osteonecrosis of the Jaw (MRONJ) and/or impact implant survival. In patients with osteoporosis, the risk of MRONJ with antiresorptive therapy is only marginally higher than observed in the general population1. Due to the invasive nature of implant placement and the increased risk of MRONJ seen in patients undergoing an oral procedure or event2, the International ONJ Taskforce further evaluated this issue.Methods: A systematic review of the literature was conducted and evaluated the outcomes of implant placement in individuals with osteoporosis or osteopenia receiving antiresorptive therapy. The risk of implant failure was evaluated in comparison to age matched individuals not on antiresorptive therapy.Results: Seven studies reported comparative risk estimates of dental implant failure with and without antiresorptive therapy for osteoporosis or osteopenia. A random-effects meta-analysis revealed a non-significant increased risk with antiresorptive agents with wide confidence intervals (RR 1.56, 0.43 - 5.70). The data were reviewed by the International Taskforce, and consensus was achieved on the graded recommendation3,4.Conclusion: In patients with osteoporosis on antiresorptive therapy, the Taskforce suggests that antiresorptive therapy does not need to be stopped prior to proceeding with dental implant (weak recommendation, very low-quality evidence). Current evidence does not suggest an association between antiresorptive therapy and implant failure. There is no evidence that cessation of bisphosphonate or denosumab therapy improves implant survival or reduces the development of MRONJ. Cessation of denosumab is not advised as it has been associated with rebound bone loss and an increased risk of multiple vertebral fractures. This presentation will provide the recommendations of the International Taskforce and also provide details regarding possible pathogenesis and differences in healing following dental extraction in comparison to implant placementReferences: 1.Khan, et al., Diagnosis and Management of ONJ: A Systematic Review and International Consensus. Perioperative Bisphosphonates Did not Impact Healing Following Osteoporotic Fracture Surgery: A Systemic Review and Meta-analysis *Guolin Meng[1], Yuhong Zeng[2], Yuan Yang[3], Jue Wang[3]. [1]Department of Orthopaedics, Xijing Hospital, Fourth Military Medical University, China. [2]Department of Osteoporosis, Red Society Hospital, Xi'an Jiaotong University, China. [3]MA & OR, Organon Research and Development, Organon China, China

Background: Treatment guidelines recommend early bisphosphonates (BPs) following fragility fracture surgery to prevent more fractures. However, the clinical practice needs evidence to guide the timing to initiate BPs. We performed a systematic review and meta-analysis to investigate the effect of perioperative initiation of BPs versus non-perioperative BP

use on healing following fragility fracture repair.Method: The study included randomized controlled trials (RCTs) and cohort studies on adults with fragility fractures at different anatomical sites for surgical procedures (including reduction or fixation). Healing rates and time to healing at the follow-up were primary outcomes and compared between perioperative BP initiation versus non-perioperative BP use [before surgery (prior use) and >=1 month postoperative (delayed use)]. The search was performed in PubMed, Web of Science, the Cochrane Library, and Embase. The analysis presented risk ratio (RR) and mean difference (MD) for binary and continuous outcomes with 95%CI. I2 statistic assessed heterogeneity.Results: The primary analysis pooled 7 studies (5 RCTs; 2 cohort studies, n=912) on patients with alendronate, risedronate, and zoledronic acid and fragility fracture repair. Fracture sites were the spine, the femoral neck, the hip, and the intertrochanteric area. Healing rates at the follow-up for fracture repair did not differ between patients with perioperative and non-perioperative BP initiation (prior or delayed BP use) (RR: 1.00, 95%CI: 0.98, 1.02, I2: 16%). Analysis of pooled RCTs suggested similar results (RR: 1.01, 95%CI: 0.96, 1.06; I2: 58%). Perioperative BP initiation did not significantly shorten the time to healing at the follow-up (MD vs. control: -0.57 week, 95% CI: -2.12, 0.97, I2: 41%). These findings were independent of fracture site or BP treatment. Perioperative BP initiation reduced screw-loosening risk (RR: 0.39, 95% CI: 0.03, 4.56, p=NS). Secondary analysis showed perioperative BP initiation resulted in significantly more reductions in VAS at month 6 (MD: -0.46, 95%CI: -0.81, -0.12) and 12 (MD: -0.75, 95%CI: -1.10, -0.41) following fracture repair than no BP initiation postoperatively.Conclusion: Perioperative BP initiation was not associated with a clinical impact on healing but remarkably improved the long-term pain following fracture repair. Findings may support perioperative BP initiation as an option for osteoporotic patients with fragility fracture surgery.

Effectiveness of zoledronic acid treatment within 14 days of hip fracture surgery. *Betiana Perez[1], Ariela Kitaigrodsky[1], Natalia Aliquo Maciel[1], Ullman Tamara[1], Lucia Coli[1], Rodrigo Greco[1], Ivan Huespe[1], Mirena Buttazzoni[1], Maria Diehl[1]. [1]Hospital Italiano de Buenos Aires, Argentina

Treatment with zoledronic acid (ZA) within 90 days after surgical repair of a hip fracture reduces the occurrence of clinical fractures and mortality. However, there is limited available data regarding the effectiveness of using ZA within the first two weeks. As lockdown limited follow-up during Covid-19 pandemic, ZA began to be indicated during hospitalization with calcium and vitamin D supplementation in our institution. AimTo evaluate the effectiveness of administering ZA within 14 days after surgical resolution of a hip fracture.MethodsRetrospective cohort study of patients >=65 years from a closed health system hospitalized in a tertiary care hospital for a fragility hip fracture between 04/2018 and 04/2022, comparing patients who received ZA within 14 days after surgery (Early-ZA) with those treated between days 15 and 90 after surgery (Later-ZA). The main outcome was the combined event of death or refracture. Analysis was made with chi2 or Fisher for qualitative variables and Wilcoxon for quantitative variables. We performed Kaplan-Meier survival analysis and Cox regressions. We adjusted the regression analysis considering age, Charlson Index and length of the initial hospital stay as potential confounders.ResultsOut of 848 patients, 220 received ZA within 90 days: 163 (74%) within 14 days following hip fracture surgery (Early-ZA) and 57 (26%) between days 15 and 90 (Later-ZA). Median age Early-ZA 88 (IQR 81-92) and Later-ZA 85 (IQR 80-88) p=0.054; 14% male without differences between groups (15.3% vs 10.5%, p=0.36). Median Charlson Comorbidity Index was significantly higher in patients receiving Early-ZA (median 5 IQR 4-5; vs Later-ZA 0 IQR 0-1; p<0.0001). Median hospitalization for hip fracture was 7 days (IQR 5-9) for both groups (p=0.76). During a median follow-up of 502 days, 38 patients died (17.3%); 27 had new fractures (12.3%). Regarding the combined outcome (death or refracture) we did not observe significant differences (Figure), with a crude HR of 1.314 (95%CI 0.74-2.35), and an adjusted HR of 1.011 (95%CI 0.46-2.22). ConclusionsZA administration during in-hospital stay enhances access to secondary fracture prevention. We did not observe differences in the combined outcome of refracture or mortality between Early-ZA and Later-ZA after hip fracture in this preliminary study. After adjusting for confounding variables, HR changed substantially, suggesting a higher burden of comorbidities in patients treated in the first two weeks.

[11]Department of Internal Medicine III with Haematology, Medical Oncology, Haemostaseology, Infectiology and Rheumatology, Oncologic Center, Paracelsus Medical University Salzburg, Salzburg, Austria, Austria. [12]Medical University of Vienna, Comprehensive Cancer Center, Vienna, Austria; ABCSG, Austrian Breast and Colorectal Cancer Study Group, Vienna, Austria, Austria

Background: The placebo controlled randomized phase III ABCSG-18 trial demonstrated that denosumab significantly reduced clinical fractures in postmenopausal patients with breast cancer. Concern exists about a potential rebound effect after treatment discontinuation with denosumab. In line with this, an earlier analysis of ABCSG-18 showed an increased risk for vertebral and multiple vertebral fractures after stopping denosumab. We have therefore conducted a randomized sub-study investigating the use of a single dose of zoledronic acid (ZA) at the end of denosumab therapy. Here we present the first data on bone turnover markers (BTM).Patients And Methods: Patients of the ABCSG-18 trial who had completed denosumab treatment were randomized to a single dose of ZA 5mg i.v. versus nil(=SOC). ZA was administered 8 months+/-4 weeks after the last dose of denosumab (day 1 of this sub-study). DXA scans, lateral spine X-rays and BTM (CTX and osteocalcin) were assessed at baseline and at 6, 12 and 18 months thereafter. New fractures were assessed throughout. The percent change from baseline was derived and compared between arms with stratified Wilcoxon rank sum tests.Results: 50 patients with a median age of 71 years were randomized into this prospective sub-study. 24 received ZA, and 26 did not. Patient groups were well balanced with respect to baseline bone health factors. All patients of the ZA arm and 25 of the SOC arm received 7 doses of denosumab in the ABCSG-18 trial. At baseline, mean CTX was 0.57 ng/ml in both arms, mean osteocalcin was 19.5 ng/ml in the ZA arm and 18.8.ng/ml in the SoC arm. Percentage change of CTX differed significantly between the two arms with a median decrease of CTX after 6 months (-50.0%) and 12 months (-49.5%) in the ZA arm, and a median decrease after 6 months (-7.0%) and after 12 months (-6.5%) in the SOC arm. Accordingly, osteocalcin decreased by a median 17.0% after 6 months and 13.9% after 12months in the ZA arm, but increased by 110.8% after 6 months and by 29.4% after 12 months in the SOC arm. No significant difference of the BTM could be seen after 18 months.

Importantly, the observed increase of BTM in the SOC arm was driven by a few patients with major changes - up to 778.6% for CTX and up to 679.6% for osteocalcin.Conclusion: These first data of the randomized sub-study of the ABCSG-18 trial demonstrate that a single dose of ZA prevents a high bone turnover state that occurs in some patients of the SOC arm after stopping denosumab.

The efficacy of sequential therapy with romosozumab followed by denosumab compared to denosumab alone in hemodialysis patients *Yuichiro Tamagawa[1], Hitoshi Tanigawa[2]. [1]Japan Community Health care Organization Shiga hospital, Japan. [2]Center for Regenerative Medicine and Skeletal Development, Uconn Health, United States

Hemodialysis patients have a high rate of osteoporosis and are a high-risk group for fractures. However, some osteoporosis drugs are contraindicated to severe renal failure patients, and treatment strategies for patients with severe osteoporosis aren't well established. Romosozumab is a monoclonal anti-sclerostin antibody that has the dual effect of increasing bone formation and suppressing bone resorption, reducing the risk of fracture within 12 months. This study aimed to compare the effects of one year of romosozumab followed by one year of denosumab (group R) to two years of denosumab (group D) on bone mineral density (BMD) and bone metabolism markers in hemodialysis patients with severe osteoporosis. This study was a single-center, retrospective study. 19 patients were in group R and 23 in group D, they are all hemodialysis patients. All patients were given these treatments as their first treatment for osteoporosis. Both groups showed significant increase in BMD(T-score) at the lumbar spine and femoral neck after 6 months treatment (group D: +0.32; group R: +0.70), with group R showing a significant increase compared to group D in BMD at the lumbar spine (p=0.0024). The bone metabolism marker P1NP increased significantly in group R at 6 months (+57.4%, p=0.002 vs baseline), and decreased significantly at 12 months (-17.4%, p=0.001 vs baseline). Adverse events were few and none were fatal, including cardiovascular events. P1NP level of group D showed a consistent decrease from baseline. The bone resorption marker TRACP-5b also showed a significant decrease compared to baseline after 6 months in both groups (group D: -42.9%; group R: -17.4%), with group D showing a consistently greater decrease in all the periods. No obvious fractures were not observed. These results suggest that romosozumab treatment followed by denosumab may be a potentially good strategy for hemodialysis patients with severe osteoporosis.

[7]Beth Israel Deaconess Medical Center, Harvard Medical School, United States

PurposeAntiosteoporosis medications are given to individuals of various ages, but we do not know whether the effect is similar in different age groups. The aim of this study was to use data from key trials of antiosteoporosis medications to determine whether the anti-fracture efficacy or BMD changes associated with treatment differ in people above and below 70 years. The threshold was set at this age as it gave similar numbers of subjects in the studies with vertebral fracture as the endpoint.MethodsWe used individual patient data from 23 randomised placebo-controlled clinical trials of antiosteoporosis medications. Data were stratified by age (<70 and >=70 years old), and the treatment-related fracture risk reduction was estimated in each subgroup, using logistic regression for morphometric vertebral fractures and Cox regression for all clinical, non-vertebral, hip and "all" (combination of non-vertebral and clinical or morphometric vertebral fractures) fractures. The treatment effect on 24-month change in BMD was estimated in each subgroup using linear regression. We performed analyses on all trials, and again separately on trials of bisphosphonates only. We tested the interaction between age subgroup and treatment in all analyses.ResultsThese analyses included 123,164 participants; 57% 0.05) (Figure). The use of antiosteoporotic drugs in people aged 70 and older resulted in significantly greater absolute and percent increases in BMD at 24 months at the total hip (3.8% [3.7, 3.9] vs. 3.1% [3.0, 3.2]), femoral neck (3.4% [3.3, 3.5] vs. 3.0% [2.9, 3.1]) and lumbar spine ((4.4% [4.2, 4.5] vs. 3.9% [3.8, 4.0]) (all p<0.0001).ConclusionsIn summary, antiosteoporotic medications reduced the risk of fractures similarly among those above and below 70 years of age but were more effective at increasing BMD among those at least 70 years.

From bench to bedside: Transcriptome profiling in a medaka fish osteoporosis model identifies CXCL9 as a blood marker that predicts the risk for osteoporotic hip fractures in men *Christoph Winkler[1], Quang Tien Phan[1], Kevin Yiqiang Chua[1], Aizhen Yin[1], Woon-Puay Koh[1]. [1]National University of Singapore, Singapore

Bone homeostasis requires reciprocal communication between bone-forming osteoblasts and bone resorbing osteoclasts to maintain bone health. Communication failures result in bone diseases, such as osteoporosis, where uncontrolled osteoclast activity results in excessive bone resorption and bone fractures. To identify novel signalling factors implicated in osteoblast-osteoclast communication, our lab had earlier conducted transcriptome profiling of bone cells in a medaka fish osteoporosis model, which allows high-resolution live imaging of dynamic bone cell behaviour in intact specimen. In this model, transgenic induction of the osteoclast inducer Rankl resulted in excessive osteoclast formation and osteoporotic bone lesions. We showed that under Rankl+ conditions, osteoblasts strongly upregulated expression of the chemokine Cxcl9l. This chemokine in turn led to osteoclast recruitment and differentiation at bone matrix and excessive bone resorption. Mutations in cxcl9l and its cognate receptor cxcr3.2, or treatment with chemical Cxcr3.2 antagonists prevented excessive osteoclast formation and protected medaka bone form osteoporotic lesions. To validate a possible association of the CXCL9 ortholog and osteoporosis or fracture risk in humans, we conducted a matched case-control study nested in the prospective, population-based Singapore Chinese Health Study. This study included 55 men and 119 women who had experienced a hip fracture with an average of 6.3 years after their blood was collected. Participants were matched individually to controls who did not develop hip fractures. We found significantly higher levels of CXCL9 in pre-fracture blood samples of men with subsequent hip fractures compared with their non-fracture controls. Surprisingly, no such differences were seen in women. This suggests that elevated CXCL9 levels affect older men and women differently, possibly due to changes in sex hormone levels during aging. These findings open the possibility that early interventions targeting CXCL9-CXCR3 signalling could be beneficial in preventing hip fractures in older men. This work is funded by a grant from the Singapore Ministry of Education (MOE-T2EP30221-0008).

Endothelin Receptor Blockade Restores SARS-CoV-2-induced Bone Loss in Hamsters *Junguo NI[1], Man Ting Au[1], Kaiming Tang[2], Marianne Lauwers[1], Cuiting Luo[2], Shuofeng Yuan[2], Chunyi WEN[3]. [1]Department of Biomedical Engineering, The Hong Kong Polytechnic University, Hong Kong. [2]State Key Laboratory of Emerging Infectious Diseases, Department of Microbiology, School of Clinical Medicine, Li Ka Shing Faculty of Medicine, The University of Hong Kong, Hong Kong. [3]Hong Kong Polytechnic University, Hong Kong

Purpose: SARS-CoV-2-induced persistent bone loss has been documented in humans and animals. Yet there is no cure for such post-COVID skeletal complications till now. Endothelin signaling, known as a key player in bone homeostasis and disease, was recently shown to upregulate in hospitalized COVID patients. Hereby, we aim to investigate the efficacy of FDA-approved endothelin receptor antagonist, Macitentan, in treating bone loss in hamsters after SARS-CoV-2 infection.Methods: A total of 10 female golden Syrian hamsters at the age of 10-16 weeks were infected intranasally at day 0 with 1×105 PFU SARS-CoV-2. They were randomly allocated to the placebo (PBS) or treatment (0.3 mg/kg Macitentan) groups, that is five hamsters per group. The treatment was initiated during the sub-acute infection phase, i.e. at 16 days post SARS-CoV-2 infection (dpi) and continued for two weeks, which was delivered intraperitoneally with the same volume of PBS as placebo. Five additional hamsters were used as control and received mock infection at the same age as the infected groups. All hamsters were sacrificed at 30 dpi and hind limbs were harvested for ?CT, histopathological and immunohistochemical analysis.Results: At 30dpi, a significant decrease in growth plat thickness, chondrocyte number, and BMD and BV/TV in primary spongiosa was observed compared to mock infection. It was accompanied by a reduction in the number of TRAP+ osteoclasts and SP7+ osteoblasts per bone perimeter. SARS-CoV-2

nucleocapsid and spike proteins were detected in bone marrow cavity in the vicinity of blood vessels. Noteworthily, the number of caspase 3-positive apoptotic growth plate chondrocytes remarkably increased with upregulated expression of endothelin type A and B receptors. Surprisedly, 2-week Macitentan treatment in the sub-acute phase of viral infection could mitigate growth plate chondrocyte apoptosis, increase the number of chondrocytes and SP7+ osteoblasts, fully restore the thickness of growth plate and bone mass.Conclusion: SARS-CoV-2 infection triggers growth plate chondrocyte dropout and causes bone loss. Endothelin receptor blockade via Macitentan is a promising therapeutic strategy to rescue growth plate injury and persistent bone loss after SARS-CoV-2 infection. This treatment remains effective even when not initiated during the acute phase of viral infection.Note: JGN, MTA, and KMT are equal contributions. CYW and SFY are the corresponding authors.

Sclerostin Loop3-LRP4 Interaction Required by Sclerostin for Antagonizing Wnt Signaling and Osteogenic Potential in Osteoblasts *Luyao Wang[1], Xiaohui Tao[1], Hewen Jiang[2], Ning Zhang[2], Dijie Li[1], Jin Liu[1], Yuanyuan Yu[1], Yihao Zhang[1], Aiping Lyu[1], Baoting Zhang[2], Ge Zhang[1]. [1]Law Sau Fai Institute for Advancing Translational Medicine in Bone and Joint Diseases (TMBJ), School of Chinese Medicine, Hong Kong Baptist University, Hong Kong. [2]The Chinese University of Hong Kong, Hong Kong

Sclerostin becomes a novel bone anabolic target. Sclerostin loop2 was reported to bind to YWTD repeats within LRP5/6 of osteoblasts, thereby antagonizing bone anabolic Wnt/?-catenin signaling pathway. Humanized sclerostin antibody which targeted sclerostin loop2 promoted bone formation, whereas imposed sever cardiovascular events in clinical trials. In our published work, sclerostin loop3 was notably found to contribute to the antagonistic effect of sclerostin on bone formation, while the cardiovascular protective effect of sclerostin was independent of loop3. Targeting sclerostin loop3 by our screened sclerostin loop3-specific aptamer promoted bone formation in SOSTki mice, ovariectomized osteoporotic rats and Col1a2+/G610C mice, without increasing cardiovascular risk. The sclerostin loop3 aptamer for osteogenesis imperfecta was granted Orphan Drug Designation by US-FDA (DRU-2019-6966). However, how sclerostin loop3 participates in the antagonistic effect of sclerostin on bone formation remains unclear. In our pull-down and biolayer interferometry (BLI) studies, sclerostin loop3 was found to bind to LRP4 in osteoblasts (Fig.1a-b). It was reported that osteoblastic LRP4 could facilitate the binding of sclerostin to LRP6 for antagonizing bone formation. After identification of the interaction residues, LRP4m (LRP4-Y200A, G201A, L214A, D215A, I216A, Y217A, H218A, C219A) was designed to genetically block sclerostin loop3-LRP4 interaction in vitro. The antagonistic effect of sclerostin on Wnt signaling and osteogenic potential in osteoblasts were inhibited upon LRP4m, while no changes in Wnt signaling and osteogenic potential were found in the absence of sclerostin before and after expression of LRP4m (Fig.1c-d). Based on the interaction, a peptide tool LRP4-Pep was designed to pharmacologically block sclerostin loop3-LRP4 interaction. The antagonistic effects of sclerostin on Wnt signaling and osteogenic potential in osteoblasts were inhibited after pretreatment of the exogenous LRP4-Pep (Fig.1e-f). Sclerostin loop3-LRP4 interaction was required by sclerostin for antagonizing Wnt signaling pathway and osteogenic potential in osteoblasts in vitro.

High Physical Activity Is Associated with Greater Cortical Bone Size, Better Physical Function, and Lower Risk of Incident Fracture Independently of Clinical Risk Factors and BMD in Older Women *Lisa Johansson[1], Kristian Axelsson[2], Henrik Litsne[3], Mattias Lorentzon[4]. [1]Institute of medicine, . [2]Institute of Medicine, Sahlgrenska Academy, Gothenburg University, . [3]Sahlgrenska Osteoporosis Centre, University of Gothenburg, Sweden. [4]Sahlgrenska Academy, University of Gothenburg, Sweden

The Physical Activity Scale for the Elderly (PASE) is a validated test to assess physical activity in older persons. It has not been investigated if physical activity level, according to PASE, can improve fracture risk prediction beyond the commonly used clinical risk factors (CRFs) in the FRAX algorithm. The purpose of this study was to evaluate if PASE score is associated with bone characteristics, physical function, and predicts incident fracture in older women, independently of CRFs in FRAX with femoral neck (FN) bone mineral density (BMD).SUPERB is a population-based study of 3,028 older Swedish women. Included women were 75-80 years, answered questionnaires regarding CRFs in FRAX, and underwent physical function tests, detailed bone phenotyping with DXA (Hologic) of the FN, and bone geometry, volumetric BMD, and microstructure at the ultradistal tibia with HRpQCT (XtremeCT). Incident fractures were x-ray verified. Cox regression models were used to assess the association between PASE score and incident fractures, with adjustments for CRFs and FN BMD.In total, 3014 women completed the PASE assessment and were divided into quartiles (PASE score median (range) Q1 52.1 (0.0-65.0), Q2 78.6 (65.1-96.1), Q3 113.9 (96.3-134.2), Q4 164.8 (134.2-385.3)). At baseline, women in Q4 had greater cortical volumetric BMD (vBMD) and cortical area than women in Q1, with quartile differences corresponding to 1.56% for cortical vBMD (p=0.007), and 4.03% for cortical area (p=0.022). Similarly, women in Q4 had shorter timed up and go test compared to women in Q1 (7.7+/-1.9 vs 10.6+/-4.7 seconds, p<0.001). During 8 years (median, range 0.20-9.9) of follow-up, 1077 women had any incident fracture, 806 had a major osteoporotic fracture (MOF; spine, hip, forearm, humerus), and 236 had a hip fracture. Women in Q4 had a 30% lower risk of any fracture, 23% lower risk of MOF, and 54% lower risk of hip fracture, compared to women in Q1. These associations remained after adjustment for CRFs in FRAX and FN BMD (Table).In conclusion, high physical activity was associated with a lower risk of any fracture, MOF, and hip fracture, independently of risk factors used in FRAX with FN BMD. Better physical function and greater cortical bone size may explain the lower fracture risk observed in those with high physical activity. These results suggest that fracture risk assessments in older women may be improved if the physical activity level is considered.

Table. Quartiles of Physical Activity According to PASE and Risk of Fracture in Older Women.

	Quartile 1 n=754	Quartile 2 n=753	Quartile 3 n=753	Quartile 4 n=754

Functional Characterization of Novel Lunatic Fringe Variants in Spondylocostal Dysostosis Type-III with Scoliosis *Parker Wengryn[1], Karina Da Costa Silveira[1], Connor Oborn[1], Carrie-Lynn Soltys[1], Alex Beke[1], Inara Chacon-Fonseca[2], Nadirah Damseh[3], Marco Quesada Rodriguez[4], Ramsés Badilla Porras[4], Peter Kannu[1]. [1]University of Alberta, Canada. [2]Lakeridge Health Oshawa, Canada. [3]University of Toronto, Canada. [4]Hospital Nacional de Niños, Costa Rica

Purpose: Rare Mendelian diseases provide a unique opportunity to investigate genetic pathways contributing to normal spinal development and variability in phenotypic presentation. Spondylocostal Dysostosis Type-III (SCD3) is a rare, autosomal recessive disorder characterized by rib fusions, vertebral abnormalities, and varying degrees of scoliosis. SCD3 is caused by variants in the Lunatic Fringe (LFNG) gene encoding a ?-1-3-N-acetylglucosaminyltransferase. This enzyme transfers N-acetylglucosamine to NOTCH1 during somitogenesis to promote normal vertebral formation. We have identified compound heterozygous LFNG variants-of-uncertain-significance (VUS; the genetic variant has an unknown effect on health) in a proband with a SCD phenotype. However, the proband is taller (Height: 10th-25th%), has a longer trunk (Arm span-to-height ratio: 1.07), and more vertebrae (>20) than the six previously reported SCD3 cases. The purpose of our study is to determine whether the c.766G>A (p.G256S) and c.521G>A (p.R174H) LFNG variants lead to diminished N-acetylglucosaminyltransferase activity, protein mis-localization, and/or dysregulated

pre-pro-processing. We hope that this will inform the relationship between genotype and phenotype.Methods: HEK293T cells were transiently transfected with 3XFLAG-hLFNG. Fusion protein was immunoprecipitated and assessed with a quantitative glycosyltransferase luciferase assay. NIH3T3 cells were transiently transfected with LFNG-HA, incubated with anti-HA and anti-GM130 antibodies, then assessed for signal colocalization through confocal microscopy. Finally, NIH3T3 cells were transfected with LFNG-HA and whole cell lysate was processed for protein, western blotted, and semi-quantitatively analyzed. Results: The p.G256S and p.R174H variants displayed significantly less enzymatic activity than wildtype. The p.G256S substituion was comparable to negative control whereas p.R174H was significantly more active than p.G256S. Both variants were correctly localized to the Golgi and normally pre-pro-processed.Conclusions: We have discovered the first hypomorphic (p.R174H) and report the fourth functionally null (p.G256S) LFNG variants associated with SCD3. This is the first clinically identified combination of partially active and completely inactive LFNG. This data may suggest that the hypomorphic variant partially rescued the probands height, trunk length, and vertebral number, but not segmentation defects nor scoliosis.

Women with Pregnancy and Lactation associated Osteoporosis (PLO) Have Substantial Volumetric BMD Deficits at the Spine by Central QCT *Sanchita Agarwal[1], Thomas Lang[2], Mafo Kamanda-Kosseh[1], Dany El-Najjar[1], Mariana Bucovsky[1], Ivelisse Colon[1], Ananya Kondapalli[1], Nayoung Kil[1], Joan M. Lappe[3], Julie Stubby[3], Robert R. Recker[3], Adi Cohen[1]. [1]Columbia University Irving Medical Center, United States, [2]School of Dentistry, University of California San Francisco, United States, [3]Creighton University Medical Center, United States

PLO is a rare, severe, early form of osteoporosis, most commonly presenting with multiple vertebral fractures (Fx) associated with pregnancy/lactation. Most women with PLO have no known secondary cause; mechanisms and etiologies are largely unknown. Herein we report central QCT (cQCT) findings at the lumbar spine (LS; L1-L2) in the largest structurally characterized cohort of PLO women to date in comparison to both (1) healthy nonosteoporotic premenopausal controls and (2) premenopausal women with idiopathic osteoporotic Fx not associated with pregnancy/lactation (nonPLO IOP).Clinical and skeletal characteristics were compared between 3 treatment naïve premenopausal cohorts: 34 controls, 49 nonPLO IOP and 48 PLO. Among PLO, 19 were studied <=12M (Recent PLO), while 29 were studied >12M postpartum (Distant PLO). NonPLO IOP and controls were studied >12M postpartum. cQCT parameters: cQCT-derived AP and lateral (LAT) 2D LS aBMD, total density (with posterior elements; Tot_vBMD), Tb density (Tb_vBMD), vertebral integral density (excludes posterior/transverse elements; Int_vBMD), and mid vertebral integral density (Mid_vBMD) and strength index (SI; =density2*area, approximating compressive strength) both computed from a 10mm vertebral body mid-section. Student's t-tests were used for between groups comparisons.Clinical presentation was more severe in PLO than nonPLO IOP: more Fx, childhood Fx, multiple Fx, and vertebral Fx (Table). Skeletal structure was also most severely affected in PLO. Compared to controls, PLO had substantial deficits in all LS aBMD and vBMD parameters (all p<0.001). Compared to nonPLO IOP, PLO also had significantly lower aBMD and vBMD, but SI did not differ.To study natural history of PLO, we compared patients at different postpartum stages. Compared to Distant PLO, Recent PLO had lower LS aBMD by DXA, and Tot_vBMD and Mid_vBMD by cQCT (all p<0.05; data not shown). These results support our hypothesis that Recent PLO, studied soon after they fractured and prior to full recovery of pregnancy/lactation related bone loss, would have the most profound structural deficits.In summary, PLO women have substantial aBMD and vBMD deficits at the LS compared to both controls and nonPLO IOP. The Recent PLO group had the most profoundly affected bone structure, particularly in the vertebral mid-section. This structural investigation increases mechanistic understanding of the spine predominant bone fragility presentation that characterizes PLO.

Table: Clinical and skeletal characteristics by DXA and cQCT in healthy premenopausal controls, nonPLO IOP and PLO (mean ± SD or %).

	Clinical characteristics

Bone microarchitecture and strength in Osteogenesis Imperfecta using HR-pQCT: comparison with normative data taking into account limb length and deviating axial scan angles *MELISSA BEVERS[1], Bert Rietbergen[2], Arjan Harsevoort[3], Koert Gooijer[3], Hans Feenstra[3], Guus Janus[3], Caroline Wyers[4], Joop Van Den Bergh[5]. [1]VieCuri Medical Center, , [2]Eindhoven University of Technology, Netherlands, [3]Expert Center for adults with Osteogenesis Imperfecta Isala Hospital, Netherlands, [4]VieCuri Medical Centre, Netherlands, [5]VieCuri MC Noord-Limburg and Maastricht UMC,

Purpose: Patients with osteogenesis imperfecta (OI) have increased bone fragility and fracture risk. High-resolution peripheral quantitative CT (HR-pQCT) has been used to study bone microarchitecture in OI as compared to non-OI groups, but short stature and bone deformities in OI may cause deviations in scanned region and limit comparison. The aim of this study was to assess bone microarchitecture and strength in adults with OI as compared to normative data using HR-pQCT with a limb-length dependent scan protocol and by taking into account deviating scanned regions. Methods: Limb-length dependent HR-pQCT scans of the distal radius and tibia were obtained from 118 adults with OI (41.8 [IQR: 25.1] year old). To evaluate potential deviations in the scanned region, the axial scan angle was computed using a new algorithm that quantifies the angle between the areal center of the bone on the first and last slice of a scan. The angle was compared to that of limb-length dependent HR-pQCT scans of 13 healthy young women. It was considered to be deviated when being outside the fence of 1.5xIQR from Q1 and Q3 in those women. Bone microarchitecture and strength were quantified and compared to normative data from literature (Warden et al. Osteoporos Int 2021). Results: 102 radius and 105 tibia scans could be analyzed, of which the axial scan angle was found to be deviating in 11 (radius; 10.8%) and 14 (tibia; 13.3%). In the radius scans without deviating angle, total BMD was low (Z-score: -1.0+/-1.8) as were trabecular BMD (Z-score: -1.6+/-1.3) and number (Z-score: -2.5+/-1.4) and total bone stiffness (Z-score: -1.4+/-1.5). Trabecular separation was high (Z-score: -2.7 [2.7]). Trabecular thickness and cortical BMD and microarchitecture were normal. Larger deviations were seen at the tibia. In the scans with a deviating axial angle, deviations from the normative data were smaller or similar (cortical bone) but more often larger (total and trabecular bone) than in the scans without deviating angle, most pronounced at the tibia (Fig.1). Conclusion: Bone microarchitecture and strength in OI are impaired, in particular at the trabecular compartment. It likely contributes to the increased fracture risk in OI and may provide valuable insights to improve treatments of reduced bone quality. Scans with a deviating scanned region, likely due to bone deformities and scan positioning limitations in OI, should be excluded in HR-pQCT studies on OI, especially when comparing study groups.

	Non-deviating	Deviating	Non-deviating	Deviating
Z<-1	51 (56%)	9 (82%)	78 (86%)	14 (100%)
Z<-4	4 (4%)	1 (9%)	5 (5%)	7 (50%)

A Prospective Study to Evaluate Patient-Reported Quality of Life Before and After Asfotase Alfa Treatment in Adults with Pediatric-Onset Hypophosphatasia *Kathryn Dahir[1], Steven Ing[2], Chad Deal[3], Andrew Messali[4], Toby Bates[4], Eric T. Rush[5]. [1]Vanderbilt University Medical Center, United States, [2]The Ohio State University Wexner Medical Center, United States, [3]Cleveland Clinic Foundation, United States, [4]Alexion, AstraZeneca Rare Disease, United States, [5]Children's Mercy Kansas City; University of Missouri - Kansas City School of Medicine, United States

Purpose: To evaluate the impact of asfotase alfa on patient-reported outcomes (PROs) in adults with pediatric onset hypophosphatasia (HPP).Methods: A longitudinal telephone-based survey was administered to adults with pediatric-onset HPP at baseline (prior to asfotase alfa initiation) and follow-up (3 [3M], 6 [6M], and 12 months [12M] post-initiation). Demographics and PROs (Patient Health Questionnaire-9 [PHQ-9], Patient-Reported Outcomes Measurement Information System [PROMIS-29], Routine Assessment of Patient Index Data 3 [RAPID3], and Work Productivity and Activity Impairment-Specific Health Problem [WPAI-SHP]) were assessed (Figure). McNemar's or Cochran-Mantel-Haenszel tests or paired t-tests were performed, as appropriate.Results: Among 50 enrolled patients, 29 were evaluable at 12M. Mean age at baseline was 46 (+/-15.4) years; 80% were female and 94% were White. At 12M, a statistically significant improvements from baseline were observed for PHQ-9 total score (10.6 baseline vs 4.2 12M, P<0.0001), PROMIS-29 domain scores (physical functioning: 38.0 vs 46.5, P<0.0001; anxiety: 57.5 vs 47.9, P<0.0001; depression: 52.6 vs 47.4, P=0.003; fatigue: 63.3 vs 51.3, P<0.0001; sleep disturbance: 58.8 vs 51.6, P=0.0008; social roles and activities: 42.6 vs 50.7, P=0.0001; pain interference: 63.8 vs 54.9, P<0.0001), and RAPID3 domain scores (functional status: 2.7 vs 1.1, P<0.0001; pain tolerance: 6.0 vs 3.2, P<0.0001; global health estimate: 5.1 vs 2.7, P<0.0001). WPAI-SHP domains showed significant improvement at 12M in presenteeism (39.6% vs 14.0%, P<0.0001), activity impairment (64% vs 30.0%, P<0.0001), and work productivity loss (41.9% vs 20.0%, P=0.012); however, the significant improvement seen at 6M in absenteeism (4.7% vs 0%, P=0.025) was not maintained at 12M (vs 8.0%, P=0.65). By 12M, the use of analgesic medications decreased from baseline (20%, n=10 vs 10.3%, n=3).Conclusion: Treatment with asfotase alfa improved anxiety, depression, physical functioning, fatigue, sleep, pain, and improved work and social relationships. These results illustrate the potential utility of adapting existing PRO instruments validated in diseases phenotypically similar to HPP.

Overview of Patient-reported Outcomes Questionnaires Collected in the Study

Information	Patient Health Questionnaire-9 (PHQ-9)	Patient-Reported Outcomes Measurement Information System (PROMIS-29)	Rourtine Assessment of Patient Index Data 3 (RAPID 3)	Work Productivity and Activity Impairment - Specific Health Problem (WPAI-SHP)
Concept of interest	• Depression	• Health-related quality of life	• Disease activity	• Work-related productivity and activity impairment
Recall period	• Past 2 weeks	• Past 7 days • Except Physical Functioning, which does not have a specified timeframe	• Over the last week for Physical Function and Pain • At this time for Patient Global Estimate	• Past 7 days
Domains covered	• Unidimensional	• Physical Function (4 items) • Anxiety (4 items) • Depression (4 items) • Fatigue (4 items) • Sleep Disturbance (4 items) • Ability to participate in Social Roles and Activities (4 items) • Pain Interference (4 items) • Pain Intensity (1 item)	• Physical Function (13 items) • Pain (1 item) • Patient Global Estimate (1 item)	• Work Productivity (5 items) • Daily Activities (1 item)
Response scale & score range	• Range: 0–27 • PHQ severity categories: minimal (0-4), mild (5-9), moderate (10-14), moderately severe (15-19), severe (20-27)	• Standardized T-score with a mean of 50 and a standard deviation of 10	• Range: 0–10 • RAPID3 qualitative description Categories: near remission (0–1.0), low severity (1.3–2.0), moderate (2.3–4.0), high (4.3–10.0)	• Scores are multiplied by 100 to be expressed as impairment percentages
Directionality	Higher = More severe depressive symptoms	Higher = Better for positively worded concepts Higher = Worse for negatively worded concepts	Higher = More active disease	Higher = Greater impairment & less productivity

Note: All PROs were measured at baseline (prior to initiation of asfotase alfa) and follow-up (3 months and 6 months post-initiation)>

FRI-489

A Multicenter Study Evaluating Hypertension in Children with X-Linked Hypophosphatemia *Irene Chen[5], Anna Ryabets-Lienhard[2], Sreya Molakalapalli[3], Jennifer Ringrose[5], Leanne Ward[4], Robert T Alexander[5], Chelsey Grimbly[5]. [5]University of Alberta, Canada, [2]Children's Hospital Los Angeles , , [3]Children's Hospital of Los Angeles, United States, [4]Children s Hospital of Eastern Ontario, Canada, [5]University of Alberta,

X-linked Hypophosphatemia (XLH) is associated with elevated fibroblast growth factor 23 (FGF23) resulting in renal phosphate wasting and decreased 1,25 dihydroxyvitamin D. It is a multi-system disease with significant co-morbidities. Current treatment options include conventional therapy (phosphate and 1,25 dihydroxy vitamin D) or burosumab (anti-FGF23 therapy). High rates of hypertension (HTN) have been reported in adults, but it is unclear if HTN develops in childhood. We present data on HTN in pediatric XLH.Methods: We evaluated medical records of children (<18 years of age) with XLH followed at two tertiary care centers, the Stollery Children's Hospital (Edmonton, Canada), and the Children's Hospital of Los Angeles (Los Angeles, United States) from 2014-2022. Patients were included if they had three or more blood pressure (BP) recordings. Clinical data was collected including laboratory and treatment data and renal ultrasound results. HTN was defined as systolic or diastolic BP (SBP, DBP) greater than the 95th percentile for age, sex and height on three or more occasions, as per the Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents. Descriptive analyses were performed. Results: Our cohort included 56 children (35 female, 63%) with XLH. HTN was found in 19 children (34% of the cohort, n=10 female), diagnosed at a mean age of 7.9 years (SD 4.2). SBP was higher than DBP with a SBP percentile average of 76 and DBP percentile average of 58 (p<0.01). 14 children had isolated systolic HTN, 4 had a combination of diastolic and systolic HTN, and 1 child had isolated diastolic HTN. HTN was not associated with body mass index, serum parathyroid hormone levels, nephrocalcinosis, or average weight-based phosphate or 1,25 dihydroxyvitamin D treatment over the study period. Furthermore, BP percentiles did not change with initiation of Burosumab therapy.Conclusion: Children with XLH demonstrate a high prevalence of hypertension as a third of our cohort met criteria for HTN. It is unclear why children with XLH develop HTN. FGF23 has been associated with vascular morbidity and elevated FGF23 drives the pathology in XLH. We did not see that anti-FGF23 treatment (Burosumab) lowered BP percentiles, but this could be confounded by a small sample size and the limited duration of follow up. HTN is an important comorbidity in XLH, and further studies are needed to identify risk factors.

Flare-Ups in Patients with Fibrodysplasia Ossificans Progressiva Reduced by Garetosmab Treatment: LUMINA-1 Data *KATHRYN DAHIR[1], Jennifer McGinniss[2], Eduardo Forle-Neto[2], Scott Mellis[2], Robert Sanchez[2], Maja Di Rocco[3], Richard Keen[4], Philippe Orcel[5], Christian Roux[6], Jacek Tabarkiewicz[7], Javier Bachiller-Corral[8], Angela Cheung[9], Mona Al Mukaddam[10], Kusha Mohammadi[2], Dushyanth Srinivasan[2], Andrew Rankin[2], Aris Economides[2], Dinko Gonzalez Trotter[2], Frederick Kaplan[11], Elisabeth Eekhoff[12], Robert Pignolo[13]. [11]University of Pennsylvania, United States. [12]Amsterdam UMC, location VU University Medical Center, Amsterdam, The Netherlands, Netherlands. [13]Mayo Clinic, United States

Purpose: Fibrodysplasia ossificans progressiva (FOP) is a rare disorder, characterized by progressive heterotopic ossification (HO) and soft tissue inflammatory events known as flare-ups. Garetosmab, an investigational, fully human monoclonal antibody against activin-A, prevents formation of new HO lesions. Here we describe the impact of garetosmab on flare-up events in the LUMINA-1 study (NCT03188666).Methods: This was an analysis of garetosmab data from LUMINA-1, a phase 2, randomized, double-blind, placebo-controlled study that evaluated the safety and efficacy of garetosmab 10 mg/kg every 4 weeks intravenous in adult patients with FOP over 28 weeks (Period 1), followed by a 28-week open-label treatment (Period 2) and open-label extension (Period 3). Patient-reported flare-ups were collected via a patient diary and symptom severity was reported as mild, moderate, or severe.Results: In Period 1, the proportion of patients reporting flare-ups (35% vs 71%, p=0.032) was significantly reduced with garetosmab (n=20) vs placebo (n=24), respectively. The overall number of patient-reported flare-ups (13 vs 34) and median days experiencing new flare-ups (15.0 days vs 48.0 days) were also reduced with garetosmab vs placebo, respectively. Most flare-ups occurred in the back in garetosmab-treated patients, and the lower extremities and back for those on placebo. Pain was the most frequent symptom in both cohorts. Severity of flare-up associated symptoms were reduced in the garetosmab-treated cohort. No patients reported severe swelling or severe decrease in movement. One patient treated with garetosmab reported severe pain and joint stiffness. In Period 2, the proportion of patients experiencing flare-ups (68% vs 14%, p=0.0005) and number of patient-reported flares (31 vs 11) was significantly reduced in patients who crossed over from placebo to garetosmab (n=22). Patients who continued on garetosmab (n=18) maintained a reduction in number of flare-ups (12 vs 6) and the proportion of patients experiencing flare-ups (33% vs 22%). Reductions were maintained through Period 3.Conclusions: Patients treated with garetosmab experienced significant and sustained reductions in the frequency, duration, and severity of flare-ups. Therefore, garetosmab may provide a meaningful therapeutic option for patients with FOP.

A Phase 1, Open-label, Dose-escalating Study to Evaluate the Safety, Tolerability, Pharmacokinetics, and Pharmacodynamics of ALXN1850 in Adults With Hypophosphatasia *KATHRYN DAHIR[1], Derek Dunn[2], Jawad Hasan[2], Amy Shannon[2], Wei-Jian Pan[2]. [1]Vanderbilt University Medical Center, . [2]Alexion, AstraZeneca Rare Disease, United States

Hypophosphatasia (HPP) is a rare, inherited disorder associated with recurrent fractures/pseudofractures, orthopedic/dental burden, pain, mobility impairments, and diminished quality of life. ALXN1850 is an investigational enzyme replacement therapy being developed for the treatment of HPP.1-3 The primary objective of this study was to assess the safety and tolerability of ALXN1850 administered by IV weekly as 1 dose and SC for 3 weeks. Secondary objectives included pharmacokinetics (PK) of 1 IV and 3 SC doses, absolute bioavailability of SC, pharmacodynamic (PD) effects of 1 IV and 3 SC doses, and immunogenicity potential of ALXN1850. Of the 23 adult patients with HPP who signed informed consent, 15 were dosed, and each cohort of 5 received ALXN1850 (15, 45, or 90 mg) as 1 IV dose weekly and SC for 3 weeks; 3 patients missed doses due to COVID-19 but did not discontinue the study. Following IV and SC doses, peak and total exposure of ALXN1850 increased dose dependently (15-90 mg). Effective t1/2 was estimated at 3-6 days depending on dose. Mean bioavailability of SC doses was ~43% (range: 6%-75%). ALXN1850 achieved maximal lowering (nadir) of plasma inorganic pyrophosphate (PPi) in 7 days; ~40% post-dose PPi concentrations were below the limit of quantification (0.75µM). Mean PPi concentration was reduced for 3-4 weeks post-dose. There was no apparent impact of immunogenicity on ALXN1850 PK/PD. ALXN1850 has acceptable safety, tolerability, and PK profiles, demonstrating a sustained reduction in PPi concentrations in patients with HPP. These results will inform the selection of an appropriate therapeutic dose in future studies.References:1. Baumgartner-Sigl S et al. Bone. 2007;40(6):1655-1661.2. Whyte MP et al. Safety Overview Table

Safety finding, n (%)	Description (N = 15) of 4 weeks treatment with ALXN1850
Any TEAE	12 (80.0%); 46 events
Related TEAE	10 (66.7%); 29 events
Injection site reactions (ISRs)	8 (53.3%); 10 out of 41 (24.4%) SC injections led to an ISR event* • Four patients with 1 ISR (erythema) • One patient with 1 ISR (soreness, swelling, and redness) • One patient with 1 ISR (erythema and bruising) • One patient with 3 ISRs, 1 per each SC administration (erythema and pruritus; erythema and ecchymosis; erythema) • One patient with 1 ISR (bruise) Four patients had 1 ISR each of erythema, not reported as TEAEs but included in this ISR total. One patient experienced induration following the IV dose, which is not included in this ISR total
Injection associated reactions • **Systemic reactions**	1 (6.7%) Headache (grade 1), considered related to study drug,*** occurred following the start of the IV dose and resolved the same day following medical intervention.
TESAE	1 (6.7%) Atrial fibrillation (grade 3) considered not drug related***
TEAE/TESAE leading to study drug withdrawal	0
Immunogenicity (ADA+)**	4 (26.7%) Only 1 (6.7%) was treatment emergent; ADAs persisted to the end of the study. Per protocol, patient was offered follow-up via the HPP registry. No patients tested NAb+

*Most cases of erythema resolved in less than 2 hours following the SC dose. There was no pattern observed in the timing of SC administration (ie, first, second, or third dose) and the occurrence of erythema.
**Assays for measuring anti-ALXN1850 antibodies and neutralizing antibodies (NAbs) were fully validated for precision, specificity, selectivity, sensitivity, robustness, and drug tolerance following the current 2019 FDA guidance on ADA method validation.
***By the investigator.
ADA, antidrug antibody; AE, adverse event; HPP, hypophosphatasia; IV, intravenous; NAb, neutralizing antibody; SC, subcutaneous; TEAE, treatment-emergent adverse event; TESAE, treatment-emergent serious adverse event.

Prevalence of ENPP1 variants among patients with ossification of the posterior longitudinal ligament *Hajime Kato[1], Shivani Srivastava[2], Paul Stabach[3], Soichiro Kimura[4], Takashi Sunouchi[4], Yoshitomo Hoshino[4], Naoko Hidaka[4], Minae Koga[4], DEMETRIOS BRADDOCK[5], Nobuaki Ito[6]. [1], . [2]Department of Pathology, Yale University, United States. [3]Department of Pathology, Yale Universty, United States. [4]Division of Nephrology and Endocrinology, The University of Tokyo Hospital, Japan. [5]YALE UNIVERSITY, United States. [6]The University of Tokyo Hospital, Japan

Background: Ossification of the posterior longitudinal ligament (OPLL) is a multifactorial disease that is caused by genetic and environmental factors. On the other hand, some hereditary FGF23-related hypophosphatemic rickets/osteomalacia (heterozygous PHEX mutation, homozygous ENPP1 mutation, homozygous DMP1 mutation) are known to develop OPLL. We, therefore, hypothesized that mild or undiagnosed cases of these diseases are included in the patients diagnosed with OPLL.Methods: We prospectively evaluated the frequency of cases with low-frequency variants (allele frequency in gnomAD: <0.5%) in the exonic regions of PHEX, ENPP1, and DMP1 genes in patients who underwent surgery for OPLL at our hospital. Clinical and biochemical data (i.e. calcium, phosphate, FGF23) of were collected. Plasma inorganic pyrophosphate (PPi) levels, which ENPP1 produces by hydrolyzing ATP, were also measured to evaluate the effect of the detected variants on ENPP1 catalytic activity.Results: The total of 50 patients with OPLL were included in this study (median age, 68 years [range, 37-86 years]; 14 women [28%]). All OPLL patients underwent genetic testing, and four types of heterozygous rare ENPP1 variants (c.802T>C [p.Y268H], c.1352A>C [p.Y451C], c.2089G>A [p.V697M], c.2335A>C [p.T779P]) were found in seven patients (14%). Clinical and biochemical data analysis showed that FGF23 levels of the OPLL patients with ENPP1 variants (median: 46 pg/mL [range: 36-102 pg/mL]) were higher than those of OPLL patients without ENPP1 variants (median: 36 pg/mL [range: 14-86 pg/mL]) (p=0.01). All of seven OPLL patients with heterozygous ENPP1 variants presented low plasma PPi levels (median: 1.8µM [range: 1.0-1.9 ?M], reference value 2-5 ?M). In vitro kinetic assays showed p.Y268H, p.Y451C, p.V697M and p.T779P variants possessed a catalytic velocity of 5%, 30%, 30%, and 1%, respectively, compared with that of wild-type ENPP1.Conclusion: This study revealed that patients with heterozygous ENPP1 variants were included in patients with OPLL and the prevalence of ENPP1 variant in this

cohort was 14%. The establishment of the appropriate diagnostic criteria to select cases with pathogenic ENPP1 variants would be warranted.

The Relationship of Flare-Ups and Heterotopic Ossification in Patients with Fibrodysplasia Ossificans Progressiva: LUMINA-1 Data *Richard Keen[1], Jennifer McGinniss[2], Eduardo Forleo-Neto[2], Scott Mellis[2], KATHRYN DAHIR[3], Maja Di Rocco[4], Ma?gorzata Szczepanek[5], Javier Bachiller-Corral[6], Angela Cheung[7], Mona Al Mukaddam[8], Jing Gu[2], Aris Economides[2], Dushyanth Srinivasan[2], Dinko Gonzalez Trotter[2], Frederick Kaplan[9], Elisabeth Eekhoff[10], Robert Pignolo[11]. [1]Centre for Metabolic Bone Disease Royal National Orthopaedic Hospital NHS Trust, United Kingdom. [2]Regeneron Pharmaceuticals, Inc., United States. [3]Vanderbilt University Medical Center, . [4]Department of Pediatrics, Unit of Rare Diseases, IRCCS Istituto Giannina, Italy. [5]Rzeszów University, Rzeszów, Poland. [6]Hospital Universitario Ramón y Cajal, Spain. [7]University Health Network, University of Toronto, Canada. [8]Departments of Orthopaedics, Medicine and the Center for Research in FOP & Related Disorders, University of Pennsylvania Perelman School of Medicine, United States. [9]University of Pennsylvania, United States. [10]Amsterdam UMC, location VU University Medical Center, Amsterdam, The Netherlands, Netherlands. [11]Mayo Clinic, United States*

Purpose: Fibrodysplasia ossificans progressiva (FOP) is an ultra-rare autosomal dominant disorder, characterized by progressive heterotopic ossification (HO) and painful soft tissue inflammatory events known as flare-ups. Flare-ups can precede HO formation, but prospective data are limited. Here, we describe the relationship between flare-ups and HO from the placebo cohort of the LUMINA-1 study (NCT03188666).Methods: This was a post hoc analysis of the placebo cohort from a phase 2, randomized double-blind placebo-controlled study that evaluated the safety and efficacy of intravenous garetosmab 10 mg/kg every 4 weeks vs placebo in adult patients with FOP over 28 weeks. Patient-reported flare-ups were collected via a patient diary. This analysis focused on new HO lesions as assessed by 18F-NaF positron emission tomography and computed tomography (CT) at week 8, and week 28. Total volume of HO was determined by CT.Results: Of the 44 individuals enrolled in the study, 24 received placebo. Seventeen of these placebo patients reported new flare-ups, 10 of which also developed HO. Furthermore, of the 29 reported new HO lesions, which developed in 11 placebo patients, 12 (41.4%) occurred in the same limb or region as a previous flare-up, and 17 (58.6%) did not. Patients with new flare-ups had a higher volume of HO lesions at week 28, with mean (SD) total volume of new lesions of 14.2 (21.6) cm3 vs 0.5 (1.2) cm3 in patients without flare-ups, resulting in a mean (SD) change from baseline of 19.0 (33.9) cm3 vs 10.9 (21.5) cm3, respectively. In patients with new HO lesions, those with flare-ups (n=10) had a higher volume of newly formed heterotopic bone at week 28, mean (SD) of 24.2 (23.7) cm3 vs 3.2 cm3 in one patient with new HO but no flare-ups.Conclusions: Most placebo patients who reported a flare-up developed new HO lesions and had a higher volume of HO lesions; however, newly developed HO did not occur at the flare-up site in most instances. These results suggest that flare-ups within a year may reflect disease activity and be a prognostic indicator of higher volumetric growth of HO lesions.

Evidence Based Guidelines On Diagnosis, Management and Monitoring of X-Linked Hypophosphatemia (XLH) in The Pediatric and Adult Population 2023 *Aliya A. Khan[1], Dalal Ali[2], MARIA LUISA BRANDI[3], Eric Rush[4], Gordon Guyatt[1], Natasha Appelman-Dijkstra[5], Catherine Chaussain[6], Suzanne Jan De Beur[7], Thomas Carpenter[8]. [1]McMaster University, Canada. [2], . [3]FONDAZIONE FIRMO, Italy. [4]Children's Mercy Kansas City, United States. [5]Leiden Center for Bone Quality, Netherlands. [6]Université Paris Cité and APHP, France. [7]Johns Hopkins University, United States. [8]Yale University School of Medicine, United States*

Background: Over the past 5 years, there have been rapid advances in our understanding of the multisystem manifestations of XLH and the development of new treatment paradigms. To offer guidance to clinicians and to promote evidence-based care, an International Working Group (IWG) of 52 experts in guideline development methodology and XLH in the pediatric and adult population has convened to develop new evidence-based guidelines on the evaluation, management, and monitoring of XLH.Methods: Four systematic reviews and meta-analyses were completed using the GRADE methodology addressing the management of XLH in relation to patient important outcomes and surrogate outcomes. In addition to the systematic reviews, expert clinical practices were captured with a comprehensive, 280 item questionnaire developed by the panel and administered to 44 experts treating patients with XLH. Data derived from the questionnaire were captured in expert-opinion based narrative reviews that address: 1) diagnosis of XLH including the role of genetic testing, 2) dental complications, 3) indications for treatment, 3) selection of treatment, 4) disease and treatment monitoring, 5) pregnancy and lactation in XLH, 5) agenda for future research.The new international guidelines on XLH will be reviewed by stakeholders including professional medical societies and patient advocacy organizations interested in endorsing these guidelines.Conclusions: These new guidelines will be presented for the first time internationally at the upcoming meeting of the ASBMR in October 2023.International Working Group Members:Aliya A. Khan (Chair), Dalal S. Ali, Maria L. Brandi, Eric Rush, Hajar Abualarob, Hatim Alalwani, Abdulrahman Alamri, Rana Aldabbagh, R.Todd Alexander, Farah Alsarraf, Natasha Appelman-Dijkstra, Signe Sparre Beck-Nielsen, Martin Biosse Duplan,Tom Carpenter, Catherine Chaussain, Martine Cohen-Solal, Rachel K. Efficacy of growth hormone therapy on height in children with achondroplasia *Takuo Kubota[1], Hirofumi Nakayama[2], Takeshi Ishimi[3], Chieko Yamada[3], Yukako Nakano[3], Ikumi Ueda[3], Tatsuya Nakamichi[3], Hiroyuki Saitou[3], Kenichi Yamamoto[4], Makoto Fujiwara[6], Yasuhisa Ohata[6], Taichi Kitaoka[1], Keiichi Ozono[1]. [1]Osaka University Graduate School of Medicine, Japan. [2]Department of Pediatrics, Graduate School of Medicine, The first Department of Oral and Maxillofacial Surgery, Graduate School of Dentistry, Osaka University , Japan. [3]Department of Pediatrics, Osaka University Graduate School of Medicine, Japan. [4]Department of Pediatrics, Division of Health Sciences, Osaka University Graduate School of Medicine, Japan. [6]Osaka University, . [6]Osaka University, Japan*

Background: Achondroplasia (ACH) is a skeletal disorder with marked short stature and short limbs. The mean adult height has been reported to be 130.4 cm in males and 124.0 cm in females, respectively, in Japan, resulting in difficulties of daily life. Growth hormone (GH) therapy is available in children with ACH in Japan, although evidence on the efficacy of GH therapy on height growth is limited. Aim: To elucidate the efficacy of GH therapy on height growth in children with ACH. Methods: Children with ACH who visited our department from January 2011 to December 2022 and received GH therapy were included in this study. Height data between a year before and 5 years after the initiation of GH therapy were collected annually. Height SD values for healthy and ACH children and annual growth velocity (AGV) were evaluated. No further data were included after discontinuation of the therapy. A height increase due to lower limb lengthening was subtracted from the height measured. Results: Forty?one children (25 males) with ACH were included in the study. The median age was 4.00 years (range: 3.04 to 8.50) at the beginning of GH therapy. Height SD at that time was ?4.95 +/- 0.75 (mean +/- SD) for healthy children and ?0.24 +/- 0.71 for children with ACH. AGV was 4.45 +/- 1.62 cm. Regarding the efficacy of the therapy, the mean height SD of ?4.28, ?4.01, ?3.69, ?3.83, and ?3.84 for healthy children significantly increased 1 to 5 years after GH therapy, respectively, compared to that at the therapy initiation. In addition, the mean height SD of 0.25, 0.51, 0.95, 1.03 and 1.18 for children with ACH significantly increased in 1 to 5 years after GH therapy, respectively. AGV was 7.40, 5.76, 5.66, 4.84 and 4.77 cm 1 to 5 years after GH therapy, respectively, and significantly higher 1 to 3 years after GH therapy compared to that at the therapy initiation. Four and one patients underwent adenotonsillectomy and lower limb lengthening, respectively, after GH therapy initiation. GH therapy in 3 patients was changed to C-type natriuretic peptide analogue treatment. Except for the medical treatment change, no discontinuation of GH therapy occurred. Discussion: Height SD for both healthy and ACH children, and annual growth velocity were improved at least 1 to 3 years during GH therapy in this study, which shows the efficacy of GH therapy on height in children with ACH. Adult height needs to be evaluated in many patients with ACH after GH therapy.

FRI-502

Bone matrix properties in adults with osteogenesis imperfecta are not adversely affected by Setrusumab - A sclerotin neutralizing antibody *Maximilian Rummler[1], Victoria Schemenz[1], Samantha McCluskey[2], Anton Davydok[3], Frank Rauch[4], Francis Glorieux[5], Matthew Harrington[6], Wolfgang Wagermeier[1], Bettina Willie[6], Elizabeth Zimmermann[6]. [1]Max Planck Inst Colloids and Interfaces, Germany. [2]Shriners Hospital for Children-Canada, Canada. [3]Deutsches Elektronen-Synchrotron , Germany. [4]Shriners Hospital for Children, Montreal, Canada. [5]Shriners Hospital for Children and McGill University, Canada. [6]McGill University, Canada*

Osteogenesis imperfecta (OI) is a skeletal dysplasia characterized by low bone mass and frequent fractures. Children with OI are commonly treated with bisphosphonates to

reduce fracture rate, but treatment options for adults are limited. In the Phase 2b ASTEROID trial, setrusumab (a sclerostin neutralizing antibody, SclAb) improved bone density and strength in adults with type I, III and IV OI. Here, we investigate bone matrix material properties in tetracycline-labeled trans-iliac biopsies from three groups: i) control: individuals with no metabolic bone disease (n = 7), ii) OI: individuals with OI (n = 4), iii) SclAb-OI: individuals with OI after six months of setrusumab treatment as part of the ASTEROID trial (n = 5). In addition to bone histomorphometry, bone mineral and matrix properties were evaluated with nanoindentation, Raman spectroscopy, second harmonic generation imaging, quantitative backscatter electron imaging, and small-angle x-ray scattering. Spatial locations of fluorochrome labels were identified to differentiate inter-label bone of the same tissue age and intra-cortical bone. No difference in collagen orientation was found between the groups. The bone mineral density distribution (Fig. 1) and analysis of Raman spectra indicate that OI and SclAb-OI groups have greater mean mineralization, greater relative mineral content and lower crystallinity than the control group, which was not altered by SclAb treatment. Finally, a lower modulus and hardness were measured in the inter-label bone of the OI-SclAb group compared to the OI group. Previous studies suggest that even though bone from OI has a higher mineral content, the extracellular matrix has comparable mechanical properties. Therefore, fragility in OI may stem from contributions from other yet unexplored aspects of bone organization at higher length scales. We conclude that SclAb treatment leads to increased bone mass while not adversely affecting bone matrix properties in individuals with OI.

A Phase 1/2, Open-Label, Multiple Ascending Dose Clinical Study to Evaluate the Safety, Tolerability, Pharmacokinetics, and Pharmacodynamics of INZ-701 in Adults with ENPP1 Deficiency *Yves Sabbagh[1], Robert Wermers[2], Rainard Fuhr[3], Dirk Schnabel[4], Terra Arnason[5], Alix Besancon[6], Borut Cizman[1], Deborah Wenkert[7], Kurt Gunter[1]. [1]Inozyme Pharma, United States. [2]Mayo Clinic, United States. [3]Parexel International GmbH, Early Phase Clinical Unit Berlin, Germany. [4]Charitè, Universitätsmedizin Center for Chronic Sick Children, Pediatric Endocrinology, Germany. [5]University of Saskatchewan, Division of Endocrinology, Canada. [6]Hôpital Universitaire Necker Enfants Malades, Endocrino-diabetologie pediatrique , France. [7]Wenkert and Young, LLC, United States

Background: ENPP1 Deficiency is a rare disorder due to inactivating mutations in the ENPP1 gene. It is characterized by low levels of inorganic pyrophosphate (PPi), a critical regulator of mineralization; subsequent pathologic soft tissue calcification results in ~50% infant mortality and life-long musculoskeletal and cardiovascular morbidities. No targeted therapy exists for this disease. INZ-701 is a recombinant ENPP1-Fc investigational product which has demonstrated efficacy in preclinical models of ENPP1 Deficiency.Purpose: To determine the safety, tolerability, immunogenicity, pharmacokinetics and pharmacodynamics of INZ-701 following subcutaneous administration in adults with ENPP1 Deficiency. Methods: Phase 1/2, multicenter, open-label, multiple ascending dose study including three cohorts of three adults each, with genetic confirmation and PPi <1300 nM (NCT04686175). Participants were dosed at Day 1, then twice weekly from Day 8 to the end of the study. Results: In all 3 dosing cohorts as of January 10, 2023, INZ-701 was well-tolerated with no related serious or severe adverse events. Low titers of non-neutralizing anti-drug antibodies (<160) were observed in 7/9 patients. Rapid increase in mean PPi from baseline of 426+/-407 nM of was noted in all patients, reaching the healthy volunteer range within 6 hours of the first dose. Mean PPi across the 0.2, 0.6, and 1.8 mg/kg dosing groups from day 32 through last data cut was 1299+/-490 nM, 1472+/-516 nM, and 1462+/-233 nM, respectively. Six of eight evaluable participants showed improvements in overall health on the Global Impression of Change (GIC) scale, as reported by both participants and clinicians. Long half-life of approximately 126 hours and drug accumulation as shown by a greater than dose proportional exposure suggests the potential for once weekly dosing. All participants enrolled in the phase 2 portion of the study.Conclusions: INZ-701 demonstrated a rapid and sustained increase in PPi levels in all participants, was well tolerated, and exhibited a favorable safety profile with a potential for once weekly dosing. Improvements in GIC score were observed in 6/8 patients and this ongoing study will elucidate the impact of INZ-701 on additional clinical and functional endpoints.

FRI-505

A Phase 1/2, Open-Label, Multiple Ascending Dose Study to Evaluate the Safety, Tolerability, Pharmacokinetics, and Pharmacodynamics of INZ-701 Followed by an Open-Label Long-Term Extension Period in Adults with ABCC6 Deficiency Manifesting as Pseudoxanthoma Elasticum (PXE): An Interim Analysis *Yves Sabbagh[1], Magdy Shenouda[2], Jorg Taubel[3], Mark Lebwohl[4], Kurt Gunter[1]. [1]Inozyme Pharma, United States. [2]Clinilabs Drug Development Corporation, United States. [3]Richmond Research Institute, St George's University of London, United Kingdom. [4]Department of Dermatology, Icahn School of Medicine, United States

Background: Pseudoxanthoma elasticum (PXE) is a rare mineralization disorder caused by mutations in the ABCC6 gene. The ABCC6 protein transports nucleotides, including ATP, into the extracellular space where it is metabolized by the ENPP1 enzyme to AMP and inorganic pyrophosphate (PPi), a critical inhibitor of mineralization. PXE therefore is associated with reduced levels of PPi and ectopic calcification. Adults with PXE experience progressive dermatologic, ophthalmologic, and cardiovascular morbidities, and there are no therapies that target the underlying disease process. INZ-701 is a recombinant ENPP1-Fc investigational product which has demonstrated efficacy in preclinical models of ABCC6 Deficiency. Purpose: To determine the safety, tolerability, immunogenicity, pharmacokinetics and pharmacodynamics of INZ-701, an ENPP1-Fc fusion protein, following subcutaneous administration in adults with ABCC6 Deficiency manifesting as PXE. Methods: Phase 1/2, multicenter, open-label, multiple ascending dose study including 3 cohorts of 3 adults in each with confirmed clinical diagnosis of PXE and biallelic ABCC6 mutations, and PPi <1300 nM (NCT05030831). Participants received 0.2, 0.6 or 1.8 mg/kg INZ-701 SC on day 1, then twice weekly from day 8 to the end of the study. Results: In all 3 dosing cohorts as of January 16, 2023, INZ-701 was generally well-tolerated with no serious or severe adverse events. Mild injection site reactions occurred in 4/9 patients. One patient was withdrawn from the study due to moderate erythema and urticaria. A rapid (within 24 hours) increase in PPi was noted in 8 patients after a single dose of INZ-701, from a mean of 947+/-193 nM at screening. From day 11-32, mean PPi across the 0.2, 0.6 and 1.8 mg/kg dosing groups was 1023 +/- 454 nM, 1119 +/- 216 nM and 1415 +/- 509 nM respectively, suggestive of a dose response relationship. A dose dependent exposure of INZ-701 in a greater than dose proportional manner was observed. The half-life of INZ-701 (~126 hrs) suggests the potential for once-weekly dosing. Eight of 9 participants transitioned to the phase 2 portion of the study and continue on INZ-701. Conclusions: At all 3 doses evaluated, INZ-701 rapidly increased PPi levels into the normal range. A PPi dose response was observed, and at the highest dose (1.8 mg/kg) mean PPi remained in the normal range through last data cut. INZ-701 was generally well tolerated and exhibited a favorable safety profile with potential for once weekly dosing.

Development of an 18F-NaF PET/CT-Based Tool for Quantification and Characterization of Soft Tissue Calcification in Hyperphosphatemic Familial Tumoral Calcinosis (HFTC) *Aaron Sheppard[1], Faraz Farhadi[2], IRIS HARTLEY[3], Rachel Gafni[7], Michael Collins[5], Babak Saboury[6], Kelly Roszko[7]. [1]NIH, United States. [2]Geisel School of Medicine, Dartmouth, United States. [3]NIDCR/NIH, . [7]National Institutes of Health, United States. [5]NIDCR, NIH, United States. [6]Clinical Center, Department of Radiology and Imaging Sciences, NIH, United States. [7]National Institutes of Health,

Hyperphosphatemic familial tumoral calcinosis (HFTC) is a rare disorder which results from a deficiency of FGF23 signaling. Biochemical abnormalities include hyperphosphatemia and an elevated calcium x phosphate product, which likely drives the development of disabling soft tissue calcification. The study of HFTC and its response to treatment suffers from the lack of a quantitative technique to measure disease burden and activity. To address this, we developed 18F-NaF PET/CT and CT only imaging and analysis techniques to characterize and quantify calcifications in the NIH HFTC cohort. 11 patients with HFTC underwent either CT or 18F-NaF PET/CT imaging and the PET and CT voxel-level data were exported to and analyzed with MIM and MATLAB software. Analyses included CT-based bone data - volume and density (Hounsfield Units, HU), and PET-based mineral metabolic activity (Standardized Uptake Value, SUV).82% of patients had ectopic calcifications. The most frequently occurring and largest lesions were at the hips (n=9) and shoulders (n=5), 546.5 +/- 573.5 cm3 and 388.8 +/- 535.1 cm3 respectively. Large variations in total lesion volume and individual lesion volume over the cohort illustrated the great degree of heterogeneity in HFTC. Calcifications were also identified in the sclera of the eye, the colonic mucosa, the brain parenchyma and meninges/dura, and the para-vertebral region of the neck. In one patient who had four CT scans, we found that surgical intervention or repeated trauma increased the rate of growth of the lesions. Another patient had two 18F-NaF PET/CT scans, and voxel-by-voxel analysis found that the lesion increased in volume and density while decreasing in metabolic activity. These data demonstrate the utility of 18F-NaF PET/CT in identifying and quantifying the presence and mineral metabolic activity of calcific lesions and illustrate that CT and PET data provide complementary information that may inform the underlying pathomechanisms of calcification in HFTC. This technique will be useful in quantifying response to treatment in HFTC and likely applicable to other diseases of ectopic calcification.

Altered Collagen I And Premature Pulmonary Embryonic Differentiation In Patients With OI type II *SILVIA STORONI[1], Luca Celli[2], Marjolein Breur[2], Dimitra Micha[2], SARA VERDONK[1], Alessandra Maugeri[2], Joost g. Van den Aardweg[2], Mara Riminucci[3], Elisabeth Eekhoff[4], Marianna Bugiani[2]. [1], Netherlands. [2]Amsterdam UMC, Netherlands. [3]University La Sapienza, Italy. [4]Amsterdam UMC, location VU University Medical Center, Amsterdam, The Netherlands, Netherlands

AbstractIntroduction Pulmonary hypoplasia and respiratory failure are primary causes of death in patients with Osteogenesis Imperfecta (OI) type II. OI is a genetic skeletal disorder caused by pathogenic variants in genes encoding collagen type I. It is still unknown if the collagen defect also affects lung development and structure, causing lung hypoplasia in OI type II.Objective The aim of this study was to investigate the intrinsic characteristics of OI embryonic lung parenchyma and to determine whether altered collagen type I may compromise airway development and lung structure.Methods Lung tissue from nine fetuses with OI type II and six control fetuses, matched by gestational age, was analyzed for TTF-1 and collagen type I expression by immunohistochemistry, to evaluate the state of lung development and amount of collagen.Results The differentiation of epithelium into type 2 pneumocytes during embryonic development was premature in OI type II fetuses compared to controls ($p<0.05$). Collagen type I showed no significant differences between the two groups. However, the amount of alpha2(I) chains was higher in fetuses with OI and the ratio of alpha1(I) to alpha2(I) lower in OI compared to controls.Conclusion Cell differentiation during lung embryonic development in patients with OI type II is premature and impaired. This may be the underlying cause of pulmonary hypoplasia. Altered cell differentiation can be secondary to mechanical chest factors or a consequence of disrupted type I collagen synthesis. Our findings suggest that collagen type I is a biochemical regulator of pulmonary cell differentiation, influencing lung development.

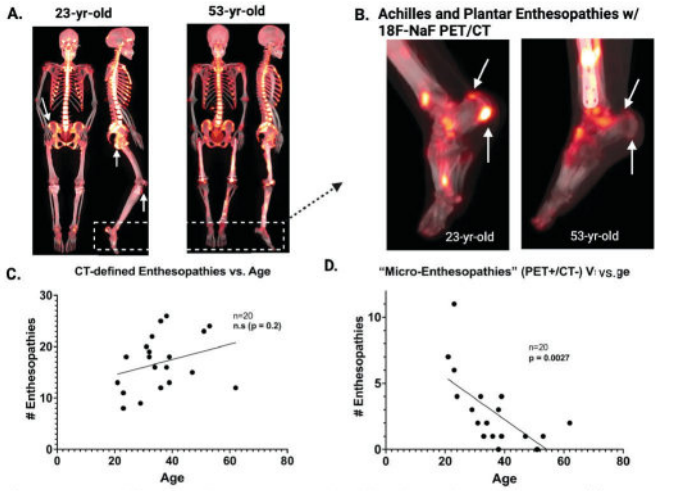
18F-NaF PET/CT is a Sensitive Tool for Detection of Prevalence and Activity of Enthesopathies in X-linked Hypophosphatemia *Aaron Sheppard[1], Babak Saboury[2], Juan Carlos Quintana[3], Oscar Contreras[3], Macarena Jimenez[4], Danisa Ivanovic-Zuvic[5], Annette Madison[5], Michael Collins[1], Pablo Florenzano[5]. [1]National Institutes of Health, National Institutes of Dental and Craniofacial Research, United States. [2]National Institutes of Health, Department of Radiology and Imaging Sciences, United States. [3]Pontificia Universidad Catolica de Chile, Radiology Department, Chile. [4]Pontificia Universidad Catolica de Chile, Endocrinology Department, Chile. [5]Pontificia Universidad Catolica de Chile, Endocrinology D, Chile

X-linked hypophosphatemia (XLH) is a rare metabolic bone disorder characterized by increased FGF23 production, which leads to chronic hypophosphatemia. Clinically, it presents with impaired skeletal mineralization and abnormal soft-tissue calcifications, including enthesopathies (Ens), leading to pain and diminished quality of life (QoL). To date, the natural history of Ens in XLH has been ill defined, due to the lack of a sensitive quantitative tool for its characterization and follow-up. Adult patients with genetically confirmed XLH were included. Clinical evaluations included severity surveys to assess QoL (SF23V), pain (BPI) and functionality (WOMAC/6MWT). 18F-NaF PET/CT scans, which can detect both the presence and metabolic activity of Ens, were acquired for all patient, and a comprehensive review of each patient's scan was performed. A subset of 14 common tendon/ligament insertion sites were chosen for further analysis, characterizing each site as CT-positive only (CT+) (macro-En) or PET-positive/CT-negative (PET+/CT-) (micro-En). Associations of macro- and micro-Ens with relevant clinical variables were performed, including linear regressions and Pearson's correlations. 20 patients were included, 70% women. Mean age at study was 35 years (21-62), with a mean age at diagnosis of 10 years (0.3-32). 18F-NaF PET was able to detect developing Ens in many locations before detection by CT (14.6% of all Ens). Notably, the number of PET+/CT- Ens was negatively correlated with age ($r=-0.634$, $p=0.0027$). The number of CT+ Ens had an insignificant positive correlation with age ($r=+0.29$, $p=0.200$). In addition, 18F-NaF PET offered synergistic information to CT,

allowing the differentiation between metabolically active (PET+) vs stable (CT+/PET-) Ens. To illustrate, only 25% of macro-Ens at the ischial tuberosity were 18F-NaF avid, while 95.7% at the Achilles tendon were 18F-NaF avid. This, the first study to describe the use of 18F-NaF PET in characterizing Ens in XLH, demonstrated the ability of this modality to detect early En development at many sites. The fact that the number of detectable micro-Ens (PET+/CT-) was negatively correlated with age, suggests a progression pattern from a metabolically active early-lesion to a more structurally detectable, inactive lesion. 18F-NaF PET/CT is a promising tool that opens a window to better understand the natural history of the disease and may be used to assess the response of early Ens to therapeutic interventions.



[18]F-NaF PET/CT differentiates between active and stable enthesopathies (Ens) in XLH. *(A) maximum intensity projection (MIP) of [18]F-NaF PET scan overlayed on CT MIP for a 23-yr-old patient and a 53-yr-old. (B) A focused look at the heel of the same 23- and 53-yr-old patients. Increased [18]F-NaF PET signal is greatest at the Achilles and plantar ligament in the younger patient, illustrating how this modality may detect the actively forming Ens earlier in life. (C) The number of CT+ Ens was insignificantly positively correlated with age, whereas (D) the number of PET+/CT- Ens was negatively correlated with age*

Osteopathia striata with cranial stenosis can be caused by a somatic missense variant in the CTNNB1 gene encoding ?-catenin *YENTL HUYBRECHTS[1], Natasha Appelman-Dijkstra[2], Ellen Steenackers[3], Wouter Van Beylen[3], Geert Mortier[4], Gretl Hendrickx[4], Wim Van Hul[3, 1], Belgium, [2]Leiden Center for Bone Quality, Netherlands, [3]University of Antwerp, Belgium, [4]University of Leuven, Belgium

Osteopathia striata with cranial sclerosis (OSCS) is a rare bone disorder with X-linked dominant inheritance, characterized by a generalized high bone mass in the skull and long bones and typical metaphyseal striations in the long bones. So far, loss-of-function variants in AMER1 (also known as WTX or FAM123B), encoding the APC membrane recruitment protein 1 (AMER1), have been described as the only molecular cause for OSCS. AMER1 promotes the degradation of ?-catenin via AXIN stabilization, acting as a negative regulator of the WNT/?-catenin signaling pathway, a central pathway in bone formation. A Dutch adult woman was seen with an OSCS phenotype, i.e. generalized high bone mass and characteristic metaphyseal striations, but without a genetic variant affecting AMER1. Whole exome sequencing led to the identification of a mosaic missense variant (c.876A>C; p.Lys292Asn) in CTNNB1, coding for ?-catenin. The variant substitutes an amino acid known to be involved in the interaction with AXIN, a key factor in the ?-catenin destruction complex. Western blotting experiments demonstrate that the p.Lys292Asn variant does not significantly affect the ?-catenin phosphorylation status, and hence stability in the cytoplasm. Additionally, luciferase reporter assays were performed to investigate the effect of p.Lys292Asn ?-catenin on canonical WNT signaling. These studies indicate an average 70-fold increase in canonical WNT signaling activity by p.Lys292Asn ?-catenin. In conclusion, this study indicates that somatic variants in the CTNNB1 gene could explain the pathogenesis of unsolved cases of osteopathia striata with cranial sclerosis.

Assessment of Serum Alkaline Phosphatase, Serum Phosphate, Rickets Severity Score, Spinal Stenosis, Nephrocalcinosis, and Renal Function with Burosumab or Conventional Therapy Among Patients with X-linked Hypophosphatemia (XLH): Results from a Multinational, Long-term, Prospective Outcomes Disease Monitoring Program (DMP) *Leanne Ward[1], KATHRYN DAHIR[7], Hamilton Cassinelli[3], Pablo Florenzano[4], Erik Imel[5], Aliya Khan[6], Jill Simmons[7], Suzanne Jan De Beur[8], Carolina Moreira[9], Anna Ryabets-Lienhard[10], Zhiyi Li[11], Zunqiu Chen[12], ANTONIO NINO[13], Thomas Carpenter[14], [1]Children s Hospital of Eastern Ontario, Canada, [7]Vanderbilt University Medical Center, , [3]CEDIE, Centro de Investigaciones Endocrinologicas Dr Cesar Bergada, Division de Endocrinologia, Hospital de Niños Ricardo Gutierrez, Argentina, [4]Pontificia Universidad Catolica de Chile, Chile, [5]Indiana University School of Medicine, United States, [6]McMaster University, Canada, [7]Vanderbilt University Medical Center, United States, [8]Johns Hopkins University, United States, [9]Endocrine Division (SEMPR), Department of Internal Medicine, Federal University of Parana, Brazil, [10]Children's Hospital Los Angeles , , [11]Kyowa Kirin, Inc., United States, [12]Ultragenyx Pharmaceutical Inc., United States, [13]Ultragenyx, United States, [14]Yale University School of Medicine, United States

Purpose: To provide an update from the XLH DMP, which is an ongoing, non-interventional, prospective study with a 10-year planned duration, that characterizes disease progression and long-term effectiveness and safety of burosumab and other treatments (NCT03651505).Methods: Children (peds; <18 years) and adults (>=18 years) at DMP enrollment (Month 0; M0) were grouped according to burosumab treatment: Group 1 (Gr1) began burosumab in a prior clinical trial and have the longest exposure among the study population; Group 2 (Gr2) began commercial burosumab prior to/during the DMP; Group 3 (Gr3) had no burosumab exposure, but most received conventional therapy (CT; eg, oral phosphate and active vitamin D). Results from patients (pts) who completed Year 3 (Y3) at data cutoff are reported.Results: As of February 2023, 347 peds and 461 adults were enrolled in the DMP; mean (SD) age at M0 was 9.0 (4.8) years and 39.0 (14.7) years, respectively. Mean duration of burosumab exposure was similar between peds (133.1 [65.5] weeks) and adults (135.0 [72.0] weeks). At Y3, mean serum alkaline phosphatase was lower in peds receiving burosumab vs CT (Gr1: 287.3 [151.6] U/L; Gr2: 277.0 [142.4] U/L; Gr3: 474.5 [170.2] U/L). Additionally, mean serum phosphate levels were higher in peds receiving burosumab vs CT (Fig 1A). Mean serum phosphate levels were also higher in Gr1 and Gr2 adults vs Gr 3 adults (Fig 1B). Rickets severity scores (RSS) in Gr1 peds remained low at Y3 (-0.1 change from M0) and improved in Gr2 peds (-0.7 change from M0); no Gr3 pts had completed RSS at Y3. At M0, 75 (16%) adults across all 3 groups reported an existing diagnosis of spinal stenosis (SS) or spinal cord (SC) compression, including 36 pts (37%) in Gr1, 28 pts (14%) in Gr2, and 11 pts (7%) in Gr3. The majority of pts who had a previous diagnosis of SS or SC compression did not report worsening of their condition and did not undergo a related surgery at Y3. Comparing M0 to Y3, 4 pts (2 each from Gr2 and Gr3) had renal ultrasound score increases of >=2 and 1 pt from Gr2 showed improvement with score decreases of >=2; no Gr1 pts had score increases >=2. Burosumab was not associated with declines in renal function (as assessed by eGFR), urinary protein/creatinine ratio, or any new safety concerns in peds or adults.Conclusions: Long-term exposure to burosumab for up to 3 years in the DMP was consistent with its previously reported benefits vs CT and positively affected markers of disease activity.

Genotype-Phenotype Correlations in Osteogenesis Imperfecta: A Retrospective Study in 294 Patients *Jay Byrd[1], Andrew White[1], Makayla Schissel[1], Matthew VanOrmer[1], Danita Velasco[1], Maegen Wallace[1], [1]University of Nebraska Medical Center, United States

BACKGROUND: Osteogenesis imperfecta (OI) is an inherited disorder characterized by bone fragility with extraskeletal manifestations. Mutations in COL1A1 and COL1A2 account for most OI, yet non-COL1A1/2 mutations are responsible for many cases. There are 16 widely accepted genes causing OI; however, literature on genotype-phenotype correlation

and incidence of non-skeletal clinical features are limited. This study aims to identify genotype-phenotype correlations in patients with OI, allowing clinicians to better inform families of prognosis, optimize patient care, and facilitate evidence-based clinical decision-making. METHODS: A retrospective review of 294 patients with OI was performed to collect demographic data, clinical characteristics, and genotypic information. Patients were stratified by COL1A1/2 vs. non-COL1A1/2 mutations to evaluate differences in phenotype. Data were summarized with descriptive statistics, followed by Chi-square or Fisher's Exact tests for categorical variables and independent samples T-tests or Wilcoxon Rank sum tests for continuous variables. A p-value of <0.05 was considered statistically significant.RESULTS: The majority of OI was due to mutations in COL1A1/2 (91%), with the remaining 9% due to non-COL1A1/2 mutations. 147 (50.0%) are male and 147 (50.0%) are female. Most patients in the COL1A1/2 group were White compared to the non-COL1A1/2 group (78% vs. 50%; p=0.004). COL1A/2 patients had higher incidence of blue sclerae (83% vs. 50%, p=0.002), dentinogenesis imperfecta (49% vs. 15%, p<0.001), and family history of OI (34% vs. 12%, p=0.03). Those in the non-COL1A1/2 group have higher rates of scoliosis compared to those in the COL1A1/2 group (62% vs. 40%, p=0.04), as well as higher rates of expressive language disorder/delay (15% vs. 0.4% in non-COL1A1/2 and COL1A1/2 patients, respectively; p<0.001).CONCLUSIONS: Identifying the underlying molecular etiology early is imperative for optimal clinical care, allowing for appropriate risk counseling, identification of affected relatives, and improved anticipatory care and management. This data supports that rare subtypes of OI occur more frequently in non-White individuals and demonstrated genetic associations with incidence of blue sclera, dentinogenesis imperfecta, scoliosis, and expressive language disorders.

OCL-IGF1-induced OCy senescence promotes RANKL production and induces pagetic bone lesions in Paget's disease *Hirofumi Tenshin[1], Jolene J. Windle[2], Mark A. Subler[2], John M Chirgwin[3], Brendan F. Boyce[4], G. David Roodman[1], Noriyoshi Kurihara[1]. [1]Division of Hematology and Oncology, Department of Medicine, Indiana University, United States; [2]Department of Human and Molecular Genetics, Virginia Commonwealth University, United States; [3]Research Service, Roudebush Veterans Administration Medical Center, United States; [4]Pathology & Laboratory Medicine, University of Rochester School of Medicine & Dentistry, United States

Paget's disease (PD) is characterized by persistent focal bone lesions, typified by increased bone resorption by abnormal osteoclasts (OCLs) that is followed by rapid formation of increased woven bone. Measles virus nucleocapsid protein (MVNP) expression in OCLs of PD patients increases OCL IGF1 production (OCL-IGF1), which in turn stimulates osteoblast differentiation. Conditional deletion of Igf1 in OCLs of TRAP-MVNP (T-MVNP) transgenic mice blocked the development of pagetic bone lesions (PDLs). These results suggest that OCL-IGF1 is sufficient to induce PDL formation in PD. To determine the role of OCL-IGF1 in PD, we generated TRAP-Igf1 (T-Igf1) transgenic mice, whose OCLs expressed similar levels of IGF1 as T-MVNP mice and developed the same PD phenotype as T-MVNP mice. PDLs were detected in vertebrae, femora, and tibiae of 50% of 16-month-old T-Igf1 mice by μ-CT and histological analysis. Thus, increased IGF1 expression in the absence of MVNP in OCLs is sufficient to induce PDLs. The results support IGF1 as a major PD-OCL product driving PDL formation in T-MVNP mice. Senescence increases RANKL expression by osteocytes (OCys), and OCy-derived RANKL is required for cortical bone loss that occurs with age (Kim HN et al, JCI-Insight 2020). We hypothesized that MVNP-expressing OCLs drive the accumulation of senescent OCys and increased RANKL expression in OCys in PD. However, we do not know if IGF1 secreted by OCLs in PD directly affects senescence to regulate RANKL production by OCys, bone resorption and development of PDLs. We determined the expression of telomere dysfunction-induced foci expression as a marker of senescence. 10% of OCys were senescent in 16-month-old WT mice, and 20% of OCys in T-Igf1 and T-MVNP mice. We used in situ hybridization to determine if mRNAs for p16INK4A and Rankl are upregulated in OCys in vivo. Rankl-expressing OCys were detected within 50 μm of OCLs, and almost all p16INK4A-positive OCys in T-MVNP mice expressed Rankl, while OCys in WT mice did not. There was no relationship between the expression of p16INK4A and IL-6 or sclerostin. OCys in MVNP-expressing PD patients showed similar levels of senescence and RANKL expression as T-MVNP mice. These results suggest that increased senescence in OCys is induced by OCL-IGF1, and accompanied by increased OCy RANKL, promoting the formation of PDLs. These findings support a model where senescent OCys expressing RANKL may initiate PDL formation in PD.

Genetic Modulation of Hedgehog Signaling Influences Exostoses Elongation, Orientation, and Proliferation in a Mouse Model of Hereditary Multiple Exostoses (HME) *Sarah Catheline[1], Christina Mundy[2], Maurizio Pacifici[3]. [1]University of Rochester, United States; [2]Children's Hospital of Philadelphia, United States; [3]The Children's Hospital of Philadelphia, United States

Hereditary Multiple Exostoses (HME) is a congenital pediatric disorder in which cartilaginous tumors called osteochondromas or exostoses develop perpendicular to growth plates of skeletal elements. Most HME patients have a mutation in?EXT1?or?EXT2 causing heparan sulfate (HS) deficiency. Normally, HS-rich proteoglycans (HSPGs) restrict growth factor availability, and the HS deficiency in HME growth plates could result in freely available growth factors, inducing exostosis formation. However, it is unknown why the exostoses grow orthogonally to the growth plate main axis. The Indian hedgehog (IHH)/PTHrP signaling axis is critical for growth plate zonal organization, and hedgehog proteins bind HSPGs. Thus, HS deficiency in HME could allow the proteins to escape the growth plate and trigger a neo IHH-PTHrP axis within perichondrium, causing orthogonal exostosis formation. To test this novel thesis, we used AggrecanCreERT2? mice to drive?Ext1?deletion in chondrocytes and perichondrium in 5 week-old mice. To ask whether hedgehog signaling is necessary and sufficient for exostosis formation, we combined this model with: (a) conditional deletion of hedgehog receptor?Smo?resulting in Hedgehog loss of function (LOF); or (b) conditional deletion of?Ptch1, a negative regulator of signaling, resulting in gain of function (GOF). Acan-Cre+/-ERT2; Ext1f/f;?Smof/f?mice displayed delayed exostosis formation 10 days after tamoxifen relative to Acan-Cre+/-ERT2; Ext1f/f?(Ext1 mutant) mice, significantly decreasing exostosis number and size 4 weeks post tamoxifen. In contrast,?Acan-Cre+/-ERT2; Ext1f/f; Ptch1f/+?mice showed greater number of exostoses at 10 days relative to Ext1?mutant mice, resulting in significantly longer, wider and more numerous exostoses by 4 weeks. Notably, Ext1 mutants showed enriched cell proliferation marked by Ki67 in perichondrium at the site of new exostoses, while LOF mice lacked proliferating perichondrial cells and GOF mice showed the greatest number of Ki67-positive cells, suggestive that hedgehog helps initiate perichondrial proliferation. ?-catenin expression throughout the exostoses, and Pthrp-LacZ specifically present at their leading edge, both increased in Ext1 mutant mice and were further increased in GOF mice, suggesting that crosstalk between these pathways is important in exostosis formation. Our current data implicate IHH/PTHrP signaling as a critical regulator of osteochondroma formation and orthogonal growth.

Figure 1. A novel mouse model for osteogenesis imperfecta type I shows altered TGF? signaling *Ellen Busschers[1], Yuqing Chen-Everson[1], I-Wen Song[1], Brian Dawson[1], Brendan Lee[1]. [1]Baylor College of Medicine, United States

Osteogenesis imperfecta (OI) is a genetic skeletal disorder that is characterized by low bone mass, frequent fractures, and bone deformities as well as multiple extra-skeletal manifestations. The vast majority of OI is caused by either quantitative defects of type I collagen or qualitative defects of type I collagen characterized by post-translational over-modification. Type I OI is caused by haploinsufficiency of collagen type 1 (COL1A1 or COL1A2). On the mild end of the disease spectrum, it accounts for more than 50% of OI cases. The previously reported Mov13 mouse model with a retroviral insertion into Col1a1 was originally reported as a putative type I OI model; however, the mice develop lymphoma which makes molecular and long-term study difficult. Therefore, we set out to generate a new mouse model of OI type 1.We generated a novel Col1a1 haploinsufficient type I OI mouse model by crossing mice with a Col1a1 floxed allele to CMV-Cre mice to create a full body heterozygous deletion of Col1a1. Micro-CT analysis showed that these mice have a decrease in both trabecular bone volume as well as a decrease in cortical thickness of the femur. Currently, there are no FDA-approved treatments for OI. Clinically, bisphosphonates have become the standard of care medication to treat bone fragility in mild OI; however, the benefit of long-term use is inconclusive. Increased TGF? signaling has been shown to be a major pathogenic driver in multiple models of moderate and severe OI characterized by collagen over modification. Here, inhibition of TGF? was shown to increase bone volume and strength. Therefore, we also measured the level of TGF? signaling in OI mice that have reduced

quantity, but otherwise normal collagen modification. We show that phospho-SMAD2 protein expression is increased by western blot and immunohistochemistry. We further saw an increase in mRNA expression of TGF? target genes by qPCR. Overall, these data suggested that TGF? signaling was also increased in these mice. To determine if inhibition of TGF? has a beneficial effect, we treated these mice for 8 weeks with the TGF? neutralizing antibody 1D11. Our preliminary results suggest this results in an increase in bone volume in these mice. Here, we describe a novel mouse model for OI type I that shows a mild OI phenotype and increased TGF? signaling in bone. These studies support extending the clinical study of anti-TGF? approach to OI type I patients as is currently in progress (NCT05231668).

Deciphering phenotypic and mechanistic variability in Bruck syndrome and Osteogenesis imperfecta, through a zebrafish model with loss of fkbp10

*Tamara Jarayseh[1], Hanna De Saffel[1], Toon Rosseel[1], Mauro Milazzo[1], Sophie Debaenst[1], Paul Eckhard Witten[2], Andy Willaert[1], Paul Coucke[1]. [1]Center for Medical Genetics, Department of Biomolecular Medicine, Ghent University, Ghent, Belgium, Belgium. [2]Department of Biology, Ghent University, Ghent, Belgium. , Belgium

Bruck syndrome (BS) is a disorder characterized by bone fragility and congenital contractures that has a clinical overlap with Osteogenesis imperfecta (OI) disease. BS is caused by recessive biallelic mutations in either the FKBP10 or PLOD2 gene. The FKBP65 protein, encoded by FKBP10, acts in the folding of collagens and is involved, together with the LH2 enzyme (PLOD2), in the hydroxylation of collagen telopeptide lysine residues, which is important for collagen crosslinking in the extracellular matrix. A pronounced phenotypic variability ranging from fractures without contractures, to fractures and contractures and even only contractures, in the presence of an identical causal genetic variant is frequently observed in Bruck syndrome patients. This suggests that modifier genes contribute to the phenotypic severity through a network of interactions with the causative gene.To further investigate the mechanistic role of FKBP10 in BS/OI pathogenesis, and to unravel the cause of this phenotypic variability, we created a zebrafish model carrying an fkbp10a frameshift mutation by using CRISPR-Cas9 technology. Deep skeletal phenotyping of the vertebral column using X-ray imaging, Alizarin red mineral staining, micro-CT scanning and bone histology for fkbp10a mutant siblings, revealed a wide phenotypic variability, similar to what is observed in human patients, with variable mineralization, fracture incidence, shortened body axis and skeletal deformations. To identify potential modifiers, we conducted whole exome sequencing of the 7 most mildly and 7 most severely affected mutant siblings, followed by SNP-based linkage analysis. This revealed a linked region (LOD score= 4.4) on chromosome 13, ~15Mb in size and contains 268 protein coding genes, which segregates with the phenotypic severity.In conclusion, FKBP10 mutant zebrafish show molecular and tissue abnormalities in the skeletal system and our findings suggest that the linked region in chromosome 13 could contain the potential modifier gene that explains the phenotypic variability, thus could lead to a novel therapeutic avenues in this syndrome.

Osteopathy in Gorham-Stout Disease Animal Model

*ERNESTO SOLORZANO[1], Gabrielle Robinson[5], Hope Ball[5], Adam Sanchez[3], Alexander Powell[3], Michael Kelly[4], Fayez Safadi[5]. [1], United States. [5]Northeast Ohio Medical University, . [3]NEOMED, United States. [4]Cleveland Clinic Foundation, United States. [5]Northeast Ohio Medical University, United States

Gorham-Stout Disease (GSD) is a rare condition associated with aggressive lymphatic invasion into bone leading to massive bone loss. To date, the mechanism of bone loss identified in GSD remains to be elucidated. Most recently, a lymphatic-specific KRAS somatic activating mutation was identified in GSD patients. A mouse model recapitulating this mutation in Prox1 expressing lymphatic cells showed detrimental lymphatic valve formation. To better understand the abnormal bone loss present in GSD patients, we generated a tamoxifen-induced lymphatic endothelial cell KRAS somatic activating mutation in mice and characterized the skeletal phenotype. These mutant animals exhibited decreased body weight compared to wild-type littermates. In addition, we observed extensive lymphatic fluid accumulation in the thoracic cavity in comparison to wild-type littermates. Soft tissue immunohistochemical analysis of LYVE-1 (lymphatic endothelial cell marker) revealed lymphatic vessel invasion into the kidneys. Subsequently, bone mineral density, content, and area were all found to be decreased in KRAS mutants compared to wild-type mice. These results were also observed in KRAS mutant spine, femur, and tibia compared to wild-type controls. In addition, a decrease in total fat and lean muscle mass was also observed. Further, we next assessed bone mRNA expression and found a decrease in Runx2 and Collagen type I in mutant mice. However, the expression of osteoclast-related markers (TRAP, DC-Stamp, and Cathepsin-K) was increased in mutants compared to wild-type animals. When assessing bone marrow-derived macrophages, we found a decrease in cell proliferation associated with decreased total osteoclast count in mutant compared to wild-type. Interestingly, TRAP activity per osteoclast was increased in mutant compared to wild-type. Our findings show how a lymphatic-specific KRAS mutation leads to a decrease in bone mass in vivo and induces cell-autonomous changes in osteoclast differentiation ex vivo. For this reason, we predict mutant lymphatic tissue actively secretes bone-regulating factors capable of modulating bone homeostasis. In conclusion, our studies are the first to describe abnormal bone phenotypes found in KRAS mutant mice. Future studies aimed to identify lymphatic secreted factors responsible for bone loss and changes in osteoclast homeostasis observed in the GSD mouse model.

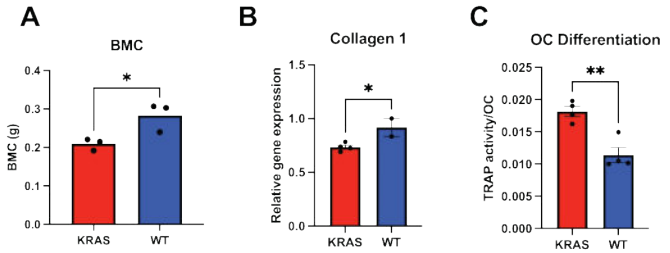

Figure 1. Osteopathic changes found in GSD animal model. Lymphatic specific KRAS activating mutation led to a decrease in bone mineral content (BMC) on mutant animals (KRAS) when compared to wild-type (WT) (**A**). Bone mRNA expression of collagen 1 was decreased in KRAS when compared to WT (**B**). Osteoclast (OC) TRAP activity per cell was higher in KRAS animals when compared to WT (**C**).

Distinct molecular mechanisms of bone and lung pathologies in a G610C Mouse Model of OI

*ELENA MAKAREEVA[1], Megan Sousa[1], Muthulakshmi Sellamani[1], Edward L. Mertz[1], Satoru Otsuru[2], Sergey Leikin[3]. [1]NIH, United States. [2]University of Maryland, United States. [3]National Institutes of Health, United States

Lung function in osteogenesis imperfecta (OI) is affected by both chest deformities and intrinsic lung tissue pathology. Alveolar disruption has been reported in mouse models and bronchial wall thickening in humans. The present study aims to provide mechanistic insights into the causes of the lung-intrinsic pathology in a G610C mouse model of moderate OI, which carries the same mutation in type I collagen alpha2(I) chain as in Old Order Amish patients. We previously demonstrated that bone pathology in G610C mice is largely caused by osteoblast and hypertrophic chondrocyte malfunction because of misfolded procollagen accumulation in the ER and consecutive cellular stress, specifically integrated stress response (ISR). Surprisingly, we found that lung pathology in G610C mice is more severe than bone pathology, homozygous (Hom) G610C neonates die at birth from lung failure caused by poorly developed saccular structures and massive parenchymal bleeding. In Hom E18.5 embryos, bone pathology was comparable to severely affected yet surviving Het animals while the lung pathology was more dramatic. In lung fibroblasts, unlike osteoblasts, we observed no ER disruption in electron microscopy (EM) and no ISR marker gene upregulation in single cell (scRNASeq) or spatially resolved (srRNASeq) RNASeq. Instead, EM, histology, immunofluorescence, scRNASeq, srRNASeq, and in situ mRNA hybridization revealed deficient extracellular matrix (ECM) deposition, myofibroblast deficiency, and disorganization of lung epithelial cells, which filled the developing lung saccules instead of lining them. Altered gene expression by myofibroblasts and epithelial cells suggested abnormal cell interactions with the deficient ECM. In Het embryos, the lung pathology was less severe, but in 3- and 5-week-old Het mice we observed alveolar disruption, reduced alveolar surface/volume ratio, and increased respiratory frequency and volume/minute at rest (potentially compensating for the alveolar surface loss). In addition, many 3- and 5-week-old Het mice had lesions with inflammatory cell infiltration and various degrees of fibrosis, probably resulting from weak ECM being prone to injury. In 10-week-old Het mice, the alveolar disruption, lesions, and respiratory abnormalities were less pronounced, likely because of continuous lung remodeling in mice. These observations suggest that disruption of rapidly forming ECM and cell-ECM interactions by secreted mutant collagen molecules in embryos and young animals is the primary cause of the lung-intrinsic pathology in G610C mice, which is distinct from bone pathology.

Osteogenic impairment in novel pre-clinical mouse model of osteofibrous dysplasia

*Jonathan Rios[1], Nandina Paria[2], Carol Wise[3], Kristin Denton[4], Aysha Khalid[4]. [1]Scottish Rite for Children, United States. [2]Texas Scottish Rite Hospital for Children, United States. [3]Texas Scottish Rite Hospital, United States. [4]Scottish Rite Hospital for Children, United States

Osteofibrous dysplasia (OFD) is a skeletal disorder affecting the periosteal surface of bone. We previously identified inherited and somatic mutations in the gene encoding the MET tyrosine kinase receptor in patients with OFD. MET gene mutations alteres the juxtamemrane domain (JMD), thereby reducing ubiquitin-mediated receptor degradation and resulting in a ligand-dependent gain-of-function mechanism. We developed the first pre-clinical mouse model of OFD by engineering mice lacking the Met JMD (Met?JMD) and com-

pared our results to mice conditionally lacking Met in the bone periosteum (Postn-cre;Met-flox/flox; herein MetPostn). We compared matched bone periosteal explant cells (PECs) to bone marrow stromal cells (BMSCs) from control mice, Met and Hgf expression was significantly higher in PECs compared to BMSCs, consistent with human OFD. Consistent with the ligand-dependent gain-of-function mechanism, Met activation following stimulation with HGF was prolonged with delayed return to baseline in BMSCs from Met+/?JMD mice compared to control . Moreover, downstream Erk activation was significantly higher in PECs from Met+/?JMD mice compared to control, which was attributed to growth factors present within the cell culture media. Osteogenic differentiation of BMSCs and PECs from Met+/?JMD mice was significantly impaired compared to control. However, µCT analysis demonstrated no significant differences in trabecular and cortical parameters between control and Met+/?JMD mice. To test the impact that inhibition of Met has on osteogenic differentiation and skeletal development, we repeated ostogenic differentiation experiments using PECs from MetPostn mice. In contrast to results from Met+/?JMD mice, osteogenic differentiation of PECs from MetPostn mice was enhanced compared to control mice. Our results identify Met as a bidirectional key regulator of osteogenic differentiation and implicate impaired osteogenic differentiation in the pathogenesis of OFD. Results from this study suggest further research into the use of MET inhibitors to treat MET?JMD -associated OFD.

[3]Division of Endocrinology and Metabolism, the Institute for Human Genetics, and the Eli and Edythe Broad Institute for Regeneration Medicine, Department of Medicine, University of California, San Francisco, CA 94143, United States. [4]Oral and Craniofacial Sciences Graduate Program, School of Dentistry, University of California, San Francisco, CA 94143, United States. [5]University of California, San Francisco, United States

G protein-coupled receptors (GPCRs) mediate many physiological functions, including skeletal development, remodeling, and repair. Fibrous dysplasia (FD) of the bone is characterized by fibrotic, expansile bone lesions caused by activating mutations in GNAS. Col1(2.3)+/Rs1+ mice with hyper-activation of Gs-GPCR signaling in osteoblastic cells develop FD-like bone lesions that can be reversed by normalizing Gs-GPCR signaling, suggesting that targeting Gs-GPCR or downstream signaling is a potential therapeutic strategy for FD. While Wnt signaling is implicated in FD pathogenesis, the specific Wnts and which cells produce them remain largely unknown. Single cell RNA sequencing on long-bone stromal cells of 9-wk-old male Col1(2.3)+/Rs1+ mice and littermate controls showed numeric and proportional stromal cell expansion in Col1(2.3)+/Rs1+ mice (6.37% (391 cells/5632 Col1(2.3)+/Rs1+ cells) v. WT 0.99% (57 cells/5767 WT cells). Pathway analysis of this cluster showed activation of Wnt/?-catenin signaling, likely driven by a predominance of Col1(2.3)+/Rs1+ cells. Subclustering found individual Wnt ligands were variably expressed by multiple fibroblastic subclusters. Wnt9a and Wnt11 were significantly upregulated in all of the fibroblastic stromal cell sub-clusters (c8.0, 8.1, 8.2, 8.5) compared to non-stromal cell lineages. Col1(2.3)+/Rs1+ mice treated with the porcupine inhibitor LGK974, which blocks Wnt signaling broadly, showed a significantly lower femoral BV/TV (0.34 vs. 0.46, $p<0.006$) and trabecular thickness (16.53 vs. 20.58 mm, $p<0.0055$) compared to vehicle-treated Col1(2.3)+/Rs1+ mice, but only qualitative changes in the craniofacial skeleton. Bone fibrosis remained evident after treatment, suggesting a dissociation between the fibrotic and trabecularization phenotypes in FD. Notably, LGK974 caused significant bone loss in control mice indicating that broad Wnt blockade is detrimental to the normal skeleton. Our scRNAseq results revealed that Col1(2.3)+/Rs1+ mice with FD-like bone lesions have a significant expansion of a fibroblastic cell population. A surprisingly broad number of cell types express Wnt ligands. Also, broadly inhibiting Wnt signaling using a porcupine inhibitor reversed established FD-like bone trabecularization in Col1(2.3)+/Rs1+ mice, but the fibrotic cell infiltrate remained unchanged. These findings will guide future studies testing how individual Wnt ligands contribute to FD pathogenesis.

Phenotype of the first mouse model of Cole Carpenter Syndrome. *Antonio Maurizi[1], Piergiorgio Patrizii[1], Katie Desmond[1], Oriana Newman[1], Elisa Pucci[1], Antonella Stoppacciaro[2], Paolo Mené[2], Anna Teti[1]. [1]University of L'Aquila - Department of Biotechnological and Applied Clinical Sciences, Italy. [2]University Sapienza, Department of Clinical and Molecular Medicine, , Italy

The Cole Carpenter Syndrome (CCS) is a rare genetic disease displaying an autosomal dominant inheritance with a prevalence 0.05). However, the bone phenotype, assessed by µCT in 1, 3, 6 and 12 months old male and female CCS mice showed marked osteopenia compared to the WT counterpart ($p<0.05$). In addition, the Indentation Distance and the Total Indentation Distance were dramatically increased (+1.7fold;$p=0.03$) in CSS femurs compared to WT, indicating a poor bone quality. Interestingly, the metabolic analysis revealed a significant reduction of postprandial blood glucose levels in 1 and 6 months old CCS male mice compared to WT (-28 and -14%, respectively, $p<0.05$), along with an unchanged glucose and insulin tolerance. This finding could be linked to renal defects found in CSS mice consisting of an extensive tubular vacuolization, along with intracellular protein deposits, intraluminal protein cylinders and glomerular shrinkage, which can lead to an excessive glucose leakage in the urines. At the subcellular level, Western blot analysis conducted in primary CCS mouse osteoblasts showed a significant reduction of type 1 collagen production (-25%;$p=0.05$) associated with an increased pro-collagen 1 expression (+2.9;$p=0.03$) compared to WT cells. In line with this, in vivo serum PINP1 levels, a marker of type I collagen turnover in the bone matrix, were lower in CCS mice as well (-60%;$p<0.01$). Overall, our data indicate the presence of a severe bone phenotype in CCS mice, consistent with the skeletal features of the human disease, and the pathogenic involvement of organs beyond the bone, such as kidneys. Moreover, we demonstrated the presence of a defective type 1 collagen biosynthesis.

Bone-targeted ENPP1-Fc suppresses spinal hyperostosis and prevents hearing loss and spinal osteoporosis in murine ENPP1 deficiency. *Shivani Srivastava[1], Paul Stabach[1], Keith Weise[1], Simon Von Kroge[2], Ralf Oheim[2], Thomas Carpenter[3], Steven Tommasini[4], Demetrios Braddock[1]. [1]Department of Pathology, Yale University School of Medicine, United States. [2]University Medical Center Hamburg-Eppendorf, Germany. [3]Department of Pediatrics, Yale University School of Medicine, United States. [4]Department of Orthopædics and Rehabilitation, Yale University School of Medicine, United States

Background: Biallelic ENPP1 deficiency is associated with GACI and ARHR2, and monoallelic ENPP1 deficiency with Diffuse idiopathic skeletal hyperostosis (DISH), Ossification of the Posterior Longitudinal Ligament (OPLL), and early onset osteoporosis. DISH and OPLL are characterized by entheses in the paraspinal tendons and ligaments, similar to the spinal phenotype in ARHR2. Moreover, increased FGF23 and decreased plasma Pi is associated with rapidly progressing OPLL, as in ARHR2. Experimental Plan: To determine the effects of soluble (1118) or bone targeted (2000) ENPP1 on the skeletal phenotype, hearing acuity, and plasma analytes in 17-week-old Enpp1 deficient (Enpp1asj) mice treated between weeks 3-17 with 1118 and weeks 5-17 with 2000. Results: We found that 2000 normalized the increased FGF23 levels in Enpp1asj mice in at 1 mg/Kg per week, which 1118 did not suppress at any level. Moreover, the elevated levels of alkaline phosphatase and PTH in Enpp1asj mice were suppressed more potently by 2000 than 1118, which required doses 2-4 times greater. The dramatic spinal hyperostosis present in Enpp1asj mice was suppressed 16% with 1 mg/Kg per week of 2000, but not with 1118 at any dose. Hearing acuity, measured by auditory brainstem response, was impaired by 193% at 8 MHz in Enpp1asj mice and was normalized with 2 mg/Kg per week of 1118 and 0.5 mg/Kg per week of 2000. Femoral maximum load until fracture was reduced 23% in Enpp1asj mice and was normalized to WT levels at 1 mg/Kg of 1118 and 2000, while post yield deflection in the femurs increased 105% and was only normalized with 2000 at doses of 0.5 mg/Kg. Finally, biomechanics in the spines of 17-week-old Enpp1asj mice revealed that spinal stiffness and maximum load until fracture was decreased by 51% and 37% respectively and was restored to WT levels at doses of 0.5 and 2 mg/Kg per week, respectively with 2000.Conclusions: Both soluble and bone targeted ENPP1 improved biomechanics and hearing loss, but only bone targeted ENPP1 suppressed paraspinal enthesopathies, normalized plasma FGF23, and corrected post-yield deflection in long bones. Moreover, bone targeted ENPP1 demonstrated increased potency correcting plasma analytes and bone microarchitecture than soluble ENPP1. Our findings have important implications for the treatment of spinal enthesopathies in OPLL, DISH, and spinal hyperostosis in Ankylosing Spondylitis.

FRI-544

Frailty is associated with greater long-term risk for fall- and fracture-related hospitalizations and mortality in community-dwelling older Australian women *Marc Sim[1], Elsa Dent[2], Jack DallaVia[1], Trent Bozanich[1], Emiel Hoogendijk[3], Abadi Gebre[1], Cassandra Smith[1], Richard Prince[4], Joshua Lewis[1]. [1]Edith Cowan University, Australia. [2]Torrens University Australia, Australia. [3]VU University, Netherlands. [4]University of Western Australia,

Frailty is a complex condition associated with declines in multiple systems with detrimental effects on capacity and quality of life. An underlying assumption being the frailer an individual is, the more likely they are to fall and fracture. We examined whether grades of frailty are related to long-term risk of hospitalized falls and fractures as well as all-cause mortality in community-dwelling older women. 1261 women (mean +/- SD 75.1 +/- 2.7 years) were followed over 14.5 years. Frailty was operationalized using a frailty index (FI) of cumulative deficits from 33 variables (as developed by Rockwood) across multiple health domains (physical, psychosocial, comorbidities) at baseline. Participants were graded as either fit (FI <=0.12), mildly frail (FI >0.12-0.24), moderately frail (FI >0.24-0.36) or severely frail (FI >0.36) based on established criteria. Fall- (n=498), any fracture (n=347) and hip fracture-related hospitalizations (n=137) and deaths (n=482) were obtained from linked health records. Associations between FI grades and each of the clinical outcomes were analyzed using multivariable-adjusted Cox-proportional hazard models including risk factors such as age, treatment (calcium/placebo), body mass index, smoking history, socioeconomic status, plasma 25-hydroxyvitamin D status plus season obtained, physical activity, self-reported prevalent falls and fractures. At baseline, women were classified as fit (n=713, 56.5%), mildly- (n=350, 27.8%), moderately- (n=163, 12.9%) and severely-frail (n=35, 2.8%). In the multivariable-adjusted analysis, compared to fit women, those with mild, moderate and severe frailty had significantly higher hazards for a fall- (46%, 104%, 168%), any fracture- (88%, 193%), hip fracture-related hospitalization (93%, 127%, 129%) and all-cause mortality (47%, 126%, 242%) (Figure). When DXA-derived hip BMD was included as an additional covariate to the multivariable-adjusted model (subset of women with available data, n=865), the results remained unchanged. For community-dwelling older women, our study supports the use of the FI to identify women at risk for falls and fractures requiring hospitalization, as well as all-cause mortality. Accordingly, the FI may be incorporated into falls assessment and fracture prevention strategies to identify older women with poorer clinical prognosis who will benefit from tailored primary prevention programs.

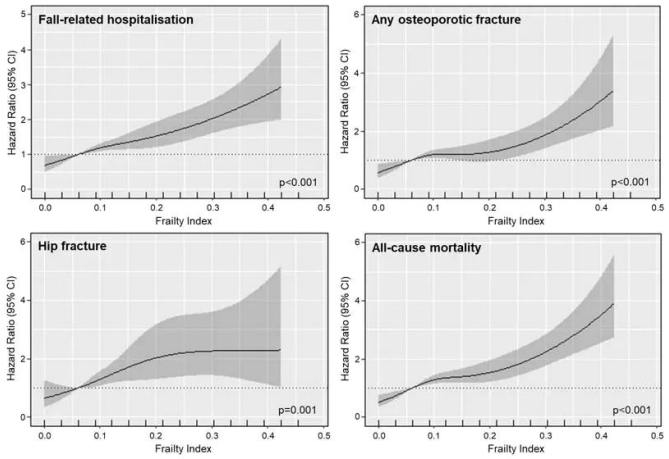

Figure. Multivariable-adjusted relationship between frailty index, fall-, any fracture- and hip fracture-related hospitalizations and all-cause mortality. Hazard ratios are obtained in comparison to the median frailty index score for mildly frail (0.16), frail (0.28) and severely frail (0.41) women, compared to fit women (0.06).

Antihyperglycemic Medications and Fall Related Injuries in a High Risk Population of Older Adults *Sarah Berry[1], Melissa Riester[2], Richa Joshi[2], Kathleen Hayes[2], Lori Daiello[2], Andrew Zullo[2], Douglas Kiel[3]. [1]Hebrew SeniorLife/Beth Israel Deaconess Medical Center, United States. [2]Brown University, United States. [3]Hinda and Arthur Marcus Institute for Aging Research Hebrew SeniorLife, United States

In the past decades, new antihyperglycemics have been approved for type-2 diabetes (T2D) including dipeptidyl peptidase-4 inhibitors (DPP-4i), glucagon-like peptide-1 receptor agonists (GLP-1-RA), and sodium-glucose cotransporter-2 inhibitors (SGLT2-i). Antihyperglycemics can increase fracture risk through long-term effects on bone and more immediately on falls risk through polyuria. Our objective was to compare the incidence of hip fracture and fall related injuries (FRI) among older adults with T2D and DPP-4i, GLP-1-RA, and SGLT2-i use. We hypothesized that SGLT2-i use would increase FRI.Our sample was comprised of Medicare beneficiaries aged ?66 years with a dispensing of a diabetes medication (2013-2019). MedPAR and Part B and D claims were linked with clinical assessments (i.e., Minimum Data Set). We restricted to patients with a T2D diagnosis and a dispensing of DPP-4i, GLP-1-RA, or SGLT2-i while receiving care in a nursing home. We excluded patients with a dispensing in the prior180 days and dialysis patients. Hip fractures and FRI were identified using hospitalization claims. Patients were followed from the date of the new antihyperglycemic dispensing until the first occurrence of fracture/FRI, death, Medicare disenrollment, or 1-year. Cause-specific Cox proportional hazards regression models that accounted for mortality were used to compare outcomes among DDP-4-I, GLP-1-RA, and SGLT2-i adjusting for 30 covariates including measures of function, comorbidities, concomitant medications, and facility-level characteristics.55,149 patients initiated DPP-4i, 6,629 GLP-1-RA, and 2,343 SGLT2-i. The mean (SD) age was 80.8 yrs (+/-8.2) and 66.1% were female. Most patients had multiple comorbidities, including dementia (67.2%). During a mean follow-up of 282 (+/-123) days, 2,993 (4.7%) experienced a FRI, and 17,598 (27.4%) died. Unadjusted rates of hip fracture were 2.19/100 person-yrs (PY) for DPP-4i, 1.32/100 PY for GLP-1-RA, and 1.78/100 PY for SGLT2-i. (Table). Adjusted models found that compared with adults using DPP-4i, the one-year rate of hip fracture and FRI was similar for GLP-1-RA and SGLT2-i users.In a large sample of older adults with T2D receiving care in a nursing home, we found no difference in the rates of hip fracture or injurious falls among persons initiating DPP-4i, GLP-1-RA, or SGLT2-i. Given the potential therapeutic advantages, these results do not suggest that any of the new antihyperglycemics increase FRI risk in a high risk population

	Incidence Rate of Injurious Falls /100 person yrs (95% CL)	Cause specific: Unadjusted Hazards ratio (95% CL)	Cause specific: Adjusted Hazards ratio (95% CL)
Hip Fractures

Higher PEN and CML Levels are Independently Associated with Increased Fracture Risk in Type 2 Diabetes with Suboptimal Glycemic Control *Ruban Dhaliwal[1], Susan Ewing[2], Bowen Wang[3], SAMUEL STEPHEN[4], Deepak Vashishth[3], Ann Schwartz[5]. [1]State University of New York Upstate Medical University, . [2]University of California San Francisco, United States. [3]Rensselaer Polytechnic Institute, United States. [4], . [5]University of California, San Francisco, United States

Advanced glycation end-product (AGE) accumulation occurs with aging and diabetes diminishing the mechanical properties of bone. We have previously shown in two separate analyses that Pentosidine (PEN), a crosslinking AGE and Carboxymethyl-lysine (CML), a

non-crosslinking AGE are risk factors for fracture in type 2 diabetes (T2D), independent of bone mineral density, glycemia and other factors. However, whether PEN and CML have independent relationships with fractures in T2D is unknown. We assessed whether PEN and CML are associated with incident clinical fractures in T2D, independent of each other, in a well characterized cohort of men and women ages 70-79 years from the Health, Aging, and Body Composition study. In addition, we examined the effect of glycemic control on these associations. Determinants of T2D were use of hypoglycemic medication or elevated fasting glucose (>=126 mg/dl). Cox proportional hazards models were used to analyze the associations between log-transformed baseline AGE and risk of clinical fractures. At baseline, mean age of T2D participants (n=501) was 73.6 +/- 2.9 years. Incident clinical fractures occurred in 97 participants over mean follow-up of 9.4 years. In multivariate models, the risk of incident clinical fractures significantly increased 32% per SD increase in log CML and 46% per SD increase in log PEN (Table 1); these estimates were not statistically different (p=0.84). In a model including CML and PEN, only PEN was independently associated with fracture risk (HR=1.37; 95% CI: 1.07, 1.77). Associations with PEN were stronger in those with suboptimal glycemia (HbA1c>7.5%) compared with optimal glycemia (all interaction p<0.10); the pattern for CML was similar but differences by glycemia status were not statistically significant. In those with suboptimal control, CML (HR=1.43; 95% CI: 1.01, 2.02) and PEN (HR=1.51; 95% CI: 1.06, 2.16) were both independently associated with fracture risk. In a sensitivity analysis, adjusting for diabetes duration did not substantially alter these results. In conclusion, crosslinking and non-crosslinking AGEs play independent roles in the pathophysiology of bone fragility in diabetes, possibly through different mechanisms on collagen and bone matrix.

Table 1. Risk of incident clinical fracture per SD increase in log CML versus log PEN in T2D and by glycemic control

	Overall HR (95% CI) (n = 501)	A1c ≤7.5% HR (95% CI) (n = 215)	A1c >7.5% HR (95% CI) (n = 286)	P-value for interaction*

Type 2 diabetes mellitus and incident fracture risk in UK Biobank: Impact of disease duration and diabetes medications *Elizabeth Curtis[1], Rebecca Moon[1], Stefania D'Angelo[1], Zahra Raisi-Estabragh[2], Cyrus Cooper[1], Nicholas Harvey[1]. [1]MRC Lifecourse Epidemiology Centre, University of Southampton, United Kingdom; [2]William Harvey Research Institute, NIHR Barts Biomedical Research Centre, Queen Mary University of London, United Kingdom

Type 2 diabetes (DM2) has been associated with increased fracture risk, but the impact of disease duration and related medications has not been well characterised in a large uniformly-assessed, prospective population. We therefore investigated these relationships in the UK Biobank cohort.DM2 diagnosis at baseline was defined using self-report, nurse interview and ICD code data. We used Poisson regression with robust standard errors to calculate incidence rate ratios (IRRs) for osteoporotic fracture during prospective follow-up in patients with DM2 versus non-diabetic controls. IRRs below and above follow-up times were compared in cumulative one-year increments. Secondly, within the cohort of DM2 patients, we examined associations between diabetic medications and incident osteoporotic fracture risk. Associations were adjusted for traditional clinical risk factors (age, sex, smoking, alcohol use, deprivation, physical activity, co-morbidities).There were 498,949 participants, 20,551 of whom had a diagnosis of DM2. The presence of DM2 was associated with an increased risk of OP fracture, independent of traditional risk factors [IRR: 1.14 95% CI (1.04,1.26)]. Associations were similar by sex. The fracture association for DM2 increased with greater duration of disease [1.01 (1.00, 1.02)], with a statistically significant effect emerging at eight years follow-up [IRR for <8 years duration: 1.12 (1.00,1.25)]. Within the DM2 cohort (users of specific medication versus all other DM2 patients), the use of insulin (n=546) and sulfonylureas (n=5,387) were associated with a trend towards increased OP fracture risk [IRR 1.64 (0.98, 2.73) and 1.19 (0.99, 1.42) respectively] and thiazolidinediones (n=2,036) were significantly associated with increased risk [IRR 1.31 (1.02, 1.67)]. Metformin use (n=11,839) was not associated with increased risk (all after adjustment for clinical risk factors).In UK Biobank, DM2 is associated with increased risk of fracture, with the association increasing in magnitude with greater duration of disease. The risk interaction with follow-up time and associations with insulin, sulfonylureas and thiazolidinediones treatment inform risk assessment in clinical practice. This work was undertaken using the UK Biobank resource under approved application 3593.

Chronic kidney disease is associated with lower cortical measures at proximal femur as assessed by 3D-DXA *M. Kužma[1], Z. Kužmová[1], L. Humbert[2], M. Lopez Picazo[2], J. Falat[1], J. Smaha[0], P. Jackuliak[1], Z. Killinger[0], J. Payer[1]. [1]5th department of Internal Medicine, Comenius University Faculty of Medicine, University Hospital , Bratislava, Slovakia, Slovakia; [2]3D-Shaper Medical, Barcelona, Spain, Spain; [0]5th department of Internal Medicine, Comenius University Faculty of Medicine, University Hospital , Bratislava, Slovakia, Slovakia

Introduction: Patients with chronic kidney disease (CKD) has 2-14 fold increase in fracture risk, especially in later stages of the CKD. The gold standard for the diagnosis of osteoporosis represents DXA, but its use is limited due to lack of possibility to measure trabecular and cortical characteristics and interference of aortic calcifications with BMD. Specific information about bone microstructure and turnover could be obtained by bone biopsy, but this is limited due to invasiveness.Aim: To compare several non-invasive DXA-derived methods used for assessment trabecular and cortical parameters, such a s trabecular bone score (TBS), 3D-Shaper and hip structure analysis (HSA) in subjects across all CKD stages.Patients and methods: In total, 89 CKD (38 females / 51 males; mean age 69,5 years) subjects were included in the analysis. According to glomerular filtration rate (GFR) there were 12; 23; 10; 14; 14 and 16 subjects in stage G1, G2, G3a, G3b, G4 and G5, respectively. BMD at lumbar spine (LS) and proximal femur (hip and neck) was analyzed by Hologic Horizon device. LS TBS was analyzed by TBS Insight software. Proximal femur parameters such as cortical and trabecular volumetric (v) BMD, cortical thickness (CTh) and surface (s) BMD and HSA parameters such as buckling ratio (BR), cross-sectional area (CSA) and section modulus (Z) were analyzed by 3D-Shaper-research v. 2.12.1. In all subjects bone turnover markers such as CTx, P1NP and Osteocalcin was measured.Results: Cross-sectional comparison between each CKD stage showed gradually decreasing LS BMD, cortical vBMD (neck and TH), TH Cth and neck BR starting from G3b, G4 and G5 stages; but not in earlier stages of CKD (G1-G3a). Comparison of means between earlier stages (G1-G3a) versus later stages (G3b-G5) of CKD showed significant differences in CTx (386 vs. 1053 ng/l); TH aBMD (0,991 vs 0,859 g/cm2), cortical vBMD at TH (831 vs 795 mg/cm3) and neck (837 vs.788 mg/cm3), TH cortical sBMD (170 mg/cm2) and TH Cth (2,03 vs 1,92 mm) (all p<0.05). Among all subjects, strong positive associations between GFR and cortical parameters (neck/TH vBMD and TH Cth) were observed (p<0.01).Conclusion: This study showed that later stages of CKD (G3b - G5) CKD have lower cortical bone parameters, such as vBMD, sBMD and CTh, as assessed by 3D Shaper. In addition, most of the cortical parameters are associated with GFR, showing direct relationship of kidney function and bone. These results agree with the previous findings provided by bone histomorphometry. As such, it is likely that 3D Shaper as non-invasive DXA derived method can be of use in assessment of fracture risk in CKD subjects especially in later stages of the disease. However, further prospective studies with greater amount of subjects and fracture data are needed.

Longitudinal changes of QCT-derived bone parameters by indices of beta cell function and insulin resistance in non-diabetic community-dwelling adults *Namki Hong[1], Graham Treece[2], Hyeon Chang Kim[3], Yumie Rhee[4]. [1]Division of Endocrinology, Republic of Korea; [2]University of Cambridge, United Kingdom; [3]Department of Preventive Medicine, Yonsei University College of Medicine, Republic of Korea; [4]Department of Internal Medicine, Endocrine Research Institute, Yonsei University College of Medicine, Republic of Korea

Beta cell dysfunction and insulin resistance, two culprit pathophysiology of type 2 diabetes mellitus, may have distinctive impact on cortical and trabecular bone parameters. We aimed to investigate longitudinal changes of QCT-derived bone parameters according to beta cell function and insulin resistance in non-diabetic community-dwelling adults. From a community-based cohort, longitudinal changes in bone parameters of individuals without diabetes mellitus aged 50 or older were analyzed using baseline and 5-year follow-up QCT scans. Homeostasis Model Assessment for beta cell function (HOMA-b) and for Insulin resistance (HOMA-IR) were calculated using fasting glucose and insulin level. Cortical bone mapping technique were applied to analyze cortical and trabecular bone parameters of hip. Mean age of participants (n=377) was 56.6 years and 68% were women. Compared to highest HOMA-b quartile (Q4, reference), individuals in lowest quartile (Q1) had lower body mass index (BMI, 24.4 vs. 23.1 kg/m2), higher fasting glucose, lower insulin and lower disposition index (HOMA-b/HOMA-IR). Individuals in HOMA-b Q1 had highest risk of new-onset T2DM (8.5%) compared to other quartiles (1.1 to 2.1%, p=0.020). Compared to HOMA-b Q4, HOMA-b Q1 had greater decrease in lumbar spine volumetric BMD (-12.0% vs. -8.6%) and total hip trabecular density (-7.5% vs. -4.8%, p<0.05 for all) at 5-year follow-up, which remained robust after adjustment for age, sex, BMI, baseline BMD, and HOMA-IR (adjusted beta -4.0, p=0.007 [Q1 vs. Q4] for lumbar spine BMD changes; adjusted beta -2.4, p=0.008 [Q1 vs. Q4] for total hip trabecular density changes). Changes in bone parameters did not differ between HOMA-IR quartiles. Spatial heterogeneity of hip bone trabecular density loss was observed, with greater loss at femoral neck and greater trochanteric regions in lower HOMA-b quartiles. In summary, beta cell dysfunction was associated with greater loss of trabecular bone density at lumbar spine and hip in non-diabetic community-dwelling adults.

Association of Sodium-Glucose Cotransporter 2 Inhibitor Use With Risk of Osteoporotic Fracture Among Older Women: A Nationwide, Population-Based Cohort Study *Seunghyun Lee[1], Min Heui Yu[2], Namki Hong[3], KYOUNG JIN KIM[4], Hae Kyung Kim[5], Yumie Rhee[6], Minyoung Lee[5], Kyoung Min Kim[7]. [1]Wonju Severance Christian Hospital, Yonsei University Wonju College of Medicine, Wonju, Korea, . [2]SENTINEL team, Division of Endocrinology, Department of Internal Medicine, Yonsei University College of Medicine, Seoul, Korea, Republic of Korea. [3]Division of Endocrinology, Republic of Korea. [4]Korea University College of Medicine, Republic of Korea. [5]Institute of Endocrine Research, Department of Internal Medicine, Yonsei University College of Medicine, Seoul, Korea, Republic of Korea. [6]Yonsei University College of Medicine, Republic of Korea. [7]Yongin Severance Hospital, Yonsei University College of Medicine, Republic of Korea

Sodium-glucose cotransporter-2 inhibitor (SGLT2i) is a widely recommended anti-diabetic medication (ADM) due to its cardioprotective and renoprotective benefits. However, the effects of SGLT2i on fracture risk have been debated. The Canagliflozin Cardiovascular Assessment Study showed that SGLT2i increased hip fracture risk during the mean 6-year follow-up period. However, in most other large randomized controlled trials of SGLT2i, SGLT2i use was not associated with increased fracture risk. Although the fracture risk associated with SGTL2i use is controversial, there are concerns regarding fracture risk due to the increased risk of falls caused by volume depletion or disturbance of calcium phosphate balance. Therefore, in the present study, the association between SGLT2i use and fracture risk in elderly women (>= 65 years of age) who were newly prescribed ADMs was investigated using a national cohort database.?We used the data for this population-based cohort study obtained from the National Health Insurance Service of Korea between January 1, 2013, and December 31, 2020. Women older than 65 years old diagnosed with type 2 diabetes mellitus who were newly prescribed ADMs other than glucagon-like peptide-1 receptor agonists and thiazolidinedione and who had available comprehensive health check-up data were included.A total of 1,333 SGLT2i users was analyzed and compared with covariate (e.g., body mass index (BMI), age-matched non-SGLT2i users at a 1:2 ratio (n = 2,626). After propensity score matching, mean age (70.3 years vs. 70.3 years, p = 0.830), BMI (27.4 kg/m2 vs. 27.4 kg/m2, p = 0.924), number of oral ADMs (1.4 vs. 1.3, p = 0.092), and other covariates were well-balanced between SGLT2i users and non-SGLT2i users. During the follow-up period, SGLT2i use was associated with a significantly increased risk of vertebral fracture compared with non-SGLT2i use (incidence rate 19.2 vs. 13.8 per 1,000 person-years; hazard ratio 1.40, 95% confidence interval 1.00-1.96, p = 0.049). Regarding the risk of other types of fracture, any fractures, hip fractures, and non-hip or non-vertebral fractures, significant differences were not observed between SGLT2i users and non-SGLT2i users.In conclusion, SGLT2i use showed a 40% higher risk of vertebral fracture than non-SGLT2i use in elderly women. Although further validation is required, SGLT2i should be cautiously prescribed in older women due to the potential association with fracture risk in this vulnerable population.

The Association between Intrahepatic Lipid Content and Bone Microarchitecture and Strength (Assessed by HR-pQCT): The Maastricht Study. *VEERLE VAN HULTEN[1], Johanna Driessen[2], Marleen van Greevenbroek[3], Carla van der Kallen[3], Annemarie Koster[4], Martijn Brouwers[3], Eline Kooi[5], Pieter Dagnelie[6], Coen Stehouwer[3], Joop Van Den Bergh[7]. [1]Maastricht University, . [2], Netherlands. [3]Department of Internal Medicine, MUMC+, Netherlands. [4]Department of Social Medicine, Maastricht University, Netherlands. [5]Department of Radiology, MUMC+, Netherlands. [6]School for Cardiovascular Diseases, Maastricht Universiity, Netherlands. [7]VieCuri MC Noord-Limburg and Maastricht UMC,

Background: It is known that type 2 diabetes (T2D) is associated with a number of comorbidities, such as an increased fracture risk, possibly due to impaired bone quality. T2D has also been associated with non-alcoholic fatty liver disease (NAFLD) characterized by a high intrahepatic lipid (IHL) content. In turn, NAFLD has been shown to be a risk factor for osteoporotic fractures.Purpose: To determine the association of IHL content with parameters of bone microarchitecture and strength assessed by high-resolution peripheral quantitative computed tomography (HR-pQCT).Methods: This study includes cross-sectional data from 2104 participants of the Maastricht Study who underwent a HR-pQCT scan (first generation) at the distal radius. MRI was performed to determine IHL content, expressed as the percentage of hepatic triglyceride content in the total liver volume. Multiple linear regression models were used to investigate the association of IHL content with HR-pQCT parameters of bone microarchitecture and strength. Analyses were stratified by sex due to inherent differences in bone metabolism, and were adjusted for glucose metabolism status, age, comorbidities, medication and lifestyle factors.Preliminary Results: We included 1057 men and 1047 women. Male participants were on average 60 (+/-8.7) years old, and female participants were on average 58 (+/-8.8) years old. After adjustment, IHL content was positively associated with total bone mineral density (BMD) and cortical BMD in the distal radius in men and women, and with trabecular BMD, cortical area, stiffness, and failure load in women (Table 1). When BMI was added to the linear regression model, all significant associations between IHL content and HR-pQCT parameters were strongly attenuated and not statistically significant.Conclusion: These findings suggest that bone quality may not be impaired in individuals with an increased IHL content, and that bone strength may even be greater in women with NAFLD. However, it is possible that this finding is at least partially due to the association of BMI with IHL content and with bone density, stiffness and failure load, since no statistically significant associations between IHL content and HR-pQCT parameters remained when BMI was added to the linear regression model.

Relation between switching from noninsulin antidiabetic drugs to insulin and hip fracture risk in Japan: a nationwide study *JUNKO TAMAKI[1], Kenji Fujimori[2], Shigeyuki Ishii[3], Sumito Ogawa[4], Shinichi Nakatoh[5], Nobukazu Okimoto[6], Masayuki Iki[7]. [1]Osaka Medical and Pharmaceutical University, Japan. [2]Tohoku University School of Medicine, Japan. [3]Tokyo University of Pharmacy and Life Sciences, Japan. [4]The University of Tokyo, Japan. [5]Asahi General Hospital, Japan. [6]Okimoto Clinic, Japan. [7]Kindai University Faculty of Medicine, Japan

Aims We aimed to identify hip fracture risks in patients who switched to or were prescribed noninsulin antidiabetic drugs in addition to insulin using a nationwide health insurance claims database in Japan.Methods This study included the information of 7,54,767 patients aged >=50 years who were started on noninsulin antidiabetic drugs at the outpatient department between 2012 and 2019 fiscal years from the National Database of Health Insurance Claims and Specific Health Check-ups of Japan (NDBJ). Of the 7,54,767 patients, 2,22,311 were selected using propensity score to predict the prescriptions of insulin agents

as second antidiabetic drugs and optimal variable rate matching revealed that 63,516 patients switched to insulin and 1,58,795 switched to noninsulin antidiabetic drugs.Results The hip fracture incidences (per 10,000 person-year) of the patients who switched to or were additionally prescribed insulin and noninsulin antidiabetic drugs were 89.1 and 35.4, respectively, during the first 2 months after the switch. The patients who switched to or were additionally prescribed insulin exhibited increased hip fracture risk compared with patients prescribed noninsulin drugs during the 2 months [log-rank test; p < 0.001, sex- and age-adjusted hazard ratio (HR) (95% CI), 2.20 (1.54, 3.16)]. The sex- and age-adjusted HR during the first half of the month after the switch was 3.09 (1.81, 5.27) with a p-value of <0.001 in the log-rank test. The sex- and age-adjusted HRs during the first 2 months among patients whose age at switching drugs were <80 and >=80 years were 3.76 (1.90, 7.44) and 1.88 (1.23, 2.89), respectively, with a p-value of <0.001 in the log-rank test for both.Conclusions Patients whose second diabetic drugs was insulin demonstrated increased risk of hip fractures compared with those prescribed with noninsulin antidiabetic drugs, especially immediately after switching to insulin. Increased fracture risk was observed in older and middle-aged patients with diabetes.

Relationship of Biomarkers of Cellular Senescence with Skeletal Parameters in Type 2 Diabetes Mellitus *Caroline Hoong[2], Joshua Farr[2], Thomas White[2], Elizabeth Atkinson[2], Amanda Tweed[2], Stephanie Vos[2], Matthew Drake[3], Nathan LeBrasseur[2], Sundeep Khosla[4], Jad Sfeir[2]. [2]Mayo Clinic, , [2]Mayo Clinic, United States, [3]College of Medicine, Mayo Clinic, United States, [4]Mayo Clinic College of Medicine, United States

Patients with type 2 diabetes (T2D) have increased risk of fractures and impaired bone microarchitecture, despite a preserved or increased areal BMD. We have previously demonstrated premature accumulation of senescent osteocytes in the bone microenvironment of T2D mice (JCI Insight 2020; 5:e135236). Here, we report on the biomarkers of cellular senescence in patients with obesity with and without T2D, and their relationship with skeletal phenotypes. We compared 27 postmenopausal women with obesity and T2D [median age 66.7 yrs (IQR 62.8-71.4); BMI 36.3 (34.0-38.7); A1c >6.5%] to 29 age-matched controls with obesity but no T2D [median age 64.7 yrs (IQR 59.7-73.7); BMI 34.7 (32.0-39.9); A1c <5.9%] and 37 age-matched lean controls [median age 70.1 yrs (IQR 63.0-72.2); BMI 22.7 (21.6-23.7); A1c <5.9%]. We measured circulating senescence-associated secretory phenotype (SASP) proteins that have been identified as biologically relevant in vitro (via commercially available multiplex magnetic beads immunoassays) and mRNA gene expression in peripheral T-lymphocytes of cyclin-dependent kinase inhibitors (p16 and p21, via rt-qPCR). Skeletal parameters included bone microarchitecture parameters using HRpQCT at the radius and tibia. Expression of p16 and p21 mRNA was significantly increased the obese group and further increased in patients with T2D. Similarly, a cluster of the SASP proteins (TNF?, IL-8, IL-6, GDF-15, TNFR1, TNFR2, Fas, Activin-A) showed increases that were most pronounced in patients with obesity and T2D (Table). Interestingly, p16 expression was associated with age in lean and obese patients but not in T2D, where it remained elevated in all age groups. There was a significant correlation between p16 and the SASP protein cluster with cortical parameters on HRpQCT in patients with T2D: p16 was negatively correlated with cortical thickness at both the radius and tibia; Fas negatively correlated with cortical thickness at the radius and cortical vBMD at the tibia; GDF-15 negatively correlated with cortical vBMD at the tibia; IL-8 negatively associated with stiffness and failure load at the radius. These findings demonstrate an increase in cellular senescence burden in patients with obesity, and further increases with T2D. Collectively, these results indicate a central role for cellular senescence in mediating skeletal fragility in patients with T2D.

Senescence markers, median (IQR)	T2D (n=27)	BMI>30 (n=29)	BMI<25 (n=37)	p value

Type 2 Diabetes is Associated with Better Bone Microarchitecture, higher BMD, but Impaired Physical Function and Increased Risk of Incident Fracture in Older Swedish Women from the SUPERB study. *Lisa Johansson[1], Kristian Axelsson[2], Mattias Lorentzon[3], Henrik Litsne[4], Michail Zoulakis[5]. [1]Institute of medicine, , [2]Institute of Medicine, Sahlgrenska Academy, Gothenburg University, , [3]Sahlgrenska Academy, University of Gothenburg, Sweden, [4]Sahlgrenska Osteoporosis Centre,University of Gothenburg, , Sweden, [5]Sahlgrenska Osteoporosis Centre, Institute of Medicine,University of Gothenburg, Sweden

Several studies have shown that type 2 diabetes mellitus (T2DM) is associated with incident fracture, but it is not clear if the risk increase is due to impaired bone microarchitecture, low bone material strength index (BMSi) or poor physical function. The aim of this study was to determine if T2DM is associated with bone microarchitecture, BMSi, physical function, and risk of incident fracture in older Swedish women.In total, 3028 Swedish women, 75-80 years old were included in the prospective SUPERB study. At baseline, information on clinical risk factors (CRFs) was collected using questionnaires. Bone mineral density (BMD) was measured with dual-energy X-ray absorptiometry, bone microarchitecture with HR-pQCT (XtremeCT), and BMSi obtained using the Osteoprobe device (n=630). Physical function was assessed using timed up and go (TUG), one leg standing (OLS), grip strength, chair stand test and by measurements of gait speed. Data on incident fractures were retrieved from a regional x-ray archive.At baseline, the 294 women with T2DM were compared to women (n=2714) without diabetes. Women with T2DM had higher BMD at all sites (total hip 4.7%, femoral neck (FN) 3.9% and lumbar spine L1-L4 5.4%, all p<0.01) than women without. At the ultradistal tibia, T2DM women had a greater cortical area (7.3%, p<0.01) and density (1.2%, p=0.03), as well as higher trabecular bone volume fraction (8.6%, p<0.01). There was no difference in BMSi between groups (n=630; T2DM 77.8+/-8.1 vs. controls 78.1+/-7.3, p=0.81). Women with T2DM performed significantly worse on all physical function tests than their non-diabetic controls. For example, grips strength was 10.1% lower, gait speed 10.2% slower, and TUG time 13.1% (p<0.001 for all comparisons) slower in women with T2DM than in those without.During 7.3 (4.4, 8,4) years (median (IQR) of follow-up there were 1071 incident any fractures, 797 major osteoporotic fractures (MOF), and 232 hip fractures. In adjusted (for age, BMI, FRAX CRFs and FN BMD) Cox regression models T2DM was associated with an increased risk of any fracture (HR 95% CI 1.26 [1.04-1.53], but the associations with MOF (HR 1.16 [0.92-1.46]) or hip fracture (HR 1.31 [0.85-2.00]) did not reach statistical significance.In conclusion, older women with T2DM have considerably better bone microarchitecture, and no different BMSi, but substantially poorer physical function than nondiabetic women, which could be the principal reason for the increased fracture risk observed in T2DM women.

Background: Achondroplasia (ACH), the most common short-limbed skeletal dysplasia, is characterized by impaired endochondral ossification resulting from gain-of-function pathogenic variants in the fibroblast growth factor receptor 3 (FGFR3) gene, a negative regulator of endochondral bone growth. People with ACH are at risk for several significant co-morbidities, including brainstem compression due to foramen magnum stenosis, sleep-disordered breathing, chronic otitis media with conductive hearing loss, and symptomatic spinal stenosis. Infigratinib is an oral, selective FGFR1-3 tyrosine kinase inhibitor being investigated for treating children with ACH.Methods: PROPEL 2 (NCT04265651) is a phase 2 dose-finding, open-label study of infigratinib in children 3?11y with ACH who participated for >=6m in PROPEL (NCT04035811), a non-interventional clinical assessment study. The PROPEL 2 dose-escalation (DE) phase includes 5 ascending dose cohorts from 0.016 to 0.25mg/kg/d. Primary endpoints: safety; change from baseline in annualized height velocity (AHV); infigratinib pharmacokinetics.Results: Children enrolled in PROPEL 2 DE completed >=6m of treatment at the assigned dose. Cohorts 1-3 (n=37; 0.016, 0.032, 0.064mg/kg/d) did not show a significant increase in AHV and these doses were assessed as non-efficacious. Treatment at the cohort 4 dose (0.128mg/kg/d) resulted in an increase in AHV from baseline of 1.52cm/y in children >=5y old (n=11; p=0.02). Infigratinib at the cohort 5 dose (0.25mg/kg/d, n=10, m6) resulted in a significant mean increase from baseline of 3.03cm/y (p=0.0022). In cohort 5, collagen X marker, a biomarker of endochondral ossification, showed a median increase of 28% from baseline at m6 (n=6). Infigratinib was well tolerated with no serious AEs or AEs leading to study discontinuation, with most AEs mild/moderate in severity. At the cohort 5 dose, no grade 3 AEs or treatment-related AEs were reported.Conclusion: Oral infigratinib in children with ACH was well tolerated and showed dose-dependent increases in AHV, with a significant mean change from baseline of +3.03cm/y at the cohort 5 dose (0.25mg/kg/d). The safety and efficacy of this oral, once-daily dose of infigratinib will be further explored in a phase 3 randomized controlled study. If these phase 2 data are confirmed, infigratinib could potentially offer children with ACH the first safe and effective oral therapy to improve growth, enhance functionality and decrease medical complications.

Sodium Fluoride-18 PET/CT Visualizes Disease Activity and New Bone Formation in Adult Chronic Nonbacterial Osteomyelitis/Synovitis, Acne, Pustulosis, Hyperostosis, Osteitis-Syndrome (CNO/SAPHO) *Anne Leerling[1], Frits Smit[2], Zita Sp?th[1], Ana Navas Cañete[3], Lioe-Fee De Geus-Oei[2], Alina Van der Burgt[4], Olaf Dekkers[5], Wouter Van der Bruggen[6], Natasha Appelman-Dijkstra[1], Dennis Vriens[2], Elizabeth Winter[1]. [1]Department of Internal Medicine, Division of Endocrinology, Center for Bone Quality, Leiden University Medical Center, Netherlands. [2]Department of Radiology, Division of Nuclear Medicine, Center for Bone Quality, Leiden University Medical Center, Netherlands. [3]Department of Radiology, Center for Bone Quality, Leiden University Medical Center, Netherlands. [4]Department of Nuclear Medicine, Alrijne Hospital, Netherlands. [5]Department of Clinical Epidemiology, Leiden University Medical Center, Netherlands. [6]Department of Nuclear Medicine, Slingeland Ziekenhuis, Netherlands

Background: Chronic nonbacterial osteomyelitis/synovitis, acne, pustulosis, hyperostosis, osteitis syndrome (CNO/SAPHO) is a rare disease characterized by inflammatory bone lesions with increased bone turnover. CNO/SAPHO lacks biochemical and radiological biomarkers that are sensitive for disease activity. Sodium fluoride positron emission tomography ([18F]NaF-PET/CT) produces quantitative data on bone turnover that correlate with disease activity in other metabolic bone disorders. We quantitate 18F-uptake in CNO/SAPHO for the first time, to evaluate its capacities as a diagnostic and disease activity biomarker.Methods: Cohort study among CNO/SAPHO patients (n=43) and mimicking controls (n=16) presenting at our expert clinic with [18F]NaF-PET/CT performed. Images were qualitatively compared between patients and controls and maximal standardized uptake values (SUVmax (g/ml)) were calculated for bone lesions and soft tissue/joint lesions plus thoracic vertebra 5 as reference bone. SUVmax was correlated with clinical disease activity. Results: Qualitative analysis of [18F]NaF-PET/CT revealed manubrial and costal sclerosis/hyperostosis, and calcification of the costoclavicular ligament as core radiologic features associated with CNO/SAPHO. SUVmax of bone lesions was higher compared to reference bone in patients (mean paired difference 11.4, 95%CI 9.4-13.5, p<0.001) and compared to controls (mean difference 12.4, 95%CI 9.1-15.8, p<0.001). Highest SUVmax was found in soft tissue/joint lesions like the costoclavicular ligament and the manubriosternal joint, and also correlated with erythrocyte sedimentation rate (r=0.546, p<0.002). Receiver operator characteristic analysis demonstrated excellent discriminatory value of SUVmax of bone and soft tissue/joint lesions (area under curve 0.95 95%CI 0.88-1.00 and 0.98 95%CI 0.96-1.00 respectively).Conclusion: Adult CNO/SAPHO patients display distinctive imaging features that are well-captured on [18F]NaF-PET/CT, and show higher SUVmax in bone and soft tissue/joint lesions compared to reference bone and controls, the latter correlating with inflammatory disease activity. SUVmax therefore qualifies as a first diagnostic and disease activity biomarker in CNO/SAPHO. Highest SUVmax was seen in soft tissue/joint areas, which are known locations of new bone formation in CNO/SAPHO. [18F]NaF-PET/CT visualizes this pathogenic process, and can invaluably steer therapeutic decision-making.

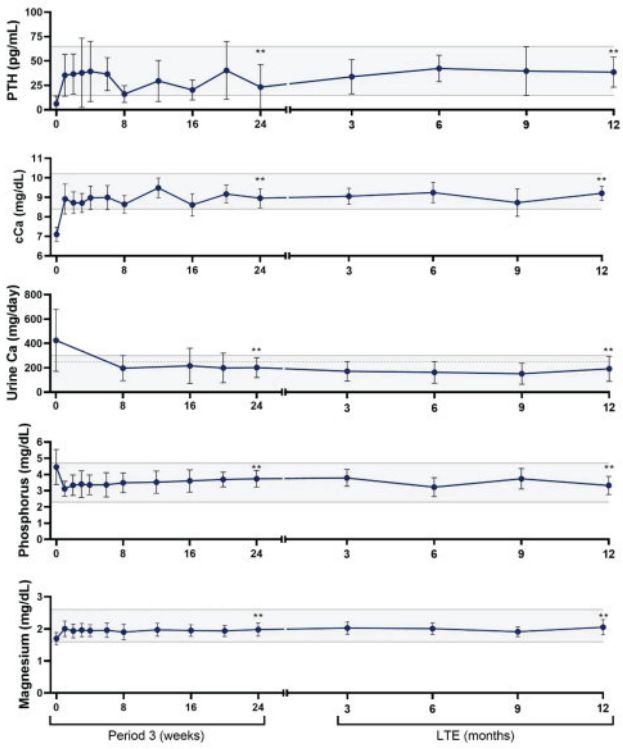
Encaleret?(CLTX-305) Normalizes Mineral Homeostasis Parameters in Patients with Autosomal Dominant Hypocalcemia Type 1 over 18 months in a Phase 2 Study (NCT04581629) *Rachel Gafni[2], Iris Hartley[2], Kelly Roszko[2], Edward Nemeth[3], Karen Pozo[2], Arun Mathew[4], Mary Scott Roberts[4], Scott Adler[4], Michael Collins[2]. [2]National Institutes of Health, United States. [2]National Institutes of Health, . [3]MetisMedica, Canada. [4]Calcilytix Therapeutics, United States

Autosomal dominant hypocalcemia type 1 (ADH1), caused by gain-of-function variants in the calcium-sensing receptor (CaSR) gene, is characterized by low parathyroid hormone (PTH), hypocalcemia, hypercalciuria, hyperphosphatemia, and hypomagnesemia. Calcium (Ca) and active vitamin D treatment worsens hypercalciuria and can lead to renal morbidity. Calcilytics (negative allosteric CaSR modulators) decrease the sensitivity of hyperactive receptors to extracellular Ca and normalize blood and urine abnormalities in ADH1 rodent models.This Phase 2b open-label study of the oral investigational calcilytic encaleret included 3 periods followed by a long-term extension (LTE). Periods 1&2 were inpatient dose-finding and safety evaluations. Period 3 (P3) assessed safety/efficacy over 24 outpatient weeks; participants then continued in the outpatient LTE.Thirteen adults with ADH1 were treated with encaleret, titrated to normalize albumin-corrected Ca (cCa). Encaleret was well-tolerated with no serious adverse events reported. There were no treatment discontinuations or withdrawals prior to the LTE; one participant withdrew in the LTE. The mean+/-SD encaleret sulfate dose was 86+/-70mg BID at P3 Week 24 (P3W24) and 75+/-66mg BID at LTE Month 12 (LTEM12). Mean mineral indices normalized over 18 months of encaleret (Figure). Analyses comparing P3W24 and LTEM12, respectively, to baseline (BL), were as follows: PTH rose from 6.3+/-7.8 pg/mL (nl 10-65) to 35.3+/-10.2 and 36.9+/-15.2 (p<0.01). Hypocalcemia (cCa=7.1+/-0.4 mg/dL [nl 8.4-10.2]) corrected and remained normal at 9.2+/-0.5 and 9.2+/-0.4 (p<0.01). BL urinary calcium of 395+/-216 mg/d (nl<250-300) decreased to 202+/-83 and 177+/-94 (p<0.05). Blood phosphate (4.5+/-1.1 mg/dL [nl 2.3-4.7]) decreased to 3.4+/-0.4 and 3.4+/-0.5 (p<0.01). Blood magnesium increased from 1.7+/-0.2 mg/dL [nl 1.6-2.6]) to 2.0+/-0.2 and 2.1+/-0.2 (p<0.01). Bone turnover markers increased from BL (n=7, CTX=253+/-111 pg/mL; P1NP=34+/-10

mcg/L) to P3W24 (n=13, CTX=744+/-565; P1NP=104+/-87) and LTEM12 (CTX=988+/-652; P1NP=83+/-49) p<0.01. Except for Total hip, DXA BMD Z-scores (n=11) did not change from BL?LTEM12: AP spine Z=2.6+/-1.5?2.5+/-1.7; Total hip Z=2.2+/-1.4?2.0+/-1.3 (p<0.05); 1/3 radius Z=0.2+/-0.9?0.5+/-0.5.This study represents a molecularly targeted, precision medicine approach to treatment of ADH1. The consistent, sustained results over 18 months of encaleret treatment support Phase 3 evaluation of encaleret efficacy/safety as the first potential treatment indicated for ADH1.



Data reported as mean±SD. Gray shading = normal range. Solid line for urine calcium = upper limit for men, dashed line = upper limit for women. Values below limit of assay quantitation recorded as "0". The measures shown for weeks 0, 8, 16, and 24 are pre-encaleret. ** p-value < 0.01 Period 3 Week 24 or LTE Month 12 compared to Baseline.

Intermittent Parathyroid Hormone Treatment Activates Osteoclast-Mediated, but not Modeling-Based, Bone Formation: A Randomized Clinical Trial in Patients with Hypoparathyroidism *Lisbeth Koch Thomsen[1], Galina Pronina[1], Tanja Sikjaer[2], Jesper Skovhus Thomsen[3], Christina M Andreasen[4], Lars Rejnmark[2], Thomas Levin Andersen[5]. [1]Molecular Bone Histology Lab, Research Unit of Pathology, Department of Clinical Research, University of Southern Denmark & Department of Pathology, Odense University Hospital, Odense, Denmark, Denmark. [2]Department of Endocrinology and Internal Medicine, Aarhus University Hospital, Aarhus, Denmark, Denmark. [3]Department of Biomedicine, Aarhus University, Aarhus, Denmark, Denmark. [4]Molecular Bone Histology Lab, Research Unit of Pathology, Department of Clinical Research, University of Southern Denmark & Department of Pathology, Odense University Hospital, Odense, Denmark, Denmark. [5]Molecular Bone Histology Lab, Research Unit of Pathology, Department of Clinical Research, University of Southern Denmark & Department of Forensic Medicine, Aarhus University, Aarhus, Denmark, Denmark

Treatment with intermittent parathyroid hormone (iPTH) has been reported to increase the proportion of osteoclast-independent modeling-based bone formation (MBF) in patients with osteoporosis. However, to our knowledge a similar investigation of osteoclast-mediated bone formation in patients with hypoparathyroidism treated with iPTH has not been made thus far.We have developed a new histological method to distinguish osteoclast-mediated formation (Remodeling Based Formation (RBF) and overflow Remodeling Based Formation (oRBF)) from MBF, utilizing the osteopontin-rich cement lines and the lamellar structure of the underlying bone in the entire bone structural unit (BSU). We applied this method to 68 iliac crest biopsies collected from patients with chronic hypoparathyroidism. As add-on to conventional therapy participants were randomized to 6 months of treatment with i) placebo (PLB6; n=25) or ii) 100 µg s.c./daily rhPTH(1-84)(PTH6; n=25) followed by 24 months open-labeled of iii) conventional treatment (CON; n=5), iv) 100 µg s.c./daily rhPTH(1-84)(PTH30; n=5), or v) rhPTH withdrawal (PTHw; n=8) (figure). Tetracycline was administered twice 8 days apart ending 2 days prior to biopsy collection. Using the tetracycline labels, bone formation at the cancellous and endocortical envelopes was identified and measured. Subsequently, the bone formation was categorized as either RBF, oRBF, or MBF based on adjacent osteopontin immunostained sections.At the cancellous envelope, PTH6 group had a 33-fold higher proportion of mineralizing surfaces (p<0.0001) relative to PLB6 and mineralizing surfaces correlated with increased P1NP-levels (p<0.05), but not with mineral apposition rate at 6 months. At month 30, PTHw had significantly reduced mineralizing surfaces (p<0.01) relative to PTH6 (median 0 versus 21%). Moreover, compared to PTH6 the PTH30 group also had significant lower mineralizing surfaces (p<0.05). RBF, oRBF, and MBF were all significantly increased in the PTH6 compared to PLB6 group, but osteoclast-mediated bone formation (RBF median 16.7% p<0.0001; oRBF median 9.0%, p<0.001), and not MBF (median 0.00% p <0.01), was by far the main type of bone formation. Interestingly, oRBF exhibited a significantly increased mineral apposition rate (3-fold, p<0.05). All data were reproduced at the endocortical envelope.Collectively, this study demonstrates that the rhPTH-induced bone formation in hypoparathyroidism is osteoclast-mediated RBF and oRBF, and not MBF.

BackgroundPaget's disease of bone (PDB) often presents with irreversible skeletal damage. Early detection of PDB coupled with prophylactic bisphosphonate therapy may help prevent progression of the disease to an advanced stage.MethodsWe conducted a randomised trial of a single infusion of 5mg zoledronic acid (ZA) versus placebo in 222 individuals who were genetically at increased risk of PDB because of pathogenic mutations in SQSTM1. The primary outcome was emergence of new bone lesions assessed by radionuclide bone scan. Secondary outcomes included change in existing lesions, biochemical markers of bone turnover and skeletal events related to PDB. Participants were followed up for a median of 84 months (range 0-127) and 180 (81%) completed the study.ResultsAt baseline, PDB lesions were present in 9 (8.1%) of the ZA group and 12 (10.8%) of the pla-

cebo group. Two participants in the placebo group developed new lesions during the study versus none in the ZA group (OR 0.41, 95% CI 0.00 to 3.43, p=0.25). Eight participants in the placebo group had a poor outcome (lesions which were new, unchanged, or progressing) compared with none in the ZA group (OR =0.08, 95% CI 0.00-0.42, p=0.003). By the end of study, there were 2 lesions in the ZA group compared with 26 in the placebo group (p<0.0001). Biochemical markers of bone turnover were significantly reduced in the ZA group throughout the study. One participant allocated to placebo required rescue therapy with ZA because of symptomatic disease. The number, severity and type of adverse events did not differ between the groups.ConclusionsGenetic testing for SQSTM1 mutations coupled with intervention with ZA is well-tolerated and has favourable effects on progression of early PDB. Association of Clinical Factors and Incident Fracture in Overweight and Obese Middle-aged and Older Persons with Type 2 Diabetes Mellitus *Rachel Elam[1], Hongyan Xu[1], Laura Carbone[1], Carlos Isales[1], Yanbin Dong[1], Karen Johnson[2]. [1]Augusta University, United States. [2]University of Tennessee Health Science Center, United States

Purpose: Persons with type 2 diabetes mellitus (T2DM) have increased bone fragility despite preserved bone mineral density. We aimed to identify clinical factors associated with incident fracture in overweight and obese persons with T2DM.Methods: A retrospective cohort study of overweight and obese adults with T2DM enrolled in the multicenter Look AHEAD (Action for Health in Diabetes) Randomized Clinical Trial was conducted. Ethnically diverse men and women 45-75 years old were recruited to Look AHEAD from 2001-2004 and randomized to an intensive lifestyle intervention versus diabetes support and education. Incident fractures were ascertained every 6 months by self-report and confirmed with central adjudication of medical records. Clinical factors ascertained at baseline included: treatment arm; age; gender; race/ethnicity; height; weight; body mass index; smoking; alcohol use; prevalent cardiovascular disease, rheumatoid arthritis, and peripheral neuropathy; age at menopause (in women); duration of T2DM; hemoglobin A1C (HbA1C); estimated glomerular filtration rate; urinary albumin-to-creatinine ratio; and medication use thought to affect bone health, including diabetes drugs. Potential covariates were screened with Least Absolute Shrinkage and Selection Operator (LASSO) Cox regression, censoring on first incident fracture, death, loss to follow-up, or study year 18, whichever was first. The final multivariate Cox model was selected with optimal LASSO penalty to maximize the Harrell C-index.Results: Over a median follow-up of 16.6 years, 649 incident fractures occurred in 4,703 persons. In the final multivariate model (C-index: 0.63), modifiable clinical factors associated with incident fracture were tricyclic antidepressant use [hazard ratio (HR):2.24, 95% confidence interval (CI):1.14-4.43], insulin use (any form) [HR:1.26, 95% CI:1.02-1.57], and higher HbA1C [HR:1.12 per 1% increase in HbA1C, 95% CI:1.04-1.20]. Other significant covariates in the final model included age [HR:1.02, 95% CI:1.01-1.04], female gender [HR:2.20, 95% CI:1.83-2.66], race/ethnicity, and estrogen use [HR:0.65, 95% CI:0.44-0.98] (Figure 1).Conclusions: Tricyclic antidepressants should be used judiciously in adults with T2DM as their use confers the highest hazard of incident fracture in our study, independent of prevalent peripheral neuropathy. Improving glycemic control, without insulin use if possible, may prevent fractures in overweight and obese adults with T2DM.

Figure 1: Hazard ratios (95% confidence intervals) for covariates in the final multivariate Cox model for incident fracture

The Association of SGLT2-Is Versus DPP4-Is as Add-on to Metformin and Fracture Risk in Patients With Type 2 Diabetes Mellitus *Veerle van Hulten[1], Johanna Driessen[2], Jakob Starup-Linde[3], Zheer Al-Mashhadi[4], Rikke Viggers[5], Olaf Klungel[6], Patrick Souverein[6], Peter Vestergaard[5], Coen Stehouwer[7], Joop Van Den Bergh[8]. [1]1Department of Clinical Pharmacy and Toxicology, Maastricht University Medical Centre+ (MUMC+), Netherlands. [2], Netherlands. [3]Department of Endocrinology and Internal Medicine, Aarhus University Hospital, Denmark. [4]Steno Diabetes Center Aarhus, Aarhus University Hospital, Denmark. [5]Steno Diabetes Center North Denmark, Denmark. [6]Division of Pharmacoepidemiology & Clinical Pharmacology, Utrecht Institute for Pharmaceutical Sciences, Utrecht University, Netherlands. [7]Department of Internal Medicine, Cardiovascular Research Institute Maastricht, Maastricht University Medical Centre+ (MUMC+), Netherlands. [8]VieCuri MC Noord-Limburg and Maastricht UMC,

Background: T2D is a major burden to public health and healthcare costs. It is known that T2D is associated with an increased fracture risk. Additionally, the use of SGLT2-Is, a relatively new class of glucose lowering drugs, has recently been linked with an increased risk of fractures.Purpose: To study if SGLT2-I use as compared to DPP4-I use as add-on to Metformin is associated with the risk of any fracture or major osteoporotic fractures (MOFs).Methods: A cohort study using the Clinical Practice Research Datalink (CPRD) Aurum database was conducted. The CPRD contains medical records of primary care practices in the United Kingdom. All patients aged 18 years and older with a first ever prescription of a DPP4-I or a SGLT2-I as add-on to Metformin between 1-1-2013 and 30-6-2020 were selected. Patients starting with SGLT2-I were matched (up to 1:3) on propensity scores to patients starting with DPP4-Is. Propensity scores were calculated based on sex, age, BMI, comorbidities, comedication and lifestyle factors. Cox proportional hazard models were used to estimate the risk of any fracture with SGLT2-I use as compared to DPP4-I use. As the secondary analysis the risk of major osteoporotic fracture (MOF) was estimated. Results: A total of 13,807 SGLT2-I users (55.4+/-10.6 y/o, 36.7% female) were included in this study, matched with 28,524 DPP4-I users (55.4+/-8.0 y/o, 36.4% female). The risk of any fracture with current SGLT2-I use was similar compared with current DPP4-I use (adjusted hazard ratio (aHR) 1.09; 95% CI: 0.91-1.31), as was the risk of MOFs (aHR 0.89; 95% CI: 0.64-1.22) and the risk of fractures at any of the individual MOF sites. Additionally, no association was found with the duration of SGLT2-I use (longest duration >811 days), with any of the individual SGLT2-I agents, or after stratification by sex and age. All analyses were repeated in CPRD GOLD and yielded similar results.Conclusion: SGLT2-I use was not associated with the risk of any fracture, MOFs or fracture at the individual MOF sites when compared to DPP4-I use.

Maternal Diabetes Is Associated with Higher Risk of Fractures in Offspring: A Population-Based Analysis *Viral Shah[1], William Leslie[2], Maria-Elena Lautatzis[3], Kun Liu[4], Heather Prior[4], Brandy Wicklow[3]. [1]University of Colorado Denver, United States. [2]University of Manitoba, Canada. [3]Department of Pediatrics and Child Health, University of Manitoba, Canada. [4]Manitoba Centre for Health Policy, Canada

Purpose: Fracture risk is 1.2-1.5 fold higher in people with type 2 diabetes and 2-to 6-fold higher in people with type 1 diabetes. The intra-uterine environment is known to affect offspring risk for type 2 diabetes and cardiovascular disease. We studied the effect of in-utero exposure to maternal diabetes (type 2 diabetes and gestational diabetes) on offspring fracture risk.Methods: Administrative data was accessed between 1980-2020 from the Manitoba Population Research Data Repository to identify a cohort of offspring born to women with and diabetes. The primary outcome was any fracture (defined using ICD-9 CM/ICD-10-CA diagnosis codes) by maternal diabetes status adjusting for potential confounders.Results: Of 585,176 total deliveries, 26,397 offspring were born to women with diabetes (mean maternal age 30.7+/-5.9) and 558,779 were born to women without diabetes (age 27.9+/-5.6). A higher percentage of offspring born to women with diabetes were large for gestational age (27.7% vs 12.0%) and had a diabetes diagnosis (2.4% vs 1.2%). After adjusting for potential confounders, risk for any fracture [HR 1.070 (95% 1.027-1.115), p=0.0012; Figure 1] was 7.0% higher and risk for non-traumatic fracture was 6.7% higher [1.067 (1.023-1.113), p=0.0026] among offspring born to women with diabetes compared to offspring of women without diabetes). There was significant increase in risk for long bone upper extremity [1.065 (1.005-1.129, p=0.033)]; however, long bone lower extremity [1.027 (0.932-1.130), p=0.59] and vertebral fractures [1.195 (0.769-1.859), p=0.42] were not significantly higher in offspring born to mother with diabetes.Conclusion: To our knowledge, this is the first study identifying increased fracture risk among offspring of women with diabetes during pregnancy. This study highlights the potentially detrimental role that intra-uterine glucose exposure may have on skeletal health of offspring. Further studies are needed to evaluate the effect of intrauterine hyperglycemia on offspring bone morphology and bone mass accrual.

High Glucose and Type 2 Diabetes Mellitus Condition Stimulate Osteocyte-Mediated Sclerostin Production by Inhibiting Autophagy *Cyril Thouverey[1], Sara Delon[1], Nicolas Bonnet[2], Serge Ferrari[3]. [1]University Hospital of Geneva, Switzerland. [2]Nestlé research, Switzerland. [3]Geneva University Hospital and Faculty of Medicine, Switzerland

Serum levels of sclerostin are elevated in patients with type 2 diabetes mellitus (T2DM), inversely related to serum levels of bone formation marker, and associated with increased fracture risk. Moreover, sclerostin is highly expressed by osteocyte-like cell lines treated with high glucose in vitro, and by osteocytes in a diabetic rat model. Since high glucose can potentially alter autophagy in osteoblast lineage cells in vitro, we hypothesized that T2DM condition and high glucose could increase sclerostin expression by affecting autophagy in osteocytes. To test this hypothesis, we cultured KUSA-A1 cells for 16 days in osteogenic medium until complete mineralization and expression of osteocyte markers, including sclerostin (Sost gene), then treated those cells with vehicle solution (Veh), 25 mM mannitol or 25 mM glucose for 6 days, and monitored autophagic flux and sclerostin expression/secretion. In addition, mice treated with a high fat diet for 3 months and receiving a single low dose of streptozotocin (HFD + STZ) were injected with Veh or 0.5 mg/kg rapamycin (to stimulate autophagy) 3 times a week for the last 2 months. Fully mineralized KUSA-A1 cells cultured under high glucose condition displayed high Sost mRNA expression (5-fold versus Veh- and mannitol-treated cells) and sclerostin protein secretion (5-fold), but unchanged expressions of osteocyte markers Gp38 and Mepe. Furthermore, mineralized KUSA-A1 cells treated with high glucose exhibited reduced autophagic flux (lower LC3II/LC3I ratio than in Veh- and mannitol-treated cells) and diminished expressions of autophagy effectors Beclin, Atg5 and Atg7. High glucose stimulated phosphorylation/activation of mammalian target of rapamycin (mTOR), while it decreased that of UNC-51-like kinase 1 (a positive regulator of autophagy whose activation is inhibited by mTOR). Inhibition of mTOR by 25 nM Torin2 restored autophagic flux and normal sclerostin secretion in high glucose-treated mineralized KUSA-A1 cells. Finally, our murine model of T2DM (HFD + STZ) showed reduced cortical bone thickness at femoral midshaft (-11% versus mice receiving a control diet, p=0.002), decreased bone tissue expressions of Beclin, Atg5 and Atg7, and elevated Sost expression (8-fold). In this context, rapamycin treatment could restore normal Sost expression and cortical thickness. In conclusion, our findings show that high glucose and T2DM condition stimulate osteocyte-mediated sclerostin production by inhibiting autophagy.

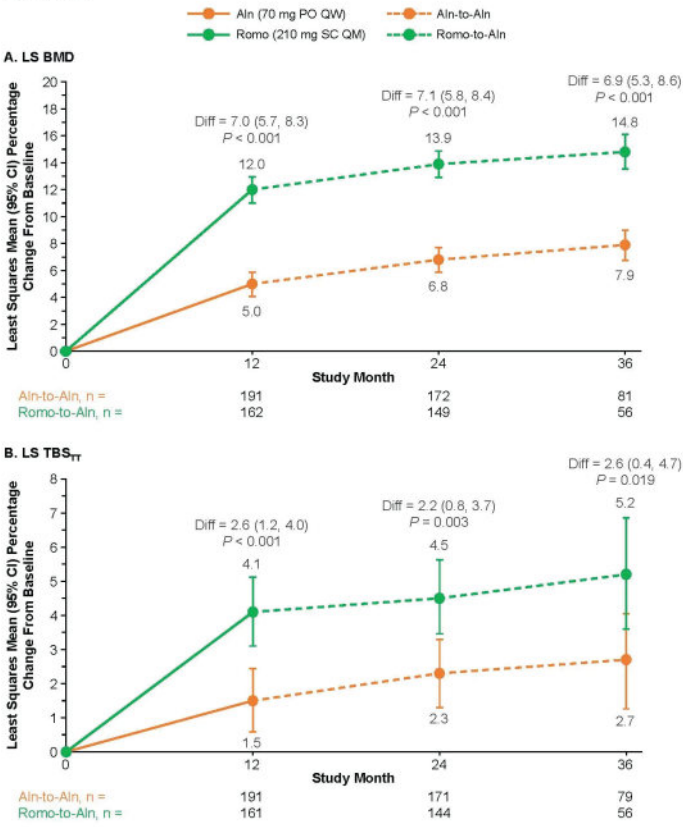
Effect of Romosozumab on Tissue Thickness-Adjusted Trabecular Bone Score in Postmenopausal Women with Osteoporosis and Diabetes: Results From the ARCH Study *Serge Ferrari[1], Donald Betah[2], Robert Feldman[3], Bente Langdahl[4], Mary Oates[2], Jen Timoshanko[5], Zhenxun Wang[2], Ruban Dhaliwal[6]. [1]Geneva University Hospital , Switzerland. [2]Amgen Inc, United States. [3]MemorialCare Saddleback Medical Center, United States. [4]Aarhus University Hospital, Denmark. [5]UCB Pharma, United Kingdom. [6]Massachusetts General Hospital, United States

Diabetes mellitus is associated with reduced bone strength and increased fracture risk (Walle 2022, Curr Osteoporos Rep). Trabecular bone score (TBS), a gray-level texture index derived from lumbar spine (LS) DXA scans, has been reported to be decreased in patients with diabetes and is associated with an increased fracture risk, independent of bone mineral density (BMD). In the ARCH trial (Saag 2017, NEJM), romosozumab (Romo), an osteoanabolic with the dual effect of increasing bone formation and decreasing bone resorption, significantly improved bone mass and bone strength leading to superior fracture risk reduction vs alendronate (Aln) alone. Here, we examined the effect of Romo-to-Aln vs Aln-to-Aln on LS BMD and TBS in ARCH patients with diabetes.In ARCH, postmenopausal women with osteoporosis and prior fracture were randomized 1:1 to Romo 210mg SC monthly or Aln 70mg PO weekly for 12 months (M), followed by Aln 70mg PO weekly for 24 M in both groups. This post hoc analysis included a subgroup of women from ARCH who had diabetes mellitus at baseline (BL) and had LS DXA scan measurements at BL and >=1 post-BL visits (Romo-to-Aln, n=195; Aln-to-Aln, n=165). BMD and TBS (determined by an updated tissue thickness-adjusted TBS algorithm [TBSTT]; TBS iNsightTM v4.0 [Medimaps]; Shevroja 2019, JBMR) were assessed on LS DXA scans at BL, M12, M24, and M36.BL LS BMD was -2.63 for Romo and -2.89 for Aln; BL LS TBSTT was 1.006 and 1.010, respectively. Romo led to significantly greater gains in LS BMD and TBSTT at M12 vs Aln, and greater gains with Romo were maintained after transition to Aln and persisted significantly at M24 and M36 vs Aln alone (Figure). In the Romo-to-Aln group, the percentage of women with "normal" TBS values (TBSTT>1.074; Hans 2022, Osteoporos Int) increased from 23.6% at BL to 50.0% at M36 and those with "degraded" TBS values (TBSTT<=1.027) decreased from 55.8% to 33.9% (P<0.001). A similar trend, albeit with smaller improvement, was observed in the Aln-to-Aln group. TBSTT percentage changes were unrelated to LS BMD percent changes from BL to M36 (Romo-to-Aln, r2=0.1493; Aln-to-Aln, r2=0.0429).In conclusion, in postmenopausal women with osteoporosis and diabetes, 12 M of Romo followed by 24 M of Aln significantly improved LS BMD and TBS as measured by TBSTT (independently of BMD) to a greater extent when compared with 36 M of Aln alone. These changes may reflect a greater improvement of bone strength by Romo vs Aln in patients with diabetes.

Figure: Percentage change from baseline by visit and treatment group for LS BMD and TBS_{TT}



LS BMD and TBS_{TT} data were analyzed based on repeated measures model adjusting for treatment, presence of severe vertebral fracture at baseline, visit, treatment-by-visit interaction, baseline BMD or TBS value as fixed effects, with machine type and baseline BMD or TBS value-by-machine type interaction as covariates, using either a compound symmetry variance covariance structure for BMD or an unstructured variance covariance structure for TBS.

Aln = alendronate; BMD = bone mineral density; CI = confidence Interval; Diff = percentage change from baseline for Romo treatment group minus percentage change from baseline for Aln treatment group; LS = lumbar spine; PO = orally; QM = monthly; QW = weekly; Romo = romosozumab; SC = subcutaneous; TBS = trabecular bone score; TBS_{TT} = tissue thickness–adjusted trabecular bone score.

I?B? Is a Central Modulator of Rheumatoid Arthritis Pathology *Gaurav Swarnkar[1], Krishna Bhan Singh[1], Dorothy Kate Mims[1], Syeda Kanwal Naqvi[1], Musarrat Naaz[1], Yousef Abu-Amer[1]. [1]Washington University School of Medicine, United States

Rheumatoid Arthritis (RA) is a chronic inflammatory autoimmune disease considered as one of the leading causes of disability worldwide. IL-1?, TNF?, IL-17, IL-6, and other highly abundant cytokines and catabolic enzymes such as MMPs from a variety of synovial

cells in RA, perpetuate a vicious inflammatory cycle in the joint tissue, leading to the demise of articular cartilage and subchondral bone. As such, current therapies targeting inflammatory cytokines show limited efficacy owing to cytokine redundancies and many adverse side effects on normal physiology. NF-?B signaling plays a crucial role in the production and function of these inflammatory cytokines. However, given the essential role of NF-?B in physiologic processes, a more effective approach is needed to target pathway downstream of NF-?B, which regulates expression of inflammatory cytokines in RA. Using transcriptomics, we have identified I?B? (gene: Nfkbiz) as a unique inflammatory signature of NF-?B that controls transcription of inflammatory cytokines only under pathologic conditions. Our qPCR, western blot, ELISA and RNAseq results show that deletion of Nfkbiz attenuates production of these inflammatory cytokines and catabolic enzymes such as MMPs in various cell types involved in RA pathology. Further, RNA-Seq of CD11b+ cell from joints of WT and LysMcre: Nfkbiz-/- knockout mice, subjected to serum-induced arthritis (STIA), showed decreased expression of IL-6, IL-17, IL-1?, TNF? and other inflammatory signals in KO mice. To determine if genetic global deletion of Nfkbiz attenuates experimental mouse arthritis, we subjected Ubc-ERT2-Cre+/-: Nfkbiz-/-, CAGG-ERT2-Cre+/-: Nfkbiz-/- and littermate wildtype (WT) control animals to STIA. Paw measurements, microCT and bulk RNAseq analysis showed significant inhibition in joint swelling, joint erosion, and decrease expression of inflammatory cytokines. Finally, we identified Dimethyl Itaconate (DI) and 8-Hydroxyquinoline (8HQ) as selective pharmacological inhibitors of I?B? activity without affecting NF-?B activity. We show that systemic administration of DI and/or 8HQ significantly inhibit joint swelling and joint erosion. In summary, our study holds promise to establish I?B? as an inflammation-specific target for therapeutic intervention in RA while sparing the broad beneficial effects of NF-?B

Conditional Deletion of MCP1 in the Colonic Epithelium is Protective in the OA of Obesity *David Villani[1], Honey Hendesi[1], Celia Mbazoa[1], Samantha Landgrave[2], Toru Ishii[1], Ann Gill[3], Lacey Favazzo[1], Karin Payne[1], Steven Gill[3], Michael Zuscik[4]. [1]CU Anschutz, United States. [2]University of Colorado Anschutz Medical Campus, United States. [3]University of Rochester, United States. [4]University of Colorado, United States

One of the leading risk factors for the development of osteoarthritis (OA) is obesity. In addition to causing joint overloading, obesity is associated with a gut microbiome dysbiosis that initiates colonic, systemic, and joint inflammation that ultimately accelerates joint degeneration in OA. It follows that obesity-associated gut microbiome dysbiosis leads to an infiltration of pro-inflammatory macrophages into the colon, which triggers colonic inflammation during obesity. This phenotype is driven by an increase in monocyte chemoattractant protein one (MCP1), a chemokine encoded by the Ccl2 gene. MCP1 is responsible for recruiting pro-inflammatory macrophage populations to the colon, an initiating factor that may drive both systemic and joint inflammation, ultimately accelerating OA progression. Here, we sought to test if knocking out Ccl2, the gene that encodes MCP1, in the intestinal epithelium, can blunt colonic inflammation and, as a result, protect against obesity-related OA. To test this idea, tamoxifen-inducible Vil1-CreERT2;Ccl2fl/fl mice (Vil-Ccl2cKO) were placed on a lean or high-fat diet. Tamoxifen was administered to conditionally delete Ccl2 from the intestinal epithelium, and OA was initiated via surgical destabilization of the medial meniscus. Three months post-injury, colon, joints, and serum were collected for molecular analysis. Flow cytometry indicated that there was a reduction in the number of macrophages and NK1.1+ NK cells within the colon of obese Vil-Ccl2cKO animals, consistent with parallel immunohistochemistry detection of reduced MCP1 levels in the colonic epithelium (Figure 1A). Serum cytokine analysis revealed decreases in circulating MCP1 and IL-1? in obese Vil-Ccl2cKO animals (Figure 1B). Finally, in DMM-injured joints, histomorphometry indicated that obese Vil-Ccl2cKO mice are protected from the accelerated OA phenotype (Figure 1C). Specifically, obese Vil-Ccl2cKO animals had an increase in both calcified and total femur cartilage area compared to diet-matched control mice (Figure 1D). In summary, using Vil-Ccl2cKO mice, we show that inhibition of colonic inflammation during the OA of obesity via deletion of Ccl2 in the intestinal epithelium, can protect against obesity associated OA. These findings suggest that approaches to reduce obesity-associated colonic inflammation may represent a novel strategy for addressing systemic and joint inflammation that leads to accelerated OA in the context of obesity.

Altered glucose and glutamine metabolism drives chondrocyte dysfunction in osteoarthritis *Steve Stegen[1], Frederique Cornelis[2], Ingrid Stockmans[1], Karen Moermans[1], Silvia Monteagudo[2], Rik Lories[2], Geert Carmeliet[1]. [1]Clinical and Experimental Endocrinology, KU Leuven, Belgium. [2]Skeletal Biology and Engineering Research Center, KU Leuven, Belgium

Osteoarthritis (OA) is the most common degenerative joint disease for which there is no curative treatment. OA etiology is multifactorial, but dysfunctional behavior of the articular chondrocytes is considered as a major contributor to disease onset and progression. Increasing evidence suggests that during OA the metabolic profile of articular chondrocytes is altered, but whether disturbed metabolism causes cellular dysfunction is still unknown. To investigate the metabolic changes in OA chondrocytes, we employed a combinatory approach of (i) single-cell RNA sequencing using the medial meniscus destabilization (DMM) mouse model and (ii) mass spectrometry-based metabolomics on OA patient-derived articular chondrocytes or cytokine-treated mouse chondrocytes. We found that OA chondrocytes displayed increased glycolysis and enhanced activity of the pentose phosphate pathway (PPP) and hexosamine biosynthesis pathway (HBP), whereas oxidative phosphorylation and glutathione synthesis were decreased. These metabolic alterations affected chondrocyte function at multiple levels. First, the typical hypertrophic and catabolic gene signature of OA chondrocytes was caused by stimulation of the HBP. More precisely, increased PPP-mediated glucose flux and glutamine metabolism into the HBP caused enhanced protein O-glycosylation, which resulted in the induction of genes involved in chondrocyte hypertrophy (Col10a1) and matrix degradation (Mmp13). Second, OA chondrocytes undergo ferroptosis, a type of cell death caused by oxidation of cell membrane lipids by reactive oxygen species (ROS). As a mechanism, more ROS was produced by NADPH-oxidases, mediated by increased PPP-driven NADPH generation, whereas less ROS was scavenged due to decreased glutamine-dependent glutathione synthesis. To causally link metabolic maladaptation to cellular dysfunction, we inhibited key enzymes in the PPP (by G6PDi) and glutamine metabolism (by EGCG), which fully normalized the oxidative stress phenotype and hypertrophic/catabolic gene expression, and prevented cartilage loss in the DMM model in mice.Together, our data show that dysbalanced glucose and glutamine metabolism in OA chondrocytes results in oxidative stress and protein O-glycosylation, leading to cell death and increased catabolic gene expression (Fig 1). Pharmacological inhibition of altered metabolic enzymes prevented cartilage loss in mice, suggesting that targeting chondrocyte metabolism is an appealing strategy to treat OA.

Functional Studies of Transcription Factor Dlx5 During Mouse Chondrogenesis and Osteoarthritis Progression *Jinnan Chen[1], Fangzhou Chen[2], Dongmei Liu[3], Tiaotiao Han[1], Huiqin Bian[1], Chen Chen[1], Xuan Wu[1], Qian Wang[1], Yaojuan Lu[3], Qiping Zheng[1]. [1]Department of Hematology and Hematological Laboratory Science, Jiangsu Key Laboratory of Medical Science and Laboratory Medicine, School of Medicine, Jiangsu University Zhenjiang, Jiangsu 212013, China, China. [2]Department of Pathology, the Affiliated People's Hospital of Jiangsu University, Zhenjiang, Jiangsu 212002, China, China. [3]Shenzhen Walgenron Bio-Pharm Co., Ltd. Shenzhen 518118, Guangdong, China, China

The transcription factor DLX5 (Distal-Less Homeobox 5) has been implicated roles in chondrocyte hypertrophy during osteoarthritis (OA) progression. We have recently reported DLX5 transactivation of the hypertrophic chondrocytes-specific Col10a1 gene expression in a mouse model of OA. Herein, we further performed the expression profiling of DLX5 in OA patients and in induced OA like cell model. The effect of DLX5 regulation of chondrocyte maturation and matrix mineralization in vitro was evaluated by Alizarin Red S, Alcian Blue, and ALP staining after ITS induction of ATDC5 cells. To gain insights about its role during endochondral ossification and OA progression, we have established a chondrocyte-specific Dlx5 knock out mouse model using the CRISPR-Cas9 and Cre-LoxP technology. Our results showed that DLX5 and COL10A1 were both significantly elevated in the damaged zone of OA patients as well as in OA-like chondrocytes after TNF-? and LPS induction. Forced expression of Dlx5 facilitated chondrocyte hypertrophy and matrix mineralization, while knock down of Dlx5 attenuated hypertrophic phenotype of ATDC5 cells. In vivo results revealed that mice with conditionally knock-out (CKO) Dlx5 in chondrocytes [Dlx5f/fCol2Cre(F/F/?)] leads to smaller body size and shortened hypertrophic zone of the ribs compared with the littermate controls Dlx5f/f (F/F). Delayed mineralization of the distal phalanges and metatarsals of the Dlx5 CKO mice was also observed after whole skeletal alcian blue-alizarin red S staining. Meanwhile, histologic analysis revealed shortened hypertrophic zones in growth plate of Dlx5 CKO mice with reduced number of trabecula bone and the inhibition of osteogenic mineralization. The DMM-induced OA mouse model was also established in Dlx5 CKO mice and their littermate controls. Relatively intact microstructure of the trabeculae with high number and connectivity of subchondral was detected in Dlx5 CKO mice with Micro-CT and Safranin O- Fast Green staining, indicating its less destruction of the knee joint. Together, our results suggest that DLX5 is an essential transcription factor for chondrocyte hypertrophy during endochondral ossification and OA progression, and may serve as a biological marker for OA diagnosis and therapeutics.

Synovium and infrapatellar fat pad share common mesenchymal progenitors and undergo coordinated changes in osteoarthritis *Jun Li[1], Tao Gui[1], Lutian Yao[1], Hanli Guo[1], Yu-Lieh Lin[1], Jiawei Lu[1], Jiankang Fang[1], Michael Duffy[1], Miltiadis Zgonis[1], Robert Mauck[1], Nathaniel Dyment[1], Yejia Zhang[2], Carla Scanzello[3], Patrick Seale[4], Ling Qin[1]. [1]Department of Orthopaedic Surgery, Perelman School of Medicine, University of Pennsylvania, United States. [2]Translational Musculoskeletal Research Center, Corp. Michael J Crescenz, VA Medical Center, United States. [3]4Translational Musculoskeletal Research Center, Corp. Michael J Crescenz, VA Medical Center, United States. [4]Department of Cell and Developmental Biology, Perelman School of Medicine, University of Pennsylvania, United States

Osteoarthritis (OA) affects multiple tissues in the knee joint. Past OA research focused on articular cartilage and bone, but often overlooked surrounding soft tissues, such as synovium (Syn) and infrapatellar fat pad (IFP). In knees, IFP attaches to Syn in a seamless fashion and both tissues undergo drastic morphologic changes in OA progression. To investigate tissue heterogeneity, we performed scRNA-seq on Syn/IFP from control (n=20 mice) and DMM-treated adult mice (1 week, n=8 mice; 2 months, n=12 mice). Unsupervised clustering of 29,763 cells revealed 9 clusters, including fibroblasts, endothelial cells, mural cells, and immune cells. Further analysis on 17,097 fibroblasts identified 5 subtypes: mesenchymal progenitor cells (MPCs), synovial lining fibroblasts (SLFs), myofibroblasts (MFs), preadipocytes 1 and 2 (preAD1 and 2). MPCs, preAD1s and 2s were largely overlapped with Dpp4+, Icam1+, and F3+ progenitors previously identified in subcutaneous white adipose tissue (sWAT). Computational analysis predicted MPCs as common progenitors for SLFs and adipocytes and for a rapid induction of MFs after DMM. Immunofluorescence imaging of Dpp4-CreER Td and Prg4-CreER Td knees, in which Td labels MPCs and SLFs, respectively, revealed that Dpp4+ MPCs reside in the synovial sublining layer and give rise to Prg4+ SLFs and adipocytes during joint development and DMM or loading-induced OA. While Syn/IFP contained much more Prg4+ cells (22.0%) than Dpp4+ cells (1.7%), CFU-F colonies formed by Syn/IFP cells were mainly derived from Dpp4+ cells but not from Prg4+ cells. Sorted Dpp4+ cells proliferated much faster than Dpp4- cells in culture and had multi-lineage differentiation ability. On the contrary, Prg4+ SLFs did not contribute to adipocytes and sorted Prg4+ cells barely grew in vitro. Lineage tracing showed that both MPCs and SLFs become highly proliferative MFs (labeled by ?SMA staining or Scx-GFP expression) after DMM. Those MFs gained myofibroblast features and remained in the thickened synovium in late OA, thus contributing to synovial and fat pad fibrosis. Importantly, Dpp4+ cells were present at a similar location in human Syn/IFP. Based on the trajectory analysis of scRNA-seq and snRNA-seq datasets from healthy and OA patients, Dpp4+ cells also gave rise to Prg4+ SLFs and adipocytes in the Syn/IFP. Taken together, we demonstrate that Syn/IFP is indeed one functional tissue sharing common mesenchymal progenitors and undergoing coordinated changes in OA.

MMP13 Regulation of Perilacunar Remodeling is Cathepsin K-Dependent and Required for Lactation-Induced Osteocytic Osteolysis and Trabecular Bone Loss *MAISA MONSEFF SILVA[1], JIAMING ZHANG[2], YINBO NIU[3], SHUANG LIANG[4], Daniel Brooks[5], Mary Bouxsein[6], Francisco Jose De Paula[7], Francesca Gori[8], Roland Baron[9, 1], [2]Harvard University, [3]Key Laboratory for Space Bioscience & Biotechnology, School of Life Sciences, Northwestern Polytechnical University, China. [4]Harvard University , United States. [5]BIDMC/MGH, [6]Beth Israel Deaconess Medical Center, Harvard Medical School, United States. [7]Ribeirao Preto Medical School- USP, Brazil. [8]Harvard School of Dental Medicine, United States. [9]Harvard Medical School and School of Dental Medicine, United States

During lactation, bone resorption supplies calcium in milk via osteoclastic bone resorption and osteocytic osteolysis during perilacunar remodeling (PLR). Osteocytes (Ocy) modulate their micro-environment and respond to hormonal and mechanical cues, engaging in matrix resorption and/or deposition, altering their lacunar space. The molecular mechanisms underlying Ocy PLR regulation during lactation and the interaction between Ocy and their microenvironment are yet to be fully elucidated. We performed bulk RNA seq of highly enriched Ocy preparations from lactating and virgin mice. As anticipated, a significant upregulation of resorption-related genes was observed. Among the key genes were cathepsin K (Ctsk) and matrix metalloproteinase 13 (Mmp13). To explore the role of these two secreted enzymes in PLR, we first generated Mmp13ocy mice using the 10 kb-Dmp1-cre. BSEM revealed that cortical Ocy lacunar area (LcA) was significantly larger (p=<0.01) in Mmp13ocy mice vs control. Thus, Mmp13 maintains a positive PLR balance at steady state. In contrast, Mmp13 deletion prevented lactation-induced LcA enlargement, suggesting that in lactating mice, MMP13 enhances the osteolytic aspect of PLR. Furthermore, virgin Mmp13ocy mice

exhibited a higher trabecular (Tb) bone volume (BV/TV) than control virgin mice and did not lose bone during lactation: ?CT analysis showed that lactating Mmp13ocy mice had significantly higher BV/TV (+86.16%, p<0.001), Tb number (Tb.N) (+60,7%, p<0.001), and Tb connectivity (Conn.D) (+188,1%, p<0.001) vs control lactating mice. Because MMP13 deletion increases Ctsk expression in Ocy, we then asked whether the increase in LcA in Mmp13ocy mice was due to increased Ctsk expression. Ocy-targeted deletion of Ctsk in Mmp13ocy (DKO) prevented LcA enlargement in virgin mice, confirming a role for Ctsk in the Mmp13ocy LcA enlargement. Furthermore, DKO not only prevented the expected increase in LcA during lactation, lactation-induced Tb bone loss but also further increased BV/TV over Mmp13ocy at both steady state and in lactation. In conclusion, counter-intuitively, Mmp13 deletion triggers Ocy osteolysis and lacunar expansion and this is prevented by the deletion of Ctsk. Thus, at steady state, Mmp13 favors a positive balance in PLR, whereas during lactation its favors Ctsk-dependent Ocy osteolysis and bone loss. These results highlight the crucial contribution of Ocy-derived Mmp13 and Ctsk in PLR and skeletal homeostasis.

Coupling of osteocytic osteolysis to functional osteoclasts during lactation *Roland Baron[1], Diana Athonvarangkul[2], John Wysolmerski[3], Zainah Salloot[4]. [1]Harvard Medical School and School of Dental Medicine, United States. [2]Yale University, United States. [3]Yale School of Mediicne, United States. [4]Harvard School of Dental Medicine, United States

Osteocytic osteolysis may contribute to bone loss in lactation. The connection between osteocytes and osteoclasts to regulate lactational bone resorption is not understood. In this study, we provide novel evidence that bone resorption in lactation is coordinated between osteocytes and osteoclasts. In particular, loss of functional osteoclasts prevents osteocytic osteolysis during lactation.We initially hypothesized that inhibition of osteoclast activity would lead to a compensatory increase in osteocytic osteolysis during lactation. We treated 10 week-old lactating CD1 mice with recombinant osteoprotegerin (OPG, 10mg/kg) to block RANKL signaling, zoledronic acid (ZA,100 ug/kg) to inhibit osteoclasts or vehicle, from delivery through mid-lactation (day 12). Eliminating osteoclast function with either OPG or ZA prevented lactational trabecular BMD loss measured by microCT. The average osteocyte lacunar area, measured by backscatter electron microscopy, did not significantly differ among the groups. However, OPG and ZA tended to prevent the shift to large osteocyte lacunae (30-60 uM) that was observed in the lactation group, reflecting loss of osteocytic osteolysis and the presence of osteocyte heterogeneity. Lactational increases in gene expression of the key resorptive enzymes tartrate-resistant acid phosphatase, cathepsin K, and matrix metallopeptidase 13 were not observed in osteocyte-enriched RNA samples from OPG and ZA groups, suggesting that loss of active osteoclasts interferes with the phenotypic switch in osteocytes.Since the above results suggested that osteocytic osteolysis depends on RANKL signaling, we asked whether osteocytes might express RANK during lactation. We crossed the mT/mG reporter mouse with the RANK-Cre mouse to identify cells expressing RANK by their switch from red to green fluorescence. All osteocytes remained red, which indicated that RANK is not expressed on osteocytes. Therefore, the inhibition of osteocytic osteolysis by OPG must be mediated indirectly by osteoclasts or another RANK-expressing cell.Here we showed that osteoclastic resorption is coordinated with osteocytic osteolysis in lactation. Our working theory is osteocytes are stimulated by RANKL-dependent coupling factor(s) from active osteoclasts to induce a bone resorption gene program. Identifying clastokines that couple the activity of osteoclasts and osteocytes could be important for pathophysiology outside of lactation and may lead to therapeutic targets for pathologic bone turnover.

Osteoclast-Independent Osteocyte Morphology Defects in Mice Bearing an Osteogenesis Imperfecta-Causing SP7 R316C Mutation *Jialiang S. Wang[1], Katelyn Strauss[1], Michael Bruce[1], Daniel J. Brooks[2], Tatsuya Kobayashi[1], Mary L. Bouxsein[2], Marc N. Wein[1]. [1]Massachusetts General Hospital, Harvard Medical School, United States. [2]Massachusetts General Hospital, Beth Israel Deaconess Medical Center, Harvard Medical School, United States

BackgroundSP7 is a transcription factor with a well-known role in osteoblast differentiation. Recent studies suggest a novel role of SP7 in osteocyte development. Rare SP7 mutations have been reported to cause recessive and dominant osteogenesis imperfecta. Homozygous SP7 R316C patients were characterized by short stature, recurrent fractures and high cortical porosity. In this abstract, mice with the osteogenesis imperfecta-causing SP7 R316C mutation show osteocyte dendrite defects and increased intracortical bone resorption. However, at present we do not understand the relationship between osteocyte morphology defects and intracortical osteoclast activity in this model. Methods/ResultsWe generated SP7R316C knock-in mice using CRISPR-Cas9 gene editing. First, skeletal analyses were performed in 8-week-old mice to recapitulate the bone development from childhood to adulthood. Compared to littermate controls, male and female mutant SP7R316C/R316C mice demonstrated significantly increased cortical porosity and reduced cortical bone mineral density. This is consistent with the phenotypes observed in R316C patients. Homozygous SP7R316C mice had osteocyte dendrite defects, increased osteocyte apoptosis, elevated Rankl expression, and increased osteoclast activity (Fig. 1A). Next, we assessed if the dendrite defect seen in SP7R316C mice is dependent on osteoclast activity by treating mice with OPG-Fc. Female mutant SP7R316C/R316C mice and their control littermates were injected once weekly with OPG-Fc or vehicle starting at 6 weeks old (four injections total). OPG-Fc treatment showed expected effects, including reduced serum CTX-1, increased trabecular bone mass, and reduced cortical porosity in both wild type and SP7R316C/R316C mice (Fig. 1B). In contrast, osteocyte dendrite defects in SP7R316C/R316C mice were not rescued by OPG-Fc treatment (Fig. 1C). Taken together, these results demonstrate that the SP7 R316C mutation leads to cortical bone loss by disrupting the osteocyte dendrite connectivity. Increased bone resorption does not cause osteocyte morphology defects in the SP7 R316C mutant mice. ConclusionsHere we report a novel mouse model of osteocyte defects due to the SP7 R316C mutation. The osteocyte defects observed in this SP7 mutant mouse model are independent of increased osteoclast activity. This model provides a valuable resource to test novel therapeutic approaches to treat osteocyte defects in addition to bone loss.

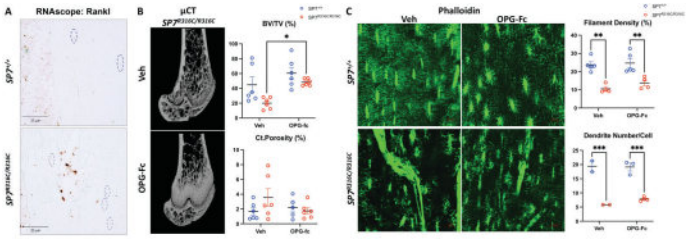

Figure 1. Osteocyte dendrite defects in $SP7^{R316C/R316C}$ mice were not rescued by OPG-Fc treatment. A. Rankl level is increased in $SP7^{R316C/R316C}$ mice compared to wild-type littermates by *in situ* hybridization (RNAscope). **B.** µCT analysis from the femur reveals increased bone mass and reduced cortical porosity in $SP7^{R316C/R316C}$ mice with OPG-Fc treatment. **C.** 10-week-old control and $SP7^{R316C/R316C}$ tibia were stained with phalloidin to visualize actin filaments within dendrites. Dendrite defects could not be rescued by OPG-Fc treatment in $SP7^{R316C/R316C}$ mice.

Prematurely Aging PolgA Mice Exhibit Sex-specific Hallmarks of Musculoskeletal Aging *Dilara Yilmaz[1], Thurgadevi Parajasingam[1], Lorena Gregorio[1], Christian Gehre[1], Francisco Correia Marques[1], Neashan Mathavan[1], Xiao-Hua Qin[1], Esther Wehrle[1], Gisela Anna Kuhn[1], Ralph Mueller[1]. [1]ETH Zurich, Switzerland

Age-related frailty is highly associated with senile osteoporosis and has been shown to be sex specific. Emerging evidence suggests that osteocytes serve as a promising therapeutic target for mitigating age-related bone loss. The PolgD257A/D257A (PolgA) mouse model displays premature aging and develops clinically relevant hallmarks of musculoskeletal aging. However, the relevance of this model in investigating age-related osteoporosis and the underlying mechanism responsible for age-associated changes in the osteocyte network remains unclear. In this study, we used male and female PolgA mice exhibiting hallmarks of premature aging to investigate age- and sex-related changes in frailty, bone structure, and osteocyte network.Frailty scoring was performed in young (12 weeks) and adult (34 weeks) male and female PolgA mice and their age-matched wild-type littermates (WT) (n=10-16 mice/group). Bone morphometric parameters were evaluated from the right femurs of PolgA mice (n=9-16 mice/group) and WT by micro-CT (voxel size: 10 µm). Phalloidin-Hoechst-stained osteocytes from the cortical bone of young (20 weeks) and old adults (40 weeks) PolgA and WT mice were imaged with 3D confocal microscopy and quantified with IMARIS (n=2-4 mice/group). Multiple t-test with Sidak-Bonferroni correction was used for statistical analysis.PolgA mice showed a higher frailty index (FI) with aging compared to young and age-matched WT mice at 34 weeks (males:+51%, females:+36%) (Figure 1B), followed by reduced cortical bone volume fraction (BV/TV) at 40 weeks (males:-10%, females:-9%)(Figure 1C). 3D visualization of osteocytes and dendrites demonstrated osteocyte sex-specific network disruption in PolgA mice with aging (Figure 1A). Osteocyte analysis revealed a significant reduction in dendrite length (males:-46% and females:-52%) and osteocyte area (males:-41%, females:-46%) in 40-week-old PolgA mice compared to WT and young PolgA mice (males:-45%, females:-44%; males:-61%, females:-63%) respectively(Figure 1D-E).We showed PolgA mice exhibited sex-specific hallmarks of musculoskeletal aging with increased frailty, reduced cortical BV/TV, and a disrupted osteocyte network, which was more pronounced in females than males. Since a similar age-related degeneration of the osteocyte network has been observed in humans, our results suggest that the PolgA mouse could be a valuable model to investigate the molecular mechanism responsible for age-related bone loss and senile osteoporosis.

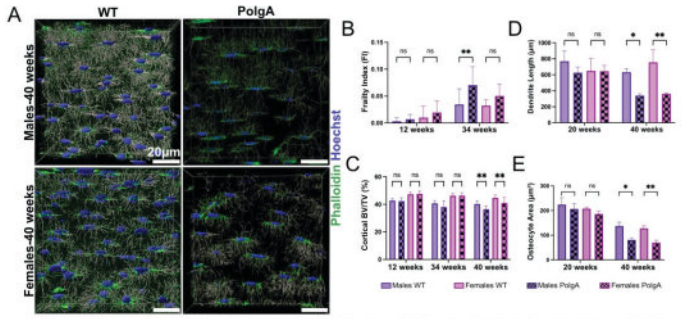

Figure 1: Age- and sex-related changes in PolgA mice: A) 3D visualization of osteocytes and their dendrites using automated filament tracing in iMARIS B) frailty index, C) cortical BV/TV, D) dendrite length, E) osteocyte area

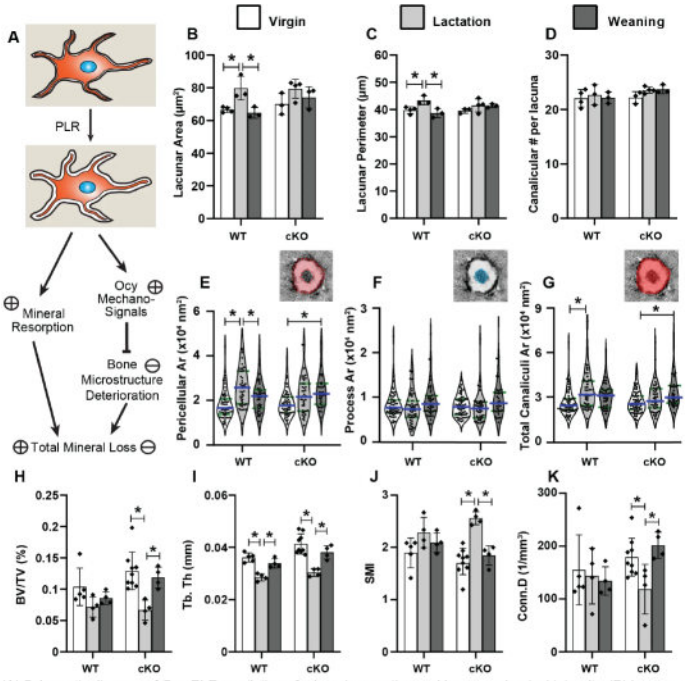
Conditional deletion of PTH1R in osteocytes abolishes lactation-induced alterations in canalicular pericellular space and increases bone microstructure deterioration *Xiaoyu Xu[1], Yilu Zhou[1], Rosa M Guerra[2], Yuanhang Li[1], Wonsae Lee[1], Tala Azar[1], Kira Lu[1], Liyun Wang[3], Xiaowei Liu[4]. [1]McKay Orthopaedic Research Laboratory, University of Pennsylvania, United States. [2]Center for Biomechanical Engineering Research, University of Delaware, United States. [3]University of Delaware, United States. [4]University of Pennsylvania, United States

During lactation, the female skeleton undergoes substantial loss of bone mineral by both osteoclast resorption and osteocyte (Ocy) perilacunar/canalicular remodeling (PLR). Our previous study suggested that PLR-induced alterations in the Ocy pericellular environment would amplify the mechanical and biochemical signal transduction to Ocys, in turn enhancing mechanical adaptation of maternal bone to maintain its load-bearing function (Fig A). Therefore, we hypothesized that abolishing Ocy PLR would result in greater bone loss and microstructure deterioration during lactation. In order to abolish lactation-induced PLR, we deleted PTH/PTHrP Receptor 1 in osteocytes (cKO: 10kb-Dmp1-Cre; PPRfl/fl) of C57BL6 mice and compared them with their wildtype (WT) littermates (n=4-6 in Virgin, Lactation, and Post-Weaning groups of both WT and cKO mice). Histology by Ploton silver nitrate staining indicated that 12-day lactation in WT mice resulted in 20% and 9% greater lacunar area and perimeter, respectively, which returned to baseline levels as in WT Virgin mice 14 days after weaning. In contrast, these lactation-induced changes were not found in the cKO mice (Fig B-D). Furthermore, transmission electron microscopy (TEM) images showed a 48% enlargement of the pericellular area surrounding the Ocy dendrite processes, leading to a 30% increase in canalicular area in WT Lactation vs. Virgin mice, whereas relevant increases were not found in cKO mice (Fig E-G). Unlike the recovered pericellular area in WT Post-Weaning mice, pericellular and total canalicular areas in cKO mice remained elevated after weaning. Interestingly, μCT results indicated greater lactation-induced bone loss and microstructure deterioration in cKO vs. WT mice (Figure H-K; cKO: 48% and 26% lower BV/TV and Tb. Th, and 48% higher SMI in Lactation vs. Virgin mice; WT: 30% lower Tb. Th in Lactation vs. Virgin mice). This is the first study that quantified the lactation-induced alterations in the ultrastructure of canaliculi and demonstrated active remodeling of the pericellular matrix surrounding Ocy dendrites during lactation and post-weaning. Inhibiting lactation-induced PLR may prevent the amplification of mechano-signal transduction in the Ocy network, leading to accelerated bone loss in lactating cKO mice (Fig A). Future studies will continue to elucidate critical roles of Ocy PLR in regulating the balance between mineral resorption and mechanical integrity of the maternal skeleton.



(A) Schematic diagram of Ocy-PLR regulation of mineral resorption and bone mechanical integrity. (B) Lacunar area, (C) lacunar perimeter , and (D) canaliculi number per lacuna derived from Ploton silver nitrate staining images of cKO and WT mice with different reproductive statuses. (E) Pericellular area of Ocy dendrite processes (area between the two red dashed lines), (F) process area (central area highlighted in blue), and (G) total canaliculi area (the area highlighted in red) derived from TEM images of tibial cortical bone of cKO and WT mice with different reproductive statuses. (H-K) L4 trabecular bone morphometry by μCT (7.5 μm) in cKO and WT Virgin, Lactation, and Post-weaning mice. Asterisk (*) indicates a significant difference between reproductive statuses (Virgin, Lactation, and Post-weaning) of cKO or WT mice by one-way ANOVA ($p<0.05$).

Low Cortical Volumetric BMD Predicts Complications in Men Undergoing Spine Fusion Surgery *Emma Billings[1], Joe Raphael[1], Alex Dash[1], Han Jo Kim[1], Matthew Cunningham[1], Darren Lebl[1], Donald McMahon[2], Jeri Nieves[3], Emily Stein[1]. [1]Hospital for Special Surgery , United States. [2]Columbia University College of Physicians and Surgeons, . [3]Columbia University and Hospital for Special Surgery,

Spine fusion surgery is one of the most common orthopedic procedures, with nearly 500,000 performed annually in the United States alone. Complications occur in up to one third of cases, increasing morbidity and health care costs. Many complications relate to poor bone quality, however; identification of high-risk patients remains a challenge. Men are infrequently referred for pre-operative skeletal evaluation, and no studies have focused on bone health in men having fusion. The FUSED SPINE (FUsion and Skeletal Evaluation in patients unDergoing SPINE surgery) ongoing prospective cohort study investigates relationships between pre-operative bone health and post-operative outcomes. This substudy focused on bone health and rates of skeletal complications in men. We hypothesized that men with microarchitectural abnormalities would have higher rates of complications. Pre-operative skeletal imaging included areal BMD by DXA, volumetric BMD (vBMD) and microarchitecture of the distal radius and tibia by high resolution peripheral QCT (HRpQCT, Xtreme CT2). Cox hazard models were used to identify the best predictors of post-operative complications among clinical indices (age, alcohol, smoking, BMI, # of vertebrae involved in surgery) and imaging measurements. Of 54 men enrolled mean age was 61 (range 25-82 yrs), and BMI 29 kg/m2. Mean Z-Scores by DXA were within or above normal at the spine (1.9), total hip (0.1), femoral neck (0.1), and 1/3 radius (0.1). Six men (11%) reported a history of atraumatic fracture. None reported use of medications for osteoporosis. Median post-operative follow-up was 12 months. Twenty-one men (39%) sustained skeletal complications. Cortical vBMD at the tibia predicted time to skeletal complication (HR 0.72, 95% CI 0.53-0.98; Figure). No other HRpQCT feature independently predicted risk of complications, nor did aBMD by DXA at any site. Our data suggests that despite normal appearing DXA, older men undergoing spinal fusion surgery have high rates of complications, and cortical deficits are associated with complication risk. As cortical bone is the site of insertion of surgical hardware, men with low cortical vBMD may lack adequate bone to provide early stability to hardware necessary for de novo bone formation and successful fusion to occur. Additional studies are needed to better elucidate the specific risk factors for complications and therapeutic strategies to improve bone quality in men.

Background: Fibroblast growth factor 23 (FGF23) has a crucial role in phosphate homeostasis. However, other factors play a role in the regulation of this hormone (e.g. anemia, inflammation, and iron status), even though the underlying mechanisms are not completely understood.Aim: To determine the behavior of FGF23 levels in a clinical condition of iron overload, i.e., hereditary hemochromatosis, following iron depletive treatment.Methods: We enrolled 26 consecutive patients with genetically confirmed hereditary hemochromatosis (HE), without organ damage (mean years +/-SD: 43.80+/-10.40) on maintenance therapy with phlebotomy every five months. They were evaluated at baseline and seven days after iron depletive treatment. Nineteen blood donors (mean age: 42.40+/-12.80) were also recruited as a control group (C). FGF23 was evaluated by both intact (DiaSorin, Stillwater, MN, USA) and C-terminal (Biomedica GmbH kit) assays.Results: We found no differences in mean values of intact FGF23 levels between the two groups neither at baseline (HE0: iFGF23 54.3+/-14.4 pg/mL vs C0: iFGF23 52.8+/-17.6 pg/mL) nor 7 days after phlebotomy (HE7: iFGF23 54.7+/-15.5 pg/mL vs C7: iFGF23 53.2+/-15.9 pg/mL). Mean basal C-terminal values were 7.4+/-3.0 pg/mL in HE vs 9.5+/-6.7 pg/mL in C. After 7 days, mean values were: HE 9.0+/-6.7 pg/mL NS vs basal values; C: 13.8+/-8.4 pg/mL, ($p < 0.014$ vs basal values). The ratio of Intact/C-terminal FGF23 was significantly reduced at 7 days in C (8.2+/-5.8 vs 5.3+/-3.7, $p < 0.017$) but unchanged in HE (8.7+/-5.3 vs 8.7+/-4.8) There we no changes in mean values of serum phosphate at 7 days in respect to basal values.Conclusion: Our data suggest that in normal subjects preservation of phosphate homeostasis is maintained by increased cleavage of intact FGF23. Other mechanisms seem to be responsible in patients with primary HE on long-term iron depletive treatment. Alternatively, an earlier peak of C-terminal FGF23 was not captured at 7 days post-phlebectomy.

The Use of Adjusted Calcium in Alberta: A Population-Based Study *Noémie Desgagnés[1], James A. King[2], Gregory A. Kline[3], Isolde Seiden-Long[4], Alexander A. Leung[5, 1] Department of Medicine, University of Calgary, Calgary, Alberta, Canada. , Canada. [2]Data and Research Services , Alberta Strategy for Patient Oriented Research Provincial Research Data Services, Alberta Health Services, Canada. [3]Division of Endocrinology and Metabolism, Department of Medicine, University of Calgary, Calgary, Alberta, Canada. , Canada. [4]Alberta Precision Laboratories and Department of Pathology and Laboratory Medicine, University of Calgary Foothills Medical Centre, Calgary, Alberta Canada, Canada. [5]Division of Endocrinology and Metabolism, Department of Medicine, University of Calgary, Calgary, Alberta, Canada. ,Department of Community Health Sciences, University of Calgary, Calgary, AB, Canada. , Canada

Background: Adjustment of total calcium is commonly performed in clinical settings in order to account for states of altered protein-binding. However, studies have shown that albumin-adjusted calcium correlates poorly with ionized calcium, and yet remains a common practice. Therefore, we aimed to describe the epidemiology of calcium measurements in the province of Alberta by evaluating the correlation between adjusted calcium and total calcium against contemporaneously measured ionized calcium as a reference standard.Methods: We assembled a population-based cohort of all adults who were tested for serum total calcium and ionized calcium within a 24-hour interval in Alberta between January 1, 2013, to October 31, 2019. When available, we extracted data for serum albumin, serum creatinine, and pH, as these variables may be incorporated into calcium adjustment formulas. We then analyzed the correlation between total calcium and adjusted calcium using the Payne (total calcium (mg/100mL) - albumin (g/100mL) + 4), Payne simplified (total calcium (mmol/L) + 0.02 [40 - albumin (g/L)]), and six other formulas against ionized calcium. Overall agreement for each pair of comparisons was assessed with correlation coefficients and linear regression methods. Furthermore, we determined the frequency of serum total calcium, ionized calcium, and albumin that were measured within 24 hours to estimate ordering pattern of serum calcium. Results: A total of 74 971 patients had total calcium and ionized calcium sampled within 24 hours, among whom 52 469 individuals also had a coinciding serum albumin measurement. Unadjusted total calcium correlated modestly with ionized calcium ($R2=51.1\%$) as well as all correction formulas ($R2=40.2$-$66.\%$). The simplified Payne formula, which is the most used method in clinical practice, performed similarly to total calcium ($R2=50.9\%$), while the original Payne formula had a weaker correlation ($R2=44.8\%$) (see Table). In the same study period, we identified 7,356,939 tests for total calcium amongst which the majority (56.5 %, N=4,156,248) also had an albumin result within 24-hour interval.Conclusion: Most total calcium tests were ordered within 24-hours of a serum albumin suggesting that albumin-adjusted calcium is still commonly used in clinical practice, however, our preliminary data showed that total calcium correlates similarly to most adjustment formulas with ionized calcium, including the commonly used simplified Payne formula.

Table. Correlation between ionized calcium and other adjusted calcium formulas

Comparison	Formulas	First per patient	
		N	R^2 (95% CI)
Total calcium		74 971	51.1% (50.6, 51.5)*
Payne	total calcium (mg/100mL)[a] – albumin (g/100mL)[b] + 4	52 469	44.8% (44.2, 45.3)*
Simplified	total calcium (mmol/L) + 0.02 [40 – albumin (g/L)]	52 469	50.9% (50.3, 51.4)*
Orrell	total calcium (mmol/L) +0.0177 [34 – albumin (g/L)]	52 469	53.0% (52.5, 53.5)*
Berry	total calcium (mmol/L) +0.0225 [46 – albumin (g/L)]	52 469	48.0% (47.5, 48.5)*
Thode	total calcium (mmol/L) x [2.7 / (1.7 + (albumin (g/L) / 42 (g/L)]	52 469	48.5% (47.9, 49.0)*
James	total Ca (mmol/L) +0.012 [39.9 – albumin (g/L)]	52 469	56.1% (55.6, 56.6)*
Antonio (A)	0.815 x total calcium$^{0.5}$ (mmol/L)	74 971	49.0% (48.6, 49.5)*
Antonio (B)	0.826 x total calcium$^{0.5}$ (mmol/L) – 0.023 x renal function (RF) where RF is: • normal function (eGFR > 60 ml/min/1.73m^2) = 0 • moderate dysfunction (eGFR 30-59ml/min/1.73m^2) = 1 • severe dysfunction (eGFR<30 ml/min/1.73m^2) = 2	8768	66.4% (65.4, 67.3)*
Antonio (C)	0.813 x total calcium$^{0.5}$(mmol/L) – 0.006 x Alb$^{0.75}$ (g/L) + 0.079	52 469	54.0% (53.5, 54.5)*
Pekar	adjusted calcium (mmol/L) = 2.567 – 2.045e -3[albumin (g/L)] – 5.601e - 4 [creatinine (mg/L)] +0.4493[total calcium (mmol/L)] – 0.307[pH]	46 824	40.2% (39.6, 40.8)*

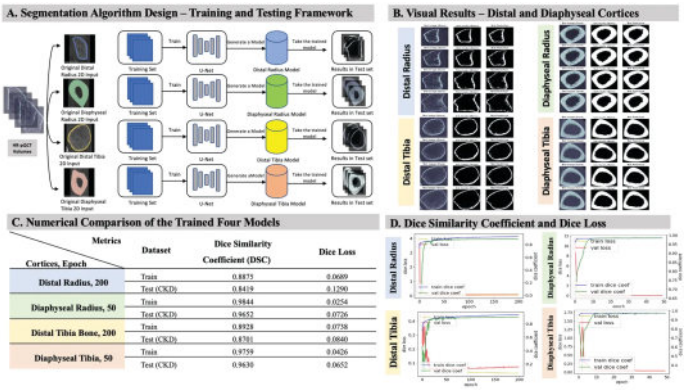
Automated Segmentation Scheme to Evaluate CKD Patient Bone HR-pQCT images using a Trained Deep Learning Model *YoungJun Lee[1], Minwoo Park[2], Sangjun Park[3], Stuart Warden[4], RACHEL SUROWIEC[5]. [1]Purdue University, [2]Department of Laboratory Medicine, St. Vincen'ts Hospital, The Catholic University of Korea, Republic of Korea, [3]Department of Radiation Therapy, Samsung Medical Center, The Sungkyunkwan University of Korea, Republic of Korea, [4]Indiana University School of Health & Human Sciences, United States, [5]Indiana University Purdue University,

Chronic kidney disease (CKD) predominately affects cortical bone resulting in trabecularization of the endocortical surface and cortical porosity development. High-resolution peripheral quantitative computed tomography (HR-pQCT) is a noninvasive imaging modality that can assess bone microarchitecture, making it particularly attractive in CKD. However, CKD's hallmark bone phenotype complicates available segmentation methods required for accurate and reproducible separation of trabecular and cortical bone. Thus, we present a deep-learning model trained with normal volunteers to evaluate skeletal abnormalities associated with CKD via HR-pQCT. HR-pQCT (XtremeCT II, SCANCO) volumes of distal and diaphyseal cortices (radius and tibia) from 3 healthy volunteers (F, 52 +/- 0.70 yrs) and one CKD patient (F, 39 yrs) were used for training and testing, respectively. Ground truth masks were segmented and produced using 3D slicer and computed using Google-Colab. The model was trained by U-Net architecture and tested for CKD patients. For evaluation metrics, we utilized the dice similarity coefficient and dice loss to compare and assess the bone density of healthy volunteers vs. CKD. The training sets for the four deep learning models -distal and diaphyseal radial and tibial cortices - had dice loss values of 0.0689, 0.0254, 0.0738, and 0.0426, respectively; thus, all models were used for the binary cross-entropy loss function, of which it took 5 to 20 minutes to train with 504 HR-pQCT images for 50 and 200 cycles, and the model inference for 169 test set images took an average of 3 and 5 seconds, respectively. Test set (CKD) model performance was excellent for dice similarity coefficients- 0.8419, 0.9652, 0.8701, and 0.9630, respectively and had low dice loss values- 0.1290, 0.0726, 0.0840, and 0.0652. Overall, the diaphyseal cortical models (radius, tibia) required lower iterations and outperformed distal cortical models. Finally, several results from the trained models visually outperformed the ground truth masks and did not overestimate the manually segmented masks.Findings indicate automated segmentation of CKD patient bone using the presented deep learning approach could improve the precision and reproducibility of HR-pQCT outcomes and could be particularly valuable for application in diseases marked by severe microarchitectural changes to the cortices and trabecularization of endosteal surfaces. Ongoing work will improve distal cortices models through varying hyperparameters and apply the model to scans from CKD patients across stages (1-5).



Cortices, Epoch	Dataset	Dice Similarity Coefficient (DSC)	Dice Loss
Distal Radius, 200	Train	0.8875	0.0689
	Test (CKD)	0.8419	0.1290
Diaphyseal Radius, 50	Train	0.9844	0.0254
	Test (CKD)	0.9652	0.0726
Distal Tibia Bone, 200	Train	0.8928	0.0738
	Test (CKD)	0.8701	0.0840
Diaphyseal Tibia, 50	Train	0.9759	0.0426
	Test (CKD)	0.9630	0.0652

A. Each cortical bones' deep learning model – distal and diaphyseal radius & tibia – was trained based on U-Net architecture 50 and 200 iterations with 3 normal volunteers and then tested with 1 CKD patient, respectively. All ground-truth masks in the training sets were manually segmented by a specialized medical researcher. Each result produced by each model was compared with evaluation metrics. B. Representative results – orderly and evenly extracted from the upper to the lower - of CKD patient tested by using the trained deep learning. The first column is the HR-pQCT image from the CKD patient, the middle column is the ground truth mask using the 3D slicer segmentation tool, and the third column is the predicted mask generated by our trained deep learning model. C. Dice similarity coefficient and dice loss values from our four models and (D) corresponding plots. All reported low values of the dice loss result from the Binary CrossEntropy loss function. Values of dice similarity vary depending on hyperparameters such as epoch, optimizer, batch size, etc. Although data is presented on a small sample, the diagnostic performance of this algorithm was high. Overall, the diaphyseal cortices models (radius and tibia) perform very well, with model inference scores of 0.9652 and 0.9630, respectively, and required a low epoch (50).

SAT-008

Difference of fat compositions in lumbar vertebral bone marrow according to age and relation to bone mineral density *Yuji Kasukawa[1], Michio Hongo[1], Koji Nozaka[1], Hiroyuki Tsuchie[1], Daisuke Kudo[1], Hayato Kinoshita[1], Ryota Kimura[1], Yuichi Ono[1], Kento Okamoto[1], Naohisa Miyakoshi[1]. [1]Akita University Graduate School of Medicine, Japan

Purpose: The proton density fat fraction (PDFF) by the Iterative Decomposition of water and fat with Echo Asymmetry and Least-squares estimation-iron quantification (IDEAL-IQ) method of magnetic resonance imaging (MRI) can quantitatively measure the amount of fat in the vertebral body. Although intravertebral fatty change may be a risk factor for fracture, it has not been investigated whether the PDFF in lumbar vertebrae varies with age or is related to bone mineral density (BMD). In this study, we investigated the relationship between (1) age-related differences in PDFF in lumbar vertebrae and (2) BMD and bone metabolic markers.Methods: (1) Age difference in PDFF: Thirty patients (18 males and 12 females), aged 14 to 87 years (median 63 years), whose PDFF was measured in the lumbar spine by the sagittal images of IDEAL-IQ method of MRI were included in this study. We compared PDFF in the trabecular bone region of the L4 vertebral body between 62 years of age or younger and 64 years of age or older, divided by a median age of 63 years. (2) Association of PDFF with BMD and bone metabolic markers: Forty-six women aged 60 years or older with PDFF measured on lumbar spine with MRI sagittal images, and measured BMD as well as bone metabolic markers within six months before and after MRI imaging were included. Intra-vertebral PDFF was evaluated by the mean value of intra-vertebral PDFF at L1 or L3 to L5 (LS PDFF or L3-5 PDFF). BMD of lumbar spine and femur were measured by dual energy x-ray absorptiometry, and bone metabolism markers were measured by serum propeptide of type I procollagen (P1NP) and tartrate-resistant acid phosphatase-5b (TRACP-5b). The association with PDFF and BMD or bone metabolic markers were evaluated by Pearson correlation coefficient.Results: (1) Intra-vertebral L4 PDFF (%) was significantly higher in patients aged 64 years or older at 62.1 than in those aged 62 years or younger at 53.6 ($p < 0.05$). Both LS PDFF and L3-5 PDFF were not significantly correlated with BMD of lumbar spine and femur, nor were serum P1NP and TRACP-5b.Conclusion: Fat mass measured with PDFF in the vertebral body of L4 increased significantly with increasing age, but there was no significant association between PDFF of lumbar spine and BMD of lumbar spine or femur in women over 60 years of age, nor with bone metabolism markers.

Comparative effectiveness of therapeutic interventions for pregnancy and lactation-associated osteoporosis: a systematic review and meta-analysis *PANAGIOTIS ANAGNOSTIS[1], KALLIOPI Lampropoulou-Adamidou[2], JULIA BOSDOU[1], GEORGE TROVAS[2], EFSTATHIOS CHRONOPOULOS[2], DIMITRIOS GOULIS[1], SYMEON TOURNIS[2]. [1]Unit of Reproductive Endocrinology, 1st Department of Obstetrics and Gynecology, Medical School, Aristotle University of Thessaloniki, Greece, [2]Laboratory for the Research of Musculoskeletal System "Th. Garofalidis", School of Medicine, National and Kapodistrian University of Athens, KAT General Hospital, Athens, , Greece

Objective: Pregnancy and lactation-associated osteoporosis (PLO) is a rare disease, which significantly affects quality of life. However, the optimal management of this entity has not yet been designated. The aim of this study was to systematically investigate and meta-analyze the best available evidence regarding the effect of different therapeutic interventions on bone mineral density (BMD) in these patients.Methods: A comprehensive search was conducted in PubMed and Scopus databases up to December 20th, 2022. Data were expressed as weighted mean difference (WMD) with 95% confidence intervals (CI). The I2 index was employed for heterogeneity.Results: Initial search provided 5503 results after excluding duplicates, 65 of which were included in the qualitative analysis (40 case-reports, 17 case-series and eight cohort studies), yielding a total of number of 454 women with PLO (follow-up time range: 6-264 months; age range: 19-42 years). The vast majority of fractures (89.2%) occurred during lactation and involved the thoracolumbar spine (number range: 1-12). Non-vertebral fractures were reported in 17 patients (3%).Calcium plus vitamin D (CaD) increased lumbar spine (LS) BMD by 2-7.5%, 9.6%, 11-12.2% and 41.8% at 12, 18, 24 and 36 months, respectively (FN BMD increase: 6.1% at 18 m). Bisphosphonates increased LS BMD by 5-36.3%, 10.2-171.9% and 20-38.9% at 12, 24 and 36 months, respectively, and FN BMD by 3.4-71.6%, 0.7-18% and 3.3% at 12, 24 and 36 months, respectively. Teriparatide increased LS BMD by 8-24.4%, 7.4-36%, 24.1-32.9% and 23.4-30.3% at 12, 18, 24 and 36 months, respectively, and FN BMD by 3.9-12.6%, 3.7-13.8%, 8.4-18.6% and 10-16.3% at 12, 18, 24 and 36 months, respectively. Denosumab increased LS BMD by 14-21.2% and 32%, and FN BMD by 0-5.6% and 13%, at 12 and 18 months, respectively New fractures occurred in 66 (14.5%) patients (six in subsequent pregnancies).Meta-analysis was performed only for two retrospective studies with teriparatide, which also included a control group. Teriparatide induced a greater increase in both LS and FN BMD, compared with CaD [11.45% (95% CI 4.89-18.01%, p=0.001; I2 50.9%) and 5.43% (95% CI 1.24-9.62%, p=0.011; I2 8.1%), respectively].Conclusions: Despite the high heterogeneity among studies, pharmaceutical intervention, mainly with teriparatide, exerts a more beneficial effect on BMD than CaD in women with PLO.

Mitigation of proximal junctional kyphosis with post to preoperative vertebral loading comparison using biomechanical analysis *Fatemeh Alavi[1], Chistopher Nielsen[1], Stephen Lewis[1], Raja Rampersaud[1], Angela Cheung[2]. [1]University Health Network (UHN), Canada. [2]University Health Network-University of Toronto, Canada

Proximal junctional kyphosis (PJK) remains one of the most common mechanical complications of adult spinal deformity (ASD) surgery. Interventions proposed to limit the rate of PJK include tethering, cementing upper instrumented vertebra (UIV) and/or UIV +1, as well as changing sagittal alignment parameters, which are still debated in ASD. We hypothesized that excessive post- to preoperative vertebral loading at proximal junction is associated with PJK development. In this retrospective study, eighteen consecutive patients (7 PJK and 11 non-PJK) with scoliosis who underwent fusion surgery from T10 to the sacrum were included. Individualized musculoskeletal models were created from pre and immediate post-operative EOS images. Then, vertebral loading including shear and compressive forces were calculated. Finally, pre and postoperative vertebral loading at UIV and UIV+1 were compared. To consider the influence of bone mineral density on PJK development, finite element (FE) analysis under the postoperative loading was performed to identify fracture location for PJK patients. In this study, we define shear difference as the difference between shear forces on the bottom and top surfaces of UIV or UIV+1. The difference in bone mass index and the average of post to preoperative compressive loading ratio between PJK and non-PJK groups were not significant. However, 85% of PJK patients experience more postoperative anterior-posterior shear loading at UIV+1 or UIV compared to their preoperative alignments (|ratio_(Post-Pre) |>1) and the ratios for 63% of non-PJK patients are less than 1. While, on average postoperative shear difference at UIV or UIV+1 for PJK group is 96 N more than preoperative shear difference, this difference for non-PJK patients with (|ratio|>1) is 31.3 N and for non-PJK patients with (|ratio|<1) is -92.9 N. The results illustrate the effect of excessive postoperative shear loading on PJK development. As shown in figure 1, we found a good agreement between FE-based predicted and actual postoperative fracture locations. Post to preoperative comparison of vertebral loading at UIV and/or UIV+1 is introduced as an effective measure to identify the risk of PJK development. Utilizing a developed framework to calculate vertebral loading based on pre and postoperative EOS images, provides the opportunity to select individualized postoperative targets to design an alignment with vertebral loading less than preoperative one and elucidates the way to mitigate PJK.

Differential Effects of Diabetes and Sodium-Glucose Co-Transporter 2 Inhibitors on Skeletal Microstructure *Sanchita Agarwal[1], Keity Okazaki[2], Ananya Kondapalli[1], Carmen Germosen[1], Ivelisse Colon[1], Nayoung Kil[1], Isabella Rosillo[1], Mariana Bucovsky[1], Marcella Walker[1]. [1]Division of Endocrinology, Department of Medicine, Columbia University, United States. [2]Department of Medicine, Columbia University Irving Medical Center, New York Presbyterian, United States

Type 2 diabetes (T2DM) is characterized by a 3-fold increased risk of fracture. The pathophysiology of skeletal fragility is unclear. Areal bone mineral density (aBMD) by DXA is normal or elevated in T2DM. Sodium-glucose co-transporter 2 (SGLT2) inhibitors may further increase fracture risk. We studied bone health in adults >= age 65 from a multi-ethnic population-based study in New York City using DXA, High Resolution peripheral Quantitative Computed Tomography (HRpQCT), and Trabecular Bone Score (TBS) in 565 women (mean age 77+/-6 yrs; 31% Black, 26% White, 42% mixed race; 55% Hispanic). Compared to non-diabetics, women with T2DM (n=175) were more likely to be mixed race, Hispanic, immigrants, and have lower education and income. Compared to non-diabetics, women with T2DM had lower alcohol use, menopause age and physical activity, had higher BMI, and were less likely to use proton pump inhibitors. All models were adjusted for covariates. T-scores by DXA were higher at all sites (all p<0.05) in T2DM, while TBS did not differ. Using HRpQCT, T2DM had higher trabecular (Tb) density and microstructure with 6% higher failure load (FL; all p<0.05) at the radius. At the distal tibia, cortical (Ct) density was 2% lower and porosity was 10% higher in T2DM, but more favorable Tb indices led to 5% higher FL. Using individual trabecula segmentation (ITS), T2DM had 6% more Tb plates and 7% more rods at the radius only. Higher glycosylated hemoglobin (9%) was not associated with worse microstructure. Among T2DM, aBMD at the hip, femoral neck, and 1/3-radius was 7%, 6% and 5% lower respectively in those with (n=72) versus those without fractures (all p<0.05). TBS was 4% lower (p=0.04) in the fracture group. By HRpQCT, T2DM with fractures had 8% lower total and 4% lower Ct density, 8% lower Ct thickness, and 13% lower FL at the radius. Similar differences were seen at the tibia with lower plate, but higher rod volume (all p<0.01). SGLT2 inhibitor use (n=19) was associated with 18-34% higher Tb heterogeneity at the radius and tibia respectively and 3% lower radial rod tissue mineral density (all p<0.05). In summary, T2DM negatively affects the bone cortex. Those with T2DM and fractures have more severe cortical deficits than those without fractures. In contrast, SGLT2 inhibitors use is associated with trabecular deficits, including poor trabecular connectivity and mineralization. Further work is needed to understand the pathophysiology by which SGLT2 inhibitors may affect bone metabolism.

Table: Differences in demographics, DXA, TBS, and HR-pQCT in type 2 diabetes (T2DM) vs controls. Data is presented as Mean ± SD. Statistical significance tested by student's t-test or chi-square test.

The Role of AGEs in Bone Fragility Associated with Type 2 Diabetes and Chronic Kidney Disease *Daniel Dapaah[1], Shoutaro Arakawa[2], Mitsuru Saito[2], Thomas Willett[1]. [1]University of Waterloo, Canada. [2]Jikei University School of Medicine, Japan

Type-2 diabetes (T2D) patients often present with normal to high BMD [1]. Elevated advanced glycation end products (AGEs) in T2D and chronic kidney disease (CKD) has been proposed as an alternate reason for increased fracture risk [1,2]. AGEs are widely thought to inhibit collagen network ductility [3]. However, beyond pentosidine measured ex vivo, there have been limited comprehensive measurements of AGE accumulation in human cortical bone. Hence, in this study, a variety of AGEs (adducts and crosslinks) and the lysyl oxidase (LOX) catalyzed crosslinks were measured in human cortical bone from donors with and without a history of T2D and/or CKD. Relationships with the state of the collagen and the cortical bone fracture toughness were explored.Single edge notched bend (SENB) specimens were prepared from 57 cadaveric human femora. Twenty-two of the donors had T2D and/or CKD. Each specimen underwent a 3-point bend fracture test from which fracture toughness measures (JIc, J-int) were determined. After fracture, de-mineralized (EDTA) por-

tions were used in mass spectrometry [4] to measure AGEs (carboxy-methyl-lysine (CML), carboxy-ethyl-lysine (CEL), 5-hydro-5-methyl-4-imidazolon-2-yl-ornithine 1 (MG-H1) and pentosidine (PEN)), as well as mature and immature LOX crosslinks. The state of the collagen was measured using differential scanning calorimetry. Differences between the donor groups (+/-T2D/CKD) were tested using Student's t-test. Pearson's correlations were generated between AGEs, LOX crosslinks, collagen network properties and fracture toughness measures.AGE contents were 30 to 80% higher in the T2D/CKD group. There were negative correlations between HLNL, an immature LOX crosslink, and all AGEs as well as between collagen's enthalpy of denaturation and all AGEs (Table 1). No significant relationships were detected between the AGE contents and the fracture toughness measures. However, HLNL and enthalpy of denaturation correlated positively with J-int, a measure of the J-integral fracture toughness at the point of crack instability. These results suggest an indirect pathway by which AGEs may negatively affect fracture resistance in cortical bone through disruption of the collagen network by obstructing immature crosslinking, specifically HLNL, and reducing the energetic cost of collagen denaturation. In turn, this may lead to reduced fracture resistance because collagen molecules mechanically denature during bone fracture [5].

Table 1: Pearson's correlations between AGEs, LOX immature crosslink HLNL, enthalpy of denaturation of the collagen, and two cortical bone fracture toughness measures (ns stands for not significant).

Pearson's correlation	J_{IC}	J-int	HLNL	Enthalpy of denaturation
CML	ns	ns	r= -0.61, p<0.001	r= -0.33, p=0.011
CEL	ns	ns	r= -0.70, p<0.001	r= -0.37, p<0.01

SAT-016

Alendronate Treatment in Fatigue-Damaged Bone Exacerbates Deleterious Effects of Microdamage on Bone Material Properties *Niovi Dollas[1] Lukasz Witek[2] Abigail Coffman[1] Mitchell Schaffler[1] [1]The City College of New York, United States [2]New York University, United States

PURPOSE: Bone microcracks (?Crks) and bisphosphonates are implicated in atypical femoral fractures, though the nature of their interaction is not well understood[1]. Previous canine studies found altered material properties after long-term alendronate (ALN) use[2]. However, canine cortical bone remodels extensively, so separating biomechanical effects of inhibiting remodeling (which increases material stiffness) from deleterious effects of ?Crks has proven challenging. To address this, we examined bone material property changes that occur in fatigue-damaged bone with ALN treatment in a model that has no baseline intracortical remodeling[3].METHODS: Diaphyseal sections were obtained from a previous study of osteocyte changes and ?Crks after long-term ALN in fatigued rat ulnar cortex[4]. Briefly, ?Crks were induced by fatigue loading of ulnar diaphyses of young-adult female Sprague Dawley rats (n=16). Material property changes were assessed in sections from fatigued-Baseline ulnae (FAT-B, no survival), fatigued-Survival rats treated with ALN for 4 months (FAT-S+ALN), and non-loaded control (NoFAT) ulnae. Nanoindentation was used to measure elastic modulus at varying distances around microcracks and equivalent regions in control tissues. Tissue modulus (ET) was calculated as mean for all indents/bone. Individual indent moduli (Ei) were also examined as a function of distance from a ?Crk.RESULTS: ET in FAT-B was reduced moderately (~20%) vs NoFAT-B bone (Fig 1). In FAT-B bone, modulus loss was localized around ?Crks (~5 ?m), beyond which Ei were similar to control (Fig 2). ET of FAT-S+ALN bone was further reduced, >40% vs controls, but this trend was not significant (p<0.1) due to limited number of available samples. Furthermore, modulus loss around ?Crks was greater in magnitude and extended further into the tissue than was observed for baseline ?Crks (Fig 2).DISCUSSION: The current studies suggest that ALN use in fatigue-damaged bone has a marked, negative effect on local tissue material properties-greater than acute fatigue ?Crks alone. How ALN exacerbated loss of material properties remains obscure. Potential mechanisms include additional matrix damage that occurs when the initial ?Crks cannot be remodeled, and osteocyte effects such as localized osteocyte death and regulatory changes in the remaining osteocytes near ?Crks that affect matrix integrity[5].REFERENCES: 1)Starr+ 2018; 2)Allen+ 2006; 3)Bentolila+ 1998; 4) Coffman+ 2021; 5)Kaya+ 2017

A Systematic Review and Meta-Analysis of the Effect of Tea, Tea Polyphenols and Tea Extracts on Bone Outcomes in Rodent Models *Rebekah S. Feld[1] Michael D. McAlpine[1] Jenalyn L. Yumol[1] Russell J. de Souza[2] Wendy E. Ward[1] [1]Brock University, Canada [2]McMaster University, Canada

Tea and its polyphenols are potential modulators of bone metabolism through anti-inflammatory or antioxidant activity. The objective of this systematic review was to determine the effect of Camellia sinensis provided as whole tea or an extract on measures of bone health in rodent models. A systematic search of Medline and 4 other databases from inception through July 8, 2021, identified 2548 studies. Of the 37 studies that met the inclusion criteria, 73% investigated green tea or extract (27/37), 16% investigated black tea or extract (6/37), and the remaining 11% included other teas or extract including white and pu-erh. The quality of each study was analyzed using both the Systematic Review Center for Laboratory Animal Experimentation (SYRCLE) risk of bias tool and the Animal Research: Reporting of In Vivo Experiments (ARRIVE) Essential 10 and Recommended Set. A random-effects meta-analysis was conducted for intervention studies in intact rats consuming a green tea extract. Pooled standardized mean differences (SMD) and corresponding 95% confidence intervals (CI) were used for areal bone mineral density (aBMD), bone volume fraction (BV/TV) and cortical thickness (Ct.Th). Analysis was performed separately at each bone site investigated (femur, tibia) and heterogeneity ($I2 > 50$) was explored for sex-specific effects. Compared to the control group, rats consuming green tea extract demonstrated greater aBMD at the femur (n = 80 rats [60 F, 20 M], SMD = 1.00, 95% CI [0.53, 1.48], $I2 = 0\%$, $P < 0.0001$). Overall, BV/TV was greater for green tea extract compared to the control intervention (overall: n = 114 rats [80 F, 34 M], SMD = 0.64, 95% CI [0.16, 1.11], $I2 = 34\%$, $P = 0.009$; femur: n = 54 rats, SMD = 0.50, 95% CI [-0.27, 1.28], $I2 = 48\%$, $P = 0.20$; tibia: n = 60 rats, SMD = 0.76, 95% CI [0.06, 1.46], $I2 = 41\%$, $P = 0.03$) but not Ct.Th (femur: n = 34 rats [20 F, 14 M], SMD = 0.61, 95% CI [-0.81, 2.03], $I2 = 74\%$, $P = 0.40$). Only the effect of tea on Ct.Th differed by sex ($P = 0.048$). One study in males (14 M) reported no significant effect, whereas the study in females (20 F) reported a positive effect. Findings from this study suggest green tea extract may support bone mineral metabolism and bone quality.

A Comparison of Bone Surface Speckle Pattern Preparation on Digital Image Correlation Efficacy *Beatriz Garcia[2] Kevin Hoffseth[2] [2]Louisiana State University, [2]Louisiana State University, United States

Purpose: This study investigates use of bone's natural microstructure in conjunction with traditional methods of speckle pattern application for digital image correlation (DIC) to determine if it can be used to improve deformation measurement during mechanical loading. Bone has a natural random and nonuniform pattern due to its microstructures[1]. Current research using DIC as a method of determining strain in cortical bones during load relies on traditional speckling methods such as paint[2]. However, overlaying a speckle pattern on a specimen results in a loss of visualization of fracture and the influence of microstructure as it propagates through the material.Methods: DIC is commonly used to measure displacements and strain of materials under mechanical loading, with growing biomedical application. Here we implement DIC with DICe software with a random nonuniform speckle pattern applied on the surface of beams under 3-point loading while recording deformation using an Edgertronic SC2+ camera at 200 FPS to provide full-field[3] values of strain and displacement of the tested specimen(s) in the speckled zone. Beams were sectioned out of bovine cortical bone and polished at a high grit to flatten the surface and minimize surface roughness. The surface of the bone specimens was prepared using traditional speckling methods as well as histological dyes, to enhance microstructure of bone.Results: Preliminary results from testing may be seen in Figure 1, which shows a comparison between traditional speckle preparation (Fig 1 A-B) and toluidine blue dyed bone (Fig 1 C-D). The microstructure of the bone is

visible in the dyed samples, but the DIC software is unable to detect as many subsets due to low contrast between the dyed and undyed areas of the bone. This problem may be remedied by manipulating the image to enhance contrast and improve visibility of microstructural features of the bone (Fig 1 E-F).Conclusions: Dyeing of bone shows promises in DIC analysis by enhancing the natural features of bone as a speckle-like pattern. More research is needed during fundamental loading configurations, for example 3-point bending conditions, to compare the accuracy of DIC results with different speckling methods.References: [1] Rho, J.; et al., Med Eng Phys 1997, 20. Distal Radius Fracture Healing: A 12-month Follow-up Using HR-pQCT and Finite Element Analysis *Ifaz Haider[1], Phillip Spanswick[1], Erin Davison[1], Robert Korley[1], Paul Duffy[1], Ryan Martin[1], Andrew Dodd[1], Steven Boyd[1], Prism Schneider[1]. [1]University of Calgary, Canada

Introduction: Distal radius fractures (DRFs) are commonly treated non-operatively with closed reduction and cast immobilization. Insufficient or overly long immobilization durations are associated with poor outcomes, but no guidelines exist for optimal immobilization duration. Finite element (FE) modeling based on high-resolution peripheral computed tomography (HR-pQCT) may help study healing after DRF. We previously documented stiffness recovery up to six months after injury and now aim to investigate changes in FE-predicted bone stiffness over 12 months in patients with DRF.Method: This is a prospective cohort of consecutive adult patients with DRF amenable to treatment with cast immobilization. HR-pQCT scans of bilateral distal radii were taken at baseline, and the injured limb was scanned 2-,4-,6-,8-,12-,26-, and 52-weeks post-fracture (68 kVP, 1.47 mA, 61 µm nominal isotropic voxel size). An FE model of 8-noded hexahedral elements was generated via voxel conversion, with bone tissue modelled as a homogeneous solid (Modulus = 8748 MPa). To characterize stiffness, the distal surface was fully constrained while both compressive or rotational displacement was applied to the proximal end. Using the baseline uninjured distal radius as reference, we computed percent difference in stiffness of the injured limb at each timepoint; one-sided t-tests were used to determine if a non-zero percent difference in stiffness was detected.Results: A total of 57 patients (50.5 yrs +/- 16.0 yrs, 46 females) are being followed. Preliminary results from the first 20 patients (51.2 yrs +/- 16.0 yrs) to complete their 52-week scan are presented here. Compared to the uninjured limb, we observed lower compressive (-12.5%, 95%CI: -20.1 to -5.0%; p = 0.002) and torsional (-14.7%, 95%CI: -22.5 to -6.8%; p = 0.0006) stiffness at week two. Stiffness increased progressively over the 52-week follow-up period up to +16.1% for compression (95%CI: 4.9 to 27.4%; p = 0.007) and +14.2% for torsion (95%CI: 4.1 to 24.4%; p = 0.008) (Figure 1).Discussion: Fractured distal radius stiffness was low at baseline and increased progressively. At 52 weeks, the injured limb demonstrated greater stiffness than the uninjured limb. Stiffness was typically restored between 12 and 28 weeks, but substantial variability between individuals was observed; follow-up to understand the source of variability is ongoing. Assessment via HR-pQCT-based FE shows promise to personalize cast removal timing decisions.

SAT-020

Region-specific Equivalent Densities for Phantomless Internal Reference Calibration *Zac Haverfield[3], Amanda Agnew[2], Lauren Hayden[3], RANDEE HUNTER[4]. [3]The Ohio State University, . [2]The Ohio State University, United States. [3]The Ohio State University, United States. [4]SKELETAL BIOLOGY RESEARCH LABORATORY, United States

Assessments of volumetric BMD (vBMD) are often quantified using phantom based (PB) or phantomless (PL) Hounsfield Unit (HU) calibration methods. While PB calibration methods are standard, phantom rods may not be available in opportunistic screening scenarios. Retrospective PL quantification of vBMD can be conducted using internal reference tissues (e.g., fat and muscle) and air for HU calibration. However, the equivalent densities (EqDen) of these media are inconsistently reported and may vary across skeletal sites. Therefore, the purpose of this study is to identify differences in EqDen of air, fat, and muscle between skeletal sites that may influence PL calibration methods.Whole-body clinical CT scans of n=100 male post-mortem human subjects (PMHS) (24-102 years of age) were analyzed. Consistent acquisition parameters of 120 or 140kVp and a reference 250mA were used for each scan that included INTableTM phantom rods. For each PMHS, skeletal site-specific volumes of interests (VOI) for air, fat, and muscle were created to obtain HU from slices associated with the left humerus, radius, femur, tibia, and calcaneus and the 2-4th lumbar vertebra regions. Using site-specific PB calibration, the EqDen of each air, fat, and muscle VOI was calculated. Kruskal-Wallis multiple comparisons tests demonstrated significant site-specific differences in air, fat, and muscle HU ($p<0.001$) and EqDen ($p<0.001$). Differences in air EqDen and HU were largely found between sites from the trunk of the body compared to the extremities. This may result from differential x-ray attenuation at denser body regions that influences calculations. Variation in fat and muscle EqDen and HU were observed across skeletal regions with the largest difference between the humerus (Hum-50) and the distal tibia (Tib-4). In addition to x-ray attenuation, these differences are also likely associated with local physiologic and mechanical loading environments.The use of PL calibration methods to quantify vBMD may provide a unique retrospective approach towards clinical assessments of bone quality. However, results from this study indicate that PL methods that use air, fat, and muscle are subject to the influence of x-ray attenuation and heterogenous fat and muscle densities. As these variations may influence resulting vBMD values, using site-specific PL calibration methods is recommended to provide more accurate assessments of bone quality and fracture risk.

Effects of An In Vitro Oxidative Damage Model on the Tensile Mechanical Properties of Cortical Bone *Faezeh Iranmanesh[1], Jindra Tupy[2], John Montesano[2], THOMAS WILLETT[3]. [1]University of waterloo, . [2]University of Waterloo, Canada. [3],

Bone is a complex tissue composed of mineral and organic components [1][2]. Collagen, the major bone protein, contributes to bone yield and post-yield mechanical properties [3]-[7]. Aging and disease can affect bone collagen structure and function [6]. Oxidative stress results from excessive reactive oxygen species produced by the body [8], and is a

major contributor to numerous diseases and age-related disorders [9]. It can damage collagen and compromise bone health [10][11]. Little is known about the effects of physiological levels of oxidative damage on bone mechanical properties. In this study, we are testing the hypothesis that in vitro oxidative damage deteriorates the tensile mechanical properties of cortical bone.Oxidative damage was induced in bovine cortical bone in vitro to assess its effects on bone tensile mechanical properties. Longitudinally-oriented tensile test specimens were cut from three bovine tibiae using a mini-CNC mill. The specimens were oxidized using neutral hypocholorous acid (HClO) solution (5% Acetic acid (HOAc), 5% Sodium Hypochlorite (NaClO). HClO is a strong and stable oxidant produced by osteoclasts and other cells in bone biology and inflammation. Two groups (n=3) were incubated for 48 and 96 hours at 37°C. Two control groups (n=3) were also prepared (submerged in PBS at 37 °C or at room temperature). Uniaxial tensile tests were conducted (?TS, Psylotech, IL, USA) while strain was measured using digital image correlation. One-way ANOVA was used to detect statistically significant differences in group means.Representative stress-strain curves for the four groups are shown in the figure below. These graphs show that the yield and post-yield tensile properties of cortical bone in the longitudinal direction decrease with increasing exposure to the oxidant solution. Yield and ultimate strengths, and ultimate strain, were all strongly and negatively related to incubation time (R^2>0.8,p<0.005). As expected, because damage of the bone mineral is not expected, correlation between the elastic modulus and oxidation time was not significant (p=0.146). One-way ANOVA detected differences among group means (p<0.008). These findings a) support our hypothesis that in vitro oxidative damage deteriorates bone mechanical properties, due to bone collagen damage, and b) suggest a new model for understanding degradation of bone quality in aging and chronic diseases.

Tailoring the Mechanical Microenvironment to Enhance Osteogenesis in Bone Tissue Engineering Scaffolds *Timothy Josephson[2,] ELISE MORGAN[2,] [2]Boston University, , [2]Boston University, United States

Skeletal cells are influenced by a variety of stimuli in their microenvironments. Two of these stimuli, surface curvature and strain, have been identified as particularly influential, for example in migration and osteogenic differentiation of marrow stromal cells (MSCs) [1-3]. Methods of delivering optimal levels of these stimuli in 3D physiological environments, such as bone injuries, are lacking. Biomaterial scaffolds are candidates for treating these injuries; further, by tuning the internal architecture of the scaffold, one can control the types and magnitudes of the stimuli delivered to the cells. Prior work on optimizing scaffold architecture has been limited by both the types of stimuli considered and the size of the design space. To overcome these limitations, we used a topology optimization approach that seeks to maximize the amount of osteogenically favorable microenvironments within the scaffold architecture.Scoring functions were developed based on published data on the influence of local cues-specifically curvature [1,3,4] and shear strain [2]-on osteogenesis. The individual scoring functions were combined multiplicatively to create a composite local score for each region within the scaffold, and the fitness of the entire scaffold was evaluated by taking an area-weighted sum of local scores. Mixed-topology scaffolds were then generated by taking weighted sums of the mathematical definitions of a set of triply periodic minimal surfaces (TPMS) architectures: primitive, gyroid, and diamond. A gradient-free optimization method was used to identify optimal scaffold designs. Different optimization cases targeted different stimuli (curvature, strain, and both), with and without constraints on the macroscale stiffness of the scaffold.Each optimization case yielded a design that improved the scaffold fitness relative to the baseline design, which was an even mix of the three TPMSs. The final design obtained by jointly optimizing for curvature and strain had a nearly 5-fold increase in fitness score over the baseline design and also outperformed all of the original three TMPS structures. These results demonstrate the potential of mixed-topology TPMS designs to achieve optimal architectures with both micro- and macroscale considerations.[1] Werner et al., Adv. Sci. 2017.[2] Prendergast et al., J Biomech. 1997.[3] Callens et al., Nat. Commun. 2023.[4] Swanson et al., Int. J. Mol. Sci. 2022.

Methodology to Analyze Stress Distribution in Long Bones using Computer-Aided Design *Kyung Kang[1, 1]Marian University, United States

Mechanical stress is an important factor to affect mechanosensing, bone-regulating osteocytes, especially in load-bearing long bones. Since signals released from osteycytes control neighboring bone-forming and bone-resorbing activities, region-specific mechanical stress is considered a key contributor to local bone remodeling. Traditional mechanical tests, such as a three-point bending, compression, and torsion, are common methods to measure macro mechanical properties, however, such tests do not provide spatial stress distribution in bones. Computer simulation has been utilized to predict the stress, while many of such research articles did not sufficiently demonstrate region-specific data with various loading cases. Therefore, we propose to use widely-used Computer-Aided Design (CAD) engineering software to estimate spatial stress distribution in long bones under various loading conditions. This research summarizes how CAD software (Fusion 360, AutoDesk) can visualize stress distribution inside a long bone under various loadings. First, a series of micro-CT DICOM scans of a mouse tibia was converted into a single STL file using 3D Slicer (open-source software). Then, the STL file was imported into Fusion 360 and converted into a meshed (solid) model. We ran static stress analysis on this solid tibia model under axial compression, torsion, and bending forces. For the static stress analysis, users can define materials property, constraints (where to fix) and loading conditions, such as types, directions, and magnitudes of loadings. The computation results demonstrate that Fusion 360 provides not only the estimated stress, but also the displacement (deformation) as well as safety factors in the entire tibia model. The stress can be visualized on any desired cross-section that is defined by users in a three-dimensional axis. These quantified results are difficult to directly compare with the macro mechanical properties from the traditional testing methods, due to the assumptions used in the computation. However, this technique provides sufficient information on relative spatial changes in stress under a given loading condition. Therefore, this will be a useful tool to identify the regional stress distribution inside bones under different loadings and/or genetic conditions, which will potentially give us an insight into stress region-specific behavior of osteocytes.

SAT-024

Determinants of juvenile trabecular bone quality *MARIANA KERSH[1,] Annette McCoy[1,] Sara Moshage[1, 1]University of Illinois at Urbana-Champaign, United States

Adult bone quality is influenced by mechanical loading during ontogeny and can also be negatively impacted by juvenile bone disorders or injury. Understanding the determinants of mechanical properties will help to provide bone quality targets for both the diagnosis of impaired bone strength and interventions designed to improve bone quality in young individuals. Bone samples were harvested from foals (age: 4 - 48 weeks) euthanized for reasons unrelated to this study. Longitudinal trabecular cores from the third metacarpal (MC3, n=85) and proximal phalanx (P1, n=49) were imaged with micro-computed tomography (µCT) at 144µm prior to compression testing. The µCT data was used to measure bone mineral density, bone volume fraction (BVTV), trabecular thickness (Tb.Th), trabecular spacing, degree of anisotropy (DA), and connectivity density. Mechanical properties quantified included elastic modulus, yield stress and strain, and ultimate stress and strain.P1 mineral density was 14% higher and connectivity density was 51% higher than the MC3 (Fig F,K). In contrast, DA was 15% higher in the MC3 (Fig J). There was no difference in the elastic moduli; however, yield and ultimate stress were 26% and 24% higher in the P1 (Fig B,C), ultimate strain was 6% higher. Mineral density was the strongest predictor of mechanical properties - in particular in the P1 (r2 = 0.81, Fig L) compared to the MC3 (r2 = 0.62, Fig M). Mineral density tended to increase with age but with more variability in the MC3. In general, the distal segments (e.g. P1) mature first in foals - likely because they are ambulatory from birth. However, the growth plates of the P1 and MC3 close at the same time suggesting that modeling occurs over a similar amount of time. Our data suggests that the rates of mineralization may be different. Curiously, Tb.Th was more strongly correlated to mechanical properties in the P1 (r2 = 0.55) compared to the MC3 (r2=0.31) despite the fact that there were no statistical differences in Tb.Th though may be explained by the moderate

increase in range of Tb.Th values in the P1. While both the P1 and MC3 are considered long bones, the mechanical environment that influences bone formation are likely different due to overall shape differences and mechanisms of load transfer during equine locomotion. Our data shed light into the interplay between compositional and microstructural determinants of bone strength.

SAT-025

A preliminary study on the effect of intramedullary pressure on bone resorption: Effects of hypertension on osteoporosis *Taekyeong Lee[1], Jaemin Kim[2], Soonmoon Jung[2], Youngho Lee[2], Hyeyeong Song[2], Yeeun Kang[2], Junghwa Hong[2]. [1]BNR R&D Center, Republic of Korea. [2]Korea University, Republic of Korea

Recently, it has been found that hypertension, one of the representative chronic diseases, greatly increases the risk of not only cardiovascular diseases but also osteoporosis(L Do Carmo et al, 2020). In addition, it has been found that bone loss in young mice with hypertension is associated with increased inflammation(EM Hennen et al, 2022), and increased inflammation affects bone density and strength(UA Gurkan, O Akkus, 2008).In other words, the hypothesis that an increase of intramedullary pressure in bone tissue interferes with bone metabolism for stable nutrient supply and waste discharge in bone tissue, resulting in a decrease in bone mass due to the expression of inflammatory proteins is accepted. However, these studies are only the results of statistical analysis or that the results of antihypertensive drugs administration affect bone loss, and there is no research result that direct pressure increase has an effect on bone loss(N Yarema et al, 2020; H Nakagami, RMorishita, 2013; K llic et al, 2013; X Hu et al, 2019; Z Hu et al, 2021).In this study, the intramedullary pressure of the bone fluid flow in the bone marrow space was increased and the cytokine were analyzed.After inserting the specimen(fabricated and processing a 5-10 mm specimen from the left/right femur of NZW Rabbit) into a tightly fitting chamber using the bone on a chip device manufactured in the previous study, a controlled medium was injected for 2 weeks. For the injection fluid pressure, 3.3 kPa was used as the control group, and 6.6 kPa, which is twice the pressure, as the experiment group, referring to the intramedullary pressure of rabbit femur through literature review, and experiments were conducted three times each(UA Gurkan, O Akkus, 2008). Bone formation/resorption analysis(ELISA) were performed though cytokine analyses of output medium.As a result of the experiment, the Rankl/Opg ratio of the experimental group to which 2 times the pressure was applied was about 1.8 times higher than that of the control group. BMP-2 and OCN were expressed relatively low in the experimental group, and CTX and COX-2 were expressed relatively high in the experimental group compared to the control group, confirming that they were affected by bone resorption, not bone formation. These results show that excessive intramedullary pressure greatly affects bone loss, suggesting that high blood pressure may increase the incidence of bone loss and osteoporosis.

Are Enzymatic Collagen Cross-links the Real Culprit in Fracture Occurence in Type 1 Diabetes Patients? *Eleftherios Paschalis[1], Laura Graeff-Armas[2], Sonja Gamsjaeger[3], Sue Bare[4], Robert Recker[5], Mohammed Akhter[6]. [1]Ludwig Boltzmann Institute for Osteology, Austria. [2]University of Nebraska Medical Center , United States. [3]Ludwig Boltzmann Institute of Osteology, Austria. [4]Osteoporosis Research Center, Creighton University, United States. [5]Creighton University, United States. [6]Creighton University Osteoporosis Research Center, United States

Increased fracture risk in type 1 diabetes (T1D) patients is not fully captured by bone mineral density outcomes, leading to the hypothesis that alterations in bone quality (material & structural properties) are responsible. Advanced glycation endproducts (AGEs) have been implicated in the increased fracture risk in T1D, yet recent publications [1, 2] question whether this is associative or causative.To test the hypothesis that enzymatic collagen cross-links rather than AGEs correlate with fracture incidence in T1D, we analyzed iliac crest biopsies from sex-matched, 5 fracturing T1D patients (T1D Fx; median age, BMI, and HbA1c values: 38, 27.1, 8.1, respectively), 6 nonfracturing T1D patients (T1D NoFx; median age, BMI, and HbA1c values:38, 24.4, 7.1, respectively), and 6 healthy subjects (HC; median age, BMI, and HbA1c values: 37, 24.2, 5.2, respectively), by Raman microspectroscopy as a function of tissue age (based on double fluorescent labels), in trabecular bone. Both T1D groups had significantly higher ($p<0.05$) HbA1c values compared to HC.The pyridinoline (Pyd; enzymatic collagen cross-link), as well as the content of two AGEs, namely CML (?-N-Carboxymethyl-L-lysine) and PEN (Pentosidine) were calculated. Data were compared by 2-way ANOVA against HC.Results are shown in Figure below. Mean and SEM are plotted as a function of tissue age (TA1 = mid-distance between the second fluorescent label and the mineralizing front; TA2 = mid-distance between the two labels; TA3 = 2 µm behind the first label), whereas the included table summarizes the mean and SD values for the three groups when all tissue ages are averaged. There were no differences between the 3 groups in either CML or PEN content. Pyd content was elevated in the T1D Fx group compared to either HC or T1D NoFx ($p<0.001$ and $p<0.001$, respectively) ones, while no differences were evident between HC and T1D NoFx.Collagen fibers with high Pyd content are more brittle. Thus, a plausible suggestion is that it is the enzymatic collagen cross-links that either by themselves or in combination with the adverse effects of increased AGEs accumulation, that result in fragility fracture in T1D.[1] M. Unal, et al, Effect of ribose incubation on physical, chemical, and mechanical properties of human cortical bone, J Mech Behav Biomed Mater 140 (2023) 105731.[2] T.L. Willett, et al, Causative or associative: A critical review of the role of advanced glycation end-products in bone fragility, Bone 163 (2022) 116485.

SAT-028

Sex- and Site-Specific Reference Data for Size-Invariant Bone Properties using Multi-Stack HR-pQCT *Simone Poncioni[1], Dominique Lüscher[1], Daniela Frauchiger[2], Michael Indermaur[1], Christian Meier[3], Philippe Zysset[1], Kurt Lippuner[2]. [1]ARTORG Centre for Biomedical Engineering Research, University of Bern, Switzerland. [2]Department of Osteoporosis, Bern University Hospital, University of Bern, Switzerland. [3]Div. of Endocrinology, Diabetes and Metabolism, University Hospital Basel, Switzerland

Reference data for bone architecture in adults were recently reported for ~10 mm distal bone sections scanned by second generation HR-pQCT [1]. To overcome the limitations of this small section size for follow-up, a multi-stack scan protocol followed by a non-linear, homogenised finite element (hFE) analysis to compute bone strength was developed and validated in our lab [2]. Here, we aimed to collect reference data with this new protocol and identify key size-independent structural and strength parameters to optimise the continuous assessment of bone health in radius and tibia. Data from 4 clinical studies conducted at the Policlinic for Osteoporosis of the University Hospital in Bern were combined. 276 healthy participants (157 M & 119 F, age 20-92) underwent double- and triple-stack scans at the distal radius and tibia, respectively, using HR-pQCT (XtremeCT II, SCANCO Medical) as described in [2]. Following standard structural evaluation, hFE was performed according to [3]. Exploratory statistical analysis stratified for sex and anatomical site was conducted. Six key size-independent variables were selected: total and cortical volumetric bone density (Tot.vBMD, Ct.vBMD), relative cortical thickness (Rel Ct.Th), cortical to trabecular area ratio (Ct./Tb.Ar), trabecular bone volume over total volume (Tb.BV/TV), and apparent ultimate stress (Ult.S). Baseline values and corresponding coefficients of variation (CV) were calculated for participants aged 37 years. T-scores were plotted in equally distributed age

groups (50, 63, 76, 89 years, Fig. 1). A minimal CV of 2% was found for Ct.vBMD. For the radius, Ult.S decreased by 1.13% and 0.88% per year in females and males respectively. For the tibia, these changes were 0.80% and 0.82%. All T-scores decreased in both females and males, with the highest change in females' Ct.vBMD: -0.16 SD and -0.08 SD per year at the tibia and radius, respectively. Ct.vBMD of the weight-bearing tibia, which includes cortical porosities at all scales, is the most sensitive variable with age. To conclude, the proposed set of size-independent variables provides a synthetic overview of distal bone health for practical follow-up in a clinical setting.References: [1] Whittier et al. In Vitro Vitamin B Treatment Reduces Formation of the Non-Enzymatic Crosslink Pentosidine in Human Cortical Bone *Christian L. Ray[1], Ramina Behzad[1], Zackery J. Silva[1], Lamya Karim[1]. [1]University of Massachusetts Dartmouth, United States

Diabetic patients are at an elevated risk of bone fractures, which may be due to having poor bone quality. Accumulation of non-enzymatic crosslinks known as advanced glycation end-products (AGEs) in bone has been suggested as one source of poor bone quality. It has been shown that Vitamin B6 (VitB) may prevent AGE formation in other tissues by inhibiting glycation reactions [1]. Our goal was to test its effects in human bone in vitro, and we hypothesized that VitB treatment will decrease fluorescent AGEs (fAGE) and the specific fAGE pentosidine (PEN), with a consequent improvement in bone mechanical properties.Sixty cortical beams (2x2x30 mm) were acquired from the midshaft of female human cadaveric tibias (young/old, diabetic/non-diabetic). Tissue mineral density (Ct.TMD) and porosity (Ct.Po) was assessed by microCT, and then beams were randomly distributed into 5 groups: Control, Ribose (R), R + 50 mM VitB, R + 75 mM VitB, and R + 100 mM VitB. They were incubated for 14 days at 37°C in solutions [2], with Ribose and VitB groups containing 0.6 M ribose and respective concentrations of VitB. 6 mm segments of the beams were mechanically tested by cyclic Reference Point Indentation (cRPI), and then hydrolyzed to extracted bone collagen. Extracts were assessed for fAGEs by a fluorometric assay and PEN by high-performance liquid chromatography (HPLC).There was no difference in Ct.TMD, Ct.Po, or cRPI properties between groups. Total fAGEs were higher in ribose vs vehicle specimens (+99%, p<=0.05), but no differences were detected between ribose and VitB groups. PEN was greater in ribose (+53%, p <=0.001) and R + 50 mM VitB (+47%, p <= 0.01) groups vs vehicles, and lower in R + VitB 100 mM group vs ribose group (-25%, p<=0.05) (Figure).There was increased glycation in the ribose group than in vehicles, indicating a successful induction of in vitro AGEs. fAGE measurement is a broad indicator of glycation that does not consider individual crosslinks. Our measurement of PEN, a single fAGE, showed that treatment of cortical bone with the highest dose of vitB reduced glycation. However, there was no change in cRPI measures, suggesting the decrease in glycation may not directly impact tissue-level mechanical properties. Other mechanical properties such as fracture toughness need to be assessed to further evaluate the impact of vitB on bone mechanical behavior.References: [1] Mascolo and Verni, Int J Mol Sci, 2020; [2] Merlo, et al., J Orthop Res, 2020

SAT-031

The Relationship between Bone Strain Index (BSI), Bone Mass, Microarchitecture and Mechanical Behavior in Human Vertebrae: an Ex Vivo Study *Jean-Paul Roux[1], Francois Duboeuf[1], Elisabeth Sornay-Rendu[1], Luca Rinaudo[2], Fabio Massimo Ulivieri[3], Julien Wegrzyn[4], Roland Chapurlat[1]. [1]INSERM UMR 1033, University of Lyon, Lyon, France., France. [2]Tecnologie Avanzate Srl, Torino, Italy., Italy [3]Casa di Cura la Madonnina, Milano, Italy., Italy [4]Department of Orthopedic Surgery, Lausanne University Hospital and University of Lausanne, Switzerland., Switzerland

The measurement of areal bone mineral density (aBMD) does not completely identify future fracture because there is an overlap of BMD in patients with or without fractures. DXA-based bone indexes were developed to improve the predictive role of BMD in clinical practice. The first was the trabecular bone score (TBS), a texture parameter evaluating local variations in gray level from DXA image of the lumbar spine to estimate bone microarchitecture. Bone Strain Index (BSI) is a new DXA-based bone index which represents the finite element analysis of the bone deformation under load. The current study aimed to assess whether the BSI is associated with 3D microarchitecture and the mechanical behavior of human lumbar vertebrae.Lumbar vertebrae (L3) were harvested fresh from 31 human donors (16 men, and 15 women, age: 76 +/- 10 yrs for men and 75 +/- 10 yrs for women). The anteroposterior BMC (g) and aBMD (g/cm2) of the vertebral body were measured using DXA (Delphi W, Hologic) and then the BSI was automatically derived with a dedicated external software from the same area. The trabecular bone volume (Tb.BV/TV), trabecular thickness (Tb.Th), degree of anisotropy (DA), and structure model index (SMI) were measured using µCT with a 35-µm isotropic voxel size (Skyscan 1076). Quasi-static uniaxial compressive testing was performed on L3 vertebral bodies under displacement control (0.5mm/min) to assess failure load (N) and stiffness (N/mm). TBS was extracted in a subset of 16 vertebrae. The BSI was significantly correlated (Pearson correlation) with failure load and stiffness (r=-0.60, -0.59; p<0.0001), aBMD and BMC (r=-0.93, -0.86; p<0.0001); Tb.BV/TV and SMI (r=-0.58, 0.51; p=0.001 and 0.004 respectively). No significant correlation was found between BSI and TBS. After adjustment for aBMD, the association between BSI and stiffness, BSI and SMI remained significant (r=-0.51; p=0.004 and r=-0.39; p=0.03 respectively, partial correlations) and the relation between BSI and failure load was close to significance (r=-0.35; p=0.06).In conclusion, the BSI was significantly correlated with microarchitecture

and mechanical behavior of L3 vertebrae and these associations remained statistically significant regardless of aBMD.

SAT-032

Establishment Of Normative Curves of Specific Microarchitecture and Bone Resistance Per Age Group and Sex Obtained By Second Generation of High-Resolution Peripheral Quantitative Computed Tomography (HR-pQCT II) In Healthy Brazilians *RODRIGO SANTOS[1], Isabela Silva[2], Edson Campos[2], Gabriela Vieira[2], Leonardo Bandeira[3], MONIQUE OHE[4], Sergio Maeda[2], MARISE LAZARETTI-CASTRO[5]. [1]Federal University of Sao Paulo, , [2]Federal University of São Paulo, Brazil. [3]Department of Endocrinology, Federal University of São Paulo, UNIFESP, Brazil, Brazil. [4]UNIFESP-EPM, Brazil. [5]Escola Paulista de Medicina, Brazil

HR-pQCT provides quantitative 3D parameters of microarchitecture and volumetric density (vBMD) from cortical (Ct.) and trabecular bone (Tb.). An upgrade of this device brought greater accuracy to the measurements but requires the definition of specific normal curves. The existence of a high degree of miscegenation, particular lifestyles, and climate make the Brazilian population unique, which further increases the need for specific normative curves for all parameters obtained from HRpQCT II. Purpose: To develop reference curves for Brazilian healthy adults grouped by age and sex of different parameters, such as microarchitecture, vBMD, and bone strength, of distal radius and tibia. Methods: 500 healthy individuals without osteoporosis from the community aged from 20 to 80 years old will be included. Non-dominant radius and tibia are scanned using HR-pQCT (XTremeCT II; Scanco, Switzerland). The standard segmentation methods are used to verify the bone parameters. Virtual bone stiffness (St) is evaluated by finite element analysis (St). Participants undergo densitometry by DXA to obtain areal BMD and total body composition. A questionary is applied to verify health history and self-reported race. The data will be described as median and quartile. Regression models will be developed according to age, biometrics variables, and lifestyles. Some parameters of interest will be associated with the Person correlations coefficient. Results: Currently, 215 volunteers have been evaluated (145 females; 70 males). An initial analysis showed that Total vBMD peaked at close to 30 years of age. Radius'Ct.Po increased by 100% in females from the third to sixth decades ($p<0.0001$). An inverse correlation was observed in the female group between age and Ct.vBMD (Fig. E) and positively with Ct. Po (Fig. C). Age correlated with Ct.Po diameter and Tb.inhomogeneity ($p=0.0006$) in males. When all individuals were analyzed in the same group, age had a significant inverse correlation with Tt.vBMD and St in both limbs (Figure). Conclusion: In healthy Brazilians, volumetric bone density peaks during the 3rd decade of life. Aging is associated with the deterioration of structural parameters and bone stiffness. Among the measures, cortical porosity increased significantly in the age group above 60. Establishing normative curves using the HR-pQCT II will be an essential database for future Brazilian studies, clinical applications, and comparative studies between different populations.

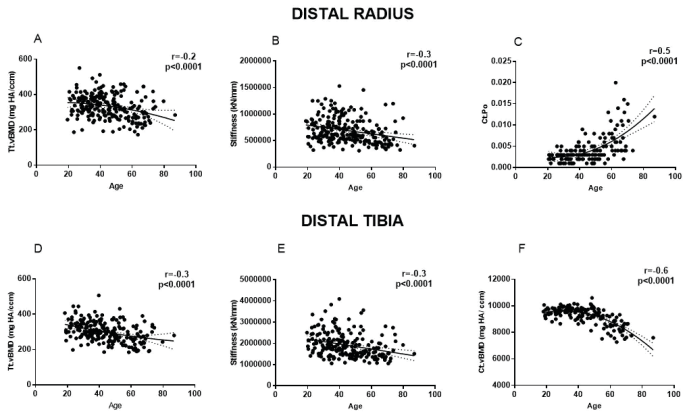

Figure 1. Abbreviations: mg HA/ccm: milligrams of hydroxyapatite per cubic centimeter; Volumetric bone mineral density, vBMD; Stiffness: Whole bone stiffness; kN/mm: Kilonewton millimeter. A) Person' correlations and Reference curves, according to age, of the parameters of vBMD, Stiffiness, and cortical porosity being (A,D) total volumetric density (Tt.vBMD) and (B, E) Stiffness of all volunteers; (C) Cortical Porosity (Ct.Po) and (F) cortical volumetric density (Ct.vBMD) of females, obtained by HR-pQCT II in the non-dominant distal radius and tibia in healthy subjects. The solid line represents the mean from the regression model, and the dashed lines represent the 95% confidence interval.

SAT-033

Collagen Denaturation Correlates With Human Cortical Bone Fracture Resistance *Corin Seelemann[1], Daniel Dapaah[1], THOMAS WILLETT[2]. [1]University of Waterloo, , [2],

Bone tissue, primarily composed of hydroxyapatite, collagen, and water, has a multi-scale structure which provides toughening mechanisms to resist fracture. Recent research has examined the relationship between collagen state and fracture resistance of cortical bone [1]. The underlying mechanisms could be vital to understanding bone fragility. Previously, we have shown in bovine cortical bone that collagen denatures during fracture. The extent of denaturation on the fracture surfaces correlated with the work to fracture [2] Here we test the hypothesis that collagen denatures because of fracture in human cortical bone, and the extent of denaturation positively correlated with the work to fracture.Five single edge notched beams from human femurs, each from a different donor (aged 19-61), were fractured under 3-point bending. The beams (2.5 mm x 5 mm x 50 mm) were fractured with the crack propagating circumferentially on the transverse plane. The R curve, a measure of fracture toughness, was calculated for each specimen, then integrated to compute the work needed to grow the crack by approximately 250 µm. This excludes large deflections, which complicate the analysis. The fracture surfaces and a negative control were cut from each specimen using a metallurgical saw. These were surface decalcified (EDTA), stained with fluorescently labelled collagen hybridizing peptides (F-CHP) and imaged using laser scanning confocal microscopy. Each negative control was polished to remove damage from preparation and was used to establish a threshold level for intrinsic denaturation. The threshold was set to exclude 99.95% of the stained pixels in the control and was applied to the fracture surface images to visualize denaturation. The percentage of pixels above that threshold within the first 250 µm of crack growth was used to measure the extent of collagen denaturation.Human bone collagen consistently denatured because of fracture. Every specimen demonstrated increased staining in the region analyzed. Collagen denaturation correlated to work done (R2 = 0.87), as shown in figure. This corroborates with our past work in bovine cortical bone [2]. One limitation of this study is that the collagen denaturation could not be analyzed over a larger range of crack growth due to large crack defections.[1]T. L. Willett, D. Y. Dapaah, S. Uppuganti, M. Granke, J. S. Nyman, Bone 2019, 120, 187.[2]C. A. Seelemann, T. L. Willett, J Mech Behav Biomed Mater 2022, 131, 105220.

Automated Detection of Bone Marrow Lesions in Acute ACL Tears using MRI *Callie Stirling[3], Nathan Neeteson[3], Richard Walker[2], Steven Boyd[3]. [3]University of Calgary, , [2]Department of Radiology, Cumming School of Medicine, University of Calgary, Canada. [3]University of Calgary, Canada

Bone marrow lesions (BMLs) represent tissue damage and bleeding within the inner bone structure following a traumatic anterior cruciate ligament (ACL) injury. BMLs are typically caused by a collision of the tibia and the femur and are indicative of significant joint damage, associated with an elevated risk of developing post-traumatic osteoarthritis (PTOA) [1]. Magnetic resonance imaging (MRI) is useful for detecting BMLs qualitatively, but quantitative assessment may be helpful to determine risk factors for PTOA. Quantitative assessment includes measuring the volume and distribution of BMLs over time. However, manual segmentation of BMLs can be time-consuming. Deep learning methods have been shown to accurately segment regions of interest, giving clinicians crucial data for diagnosis, prognosis, and treatment [2-5].This study aims to develop a model that accurately locates, segments, and measures BMLs in patients with ACL injuries using knee MRI scans performed within 6 weeks of injury. To enhance the generalization ability of the model, pre-processing steps such as intensity normalization, bias field correction, and data augmentation techniques were employed on fat-suppressed fast spin echo T2-weighted MRI images. The model was initially trained on a labelled dataset. Any discrepancies in the resulting segmentation were corrected, and the newly labelled data was integrated into the training set. The re-segmented images were then used to retrain the model. The iterative training approach allowed the model to learn from its mistakes and improve its accuracy.To assess the performance of the final segmentation model, a four-fold cross-validation method was used, and the Dice similarity coefficient (DSC) was calculated between the ground truth and predicted segmentations. The initial iteration of the model yielded a DSC of 0.78, indicating good agreement between the manual and predicted segmentations. Continued iterative training aims at achieving a DSC greater than 0.85. By identifying and quantifying BMLs through

automated detection and segmentation, clinicians and researchers can more accurately estimate the severity of ACL injuries and track bone changes over time. BMLs are also a potential imaging biomarker to identify patients at elevated risk of PTOA.1 Keil, Experimental Orthopaedics, 20222 Dang, BRO Neuroscience Reports, 20223 Paing, Entropy, 20224 Ronneberger, Springer International, 20155 Mauer, Int J Legal Med, 2021

SAT-035

The Effect of Chemically Induced Diabetes on Bone Architecture Changes Across Bone Length *Carlos Urrego[1], Morgan Bolger[1], David Kohn[2]. [1]University of Michigan, Ann Arbor Dept. of Biomedical Engineering, United States. [2]University of Michigan, United States

Type 1 diabetes (T1D) decreases bone quality and increases fracture risk. Conventional fracture risk assessment tools underdiagnose diabetic subjects due to the lack of understanding of the effects of T1D on bone quality. Moreover, bone quality changes spatially in healthy bone, but the spatial effects of T1D are unknown. The purpose of this study is to evaluate how T1D affects bone architecture along the length and within the cross-section of the femur using a mouse model of chemically induced diabetes, to determine the spatial effect of T1D on bone architecture. Femoral proximal metaphysis, diaphysis, and distal metaphysis of 22 weeks-old Streptozotocin-induced diabetic male mice (n=12) were evaluated. Micro-Computed Tomography was used to evaluate bone mineral density (BMD), bone volume (BV), bone fraction (BV/TV), cross-sectional moments of inertia and rotation of the principal axis (?). No significant effect of diabetes was found in trabecular bone, whereas cortical bone exhibited changes in all regions evaluated. Diabetic femoral distal metaphysis BV was significantly lower compared to age and weight-matched nondiabetic controls (p=0.0427). Diabetic diaphyseal BMD and BV/TV were significantly lower compared to control (p=0.0082 and p=0.0108 respectively). At the proximal metaphysis, BV, BMD, and BV/TV were significantly lower in diabetic samples compared to controls (p= 0.0198, p=0.0159 and p=0.002 respectively). While no changes were found in cross-sectional moments across bone length, ? increased significantly at the proximal metaphysis in the diabetic group compared to control (p=0.0328). T1D femora displayed increased distance from the centroid to the anterior surface at the proximal metaphysis (p=0.0341), decreased distance to the anterior surface at the distal metaphysis (p=0.0257) and decreased distance to the medial surface at the proximal metaphysis (p=0.0013) compared to control. The effect of diabetes on bone architecture increases from the distal end towards the proximal metaphysis, affecting only cortical tissue. The significant increase in the rotation of the principal axis may be a compensatory response to reduce the effect of architecture changes on bone strength. The strong location-dependent effect of T1D on bone suggests that standard femoral neck BMD may not represent the spatial effect of T1D on bone, and that additional properties and areas of interest should be considered.

Molecular-Level Porosity Differences in Osteogenesis Imperfecta Bone Revealed by Positron Annihilation Lifetime Spectroscopy (PALS) Imaging *Richard Vallery[1], David Gidley[2], Taeyong Ahn[3], Mark Banaszak-Holl[4], Kenneth Kozloff[2]. [1]Grand Valley State University, United States. [2]University of Michigan, United States. [3]Indiana University School of Medicine, United States. [4]University of Alabama, United States

Bone is a complex hierarchical material composed primarily of collagen, mineral, and water. How bone quality, and thus fragility, is regulated at the level of the collagen fibril and mineral interface remains incompletely described. Positron annihilation lifetime spectroscopy (PALS) is a metrology that correlates the positron annihilation lifetime and intensity with nanoscale pore size and relative volume fraction respectively. We demonstrated that PALS is an effective probe of the nanoscale porosity in bone in multiple species, which all showed four distinct pore populations with sizes less than 10 nm. Here we have extended the technique to evaluate nanoscale porosity changes in models of altered collagen structure resulting in varying skeletal fragility.Femora from four 10 wk female heterozygous mouse models of osteogenesis imperfecta (OI) (n=3/genotype plus n=3 WT) were prepared. Brtl/+ and G610C/+ arise from Gly->Cys substitution in col1a1 and col1a2 respectively, resulting in moderate fragility. Jrt/+ arises from a premature splice site mutation in col1a1 (severe) while Mov13/+ is haploinsufficient for col1a1 (mild). Femora were harvested, lightly pulverized, and subject to PALS measurements in dehydrated conditions. Differences in OI mouse spectra were compared to corresponding WT (Figure).The average intra-collagen lifetime/pore size was conserved vs. WT among all mice, while the density of these voids was substantially reduced, suggesting reductions in collagen content. In the three larger pores, the lifetimes/ pore sizes indicate minor differences with WT but all present significantly higher density of pores, consistent with reduced collagen content. Moreover, three of the genotypes presented smaller voids at the collagen-mineral interface suggesting the mineral plate spacing is reduced- consistent with higher mineralization with OI. We have confirmed this reduced plate spacing for deproteinated male Brtl/+ samples. Finally we note that Jrt/+, which exhibits the greatest collagen molecular structural change and the most severe OI symptoms, also presented the most extreme differences in PALS lifetimes and intensities.By probing bone at the nanoscale level, we reveal novel measures of bone quality differences arising from collagen deficiency and structural mutation. Jrt/+ showed the greatest dysregulation of terminal collagen spacing and collagen-mineral interface, suggesting the importance of these features in contributing to bone fragility.

Accuracy of BMD measurement in weight bearing, cone-beam CT *Tadiwa Waungana[3,] Keven Qiu[2,] Justin Tse[3,] Donald Anderson[4,] Sarah Manske[3,] [3]University of Calgary, [,2]University of Waterloo, Canada[,3]University of Calgary, Canada[,4]University of Iowa, United States

PurposeKnee osteoarthritis (KOA) is a common, painful, and disabling joint disorder. Changes in BMD at the knee are associated with worsening clinical and radiographic outcomes, such as pain and structural progression of KOA. Weight-bearing, cone-beam CT (WBCT) allows cross-sectional, functional imaging of the knee for assessment of bone and joint structures but is challenged by artefacts that may compromise the accuracy and precision of BMD measures. Therefore, we compared BMD measurement accuracy between WBCT and multi-slice CT (MSCT) using a BMD calibration phantom. In addition, we sought to determine the dependence of BMD measurement on the presence of a participant to determine whether synchronous BMD calibration is feasible.MethodsWe scanned a BMD calibration phantom (QRM, Möhrendorf, Germany) including three hydroxyapatite cylindrical inserts of 100, 400 and 800 mgHA/cm3 with WBCT (HiRise, CurveBeam) and MSCT (Revolution GSI, GE). Two image acquisitions were completed with each scanner: 1) a phantom image (asynchronous calibration) and 2) a phantom + participant image (synchronous calibration). Within each BMD insert, we selected four regions of interest to facilitate BMD calibration and uniformity analysis. We used one sample t-tests and relative error measurements to compare measured BMD to true BMD, whilst paired t-test, regression and Bland-Altman analysis were used to compare measured BMD between scanners and calibration techniques.ResultsFor all CT scans, measured BMD values were significantly different from the true BMD value ($p < 0.001$; Fig. 1). Relative errors from true BMD were larger for WBCT (-16% to 8%) than for MSCT (-1.3% to 3%). Although the mean BMD measurements for synchronous WBCT images were closer to the true BMD, the standard deviations were 2.0% - 10.3% higher (w.r.t. true BMD) compared to asynchronous images. In contrast, MSCT scans were unaffected by the presence of a participant. Whilst regression analysis showed a high association between WBCT and MSCT measures (R2>0.99), Bland-Altman analysis suggested that WBCT and MSCT showed better agreement when BMD was measured asynchronously.ConclusionOur results suggest that WBCT BMD measures are more variable than MSCT measures. Furthermore, WBCT measures are more accurate when measured with a participant in the scan and may need to be calibrated at the height where BMD will be measured. Together, our data support the use of synchronous calibration for BMD measurement using WBCT.

A Systematic Review and Meta-Analysis of the Effect of Probiotics on Bone Outcomes in Rodent Models *Jenalyn L. Yumol[1,] William Gittings[1,] Russell J. de Souza[2,] Wendy E. Ward[1,] [1]Brock University, Canada[,2]McMaster University, Canada

Probiotics are live bacteria intended to produce a health benefit, one of which may include supporting a strong, healthy skeleton. The purpose of this systematic review was to determine if probiotic supplementation, compared to no supplementation, improves bone mineral density (BMD) and bone structure outcomes in rodent models. A systematic search of the literature using MEDLINE and Embase via OVID and CINAHL Complete was performed on August 27, 2021. Intervention studies (N = 51) examining the effect of oral consumption of any probiotic strain on BMD or bone structure in rodents were included. Risk of bias and quality assessment were performed using the Systematic Review Center for Laboratory Animal Experimentation risk of bias tool and the Animal Research: Reporting of In Vivo Experiments Guidelines, respectively. Meta-analyses were conducted separately by study model (ovariectomized, intact) and bone site (femur, tibia, spine) to determine the pooled standardized mean difference (SMD) between treatment and control groups for volumetric BMD (vBMD), bone volume fraction (BV/TV) and cortical thickness (Ct.Th) following supplementation. Heterogeneity was explored (probiotic genus, sex, mice versus rats). Using an ovariectomized model, probiotic supplementation resulted in greater vBMD at the femur (SMD = 1.35, 95% CI [0.92, 1.78], I2 = 25%, $P < 0.05$) and tibia (SMD = 1.88, 95% CI [0.89, 2.86], I2 = 59%, $P < 0.05$) but not at the spine (SMD = 1.29, 95% CI [-0.08, 2.66], I2 = 83%, P = 0.06) when compared to the control. At these sites, there was higher BV/TV (femur: SMD = 1.03, 95% CI [0.56, 1.50], I2 = 52%, $P < 0.05$; tibia: SMD = 2.66; 95% CI [0.93, 4.40], I2 = 86%, $P < 0.05$; spine: SMD = 1.92, 95% CI [0.77, 3.08], I2 = 82%, $P < 0.05$) and Ct.Th (femur: SMD = 0.57, 95% CI [0.17, 0.96], I2 = 0%, $P < 0.05$; tibia: SMD = 2.16; 95% CI [0.15, 4.18], I2 = 87%, $P < 0.05$) with the probiotic compared to the control. The effects were not modified by probiotic genera or rodent species. In intact rodents, probiotic supplementation increased vBMD at the femur (SMD = 0.61, 95% CI [0.20, 1.02], I2 = 12%, $P < 0.05$) without changes in bone structure (BV/TV: SMD = 0.33, 95% CI [-0.03, 0.68], I2 = 31%, P = 0.07; Ct.Th: SMD = 0.19, 95% CI [-0.20, 0.57], I2 = 9%, P = 0.32). In conclusion, probiotic use may be a beneficial strategy for improving bone outcomes in rodent models. However, high-quality studies are needed to define intervention dose and duration.

Correlation between lattice element (LE) and finite element (FE) methods in prediction of trabecular bone apparent elastic modulus *Mahsa Zojaji[1], Keyvan Ferasat[1], Roshni Rainbow[1], Heidi-Lynn Ploeg[1], Laurent Karim Béland[1]. [1]Dept. of Mechanical and Materials Engineering, Queen's University, Kingston, ON, Canada, Canada

Prediction of bone mechanical properties including apparent elastic modulus is commonly used in pre-clinical diagnosis of bone disorders such as osteoporosis and bone cancer. The objective of this study is to utilize lattice element method (LEM) implemented in an open-source package as an alternative method to finite element analysis (FEA). The LEM builds a discretized continuum solid using particles and springs. The spring constants are calculated by equalizing the total elastic energy from LEM and continuum mechanics. We proposed a new scheme for LEM-firm and floppy boundary method (FFLEM)-that is more cost- and time-efficient than the FEA. Fifteen trabecular bone cores were ?-CT scanned (20x20 microns), segmented, and surface mesh refinement were completed in 3-Matic (Materialise, version 16.0) before exporting to Abaqus/CAE (version 2017, Simulia, Johnston, RI, USA) for further mesh generation (quadratic tetrahedral with a max edge length size of 2.00 microns). FFLEM is a capable and reliable alternative to FEA to study elastic response of trabecular bones.

A Multimodal Analysis of Cement Lines in Human Osteonal Bone *Astrid Cantamessa[1], Stéphane Blouin[5], Shahrouz Amini[3], Maximilian Rummler[3], Andrea Berzlanovich[4], Richard Weinkamer[3], Markus A. Hartmann[5], Davide Ruffoni[6]. [1]University of Liège, , [5]Ludwig Boltzmann Institute of Osteology, Austria. [3]Max Planck Institute of Colloids and Interfaces, Germany. [4]Center of Forensics Medicine, Austria. [5]Ludwig Boltzmann Institute of Osteology, Germany. [6]University of Liege, Belgium

Cement lines (CLs) are thin layers separating secondary osteons from each other or from interstitial bone. Previous evidence suggests that CLs protect osteons by deflecting microcracks. However, their composition and structure still remain uncertain. In the present study, we characterize CLs mineral content and mechanical properties at the micrometer scale using cortical bone samples from 2 human femurs. We perform backscattered electron imaging, both quantitative (qBEI) and at higher resolution (hrBEI), to obtain 2D maps of mineral content and nanostructural features of 74 osteons. We manually segment CLs from their corresponding osteon, also considering concentric layers of bone (~1.1 ?m in width) adjacent to the CLs. We compare the mineral content of CLs to the mineral content of the inside and outside neighboring layers of their corresponding osteon. We also measure the reduced modulus (Er) and hardness across the CLs using nanoindentation (nIND) in 25 selected regions to correlate them with mineral content. At the micrometer scale, CLs appear 10 +/- 3.5% more mineralized than their corresponding osteon. The CL mineral content is quite heterogeneous but has a stronger spatial correlation with the mineral content of the layers outside rather than inside the osteon ($p < 0.01$). This may suggest an interplay between the CLs mineralization and the mineral content of the surrounding bone, which is locally recycled to build the new osteon [Roschger, Acta Bio 2020]. As illustrated with a specific region in Fig. 1, we exploit indentation maps to compute the average Er inside each CL, as well as within stiffer and more compliant lamellae (here 26.45 +/- 1.31 GPa, 22.98 +/- 2.71 GPa and 20.69 +/- 2.05 GPa, respectively) by analyzing the corresponding post-nIND hrBEI image. Overall, we highlight a periodic alternation of stiffer and softer regions ($p < 0.01$) corresponding to lamellae of different fibers orientations. Additionally, CLs are stiffer and harder ($p < 0.01$) than their corresponding osteon. This mechanical contrast between CLs and lamellar regions may be one additional factor for hampering cracks entering the osteons. Recent findings that CLs have reduced nanoscale porosity in comparison to adjacent lamellar bone could explain the measured higher mineral content and stiffness [Tang, JBMR 2023]. Ongoing work focuses on the mineral properties of CLs measured with X-ray scattering as well as on the interplay between CLs and the osteocyte lacuno-canalicular network.

Longitudinal Evaluation of Female Distal Radius Bone Properties Viewed through 3 Maturational Lenses: Implications for Adolescent Fracture Risk and Site-specific Peak Bone Mass *Jodi Dowthwaite[1], Stephanie Kliethermes[2], Tim Cole[3], Tamara Scerpella[4]. [1]SUNY Upstate Medical University; Binghamton University, United States. [2]University of Wisconsin - Madison, United States. [3]University College London, United Kingdom. [4]University of Wisconsin, United States

Purpose: Distal radius fracture risk is high in adolescence and senescence, and peak young adult bone values set baseline adult fracture risk. Adolescent fracture risk is high at peak height velocity (PHV), while menarche represents increased estrogen exposure, which modulates epiphyseal fusion and bone structure. To assess forearm bone accrual patterns in these contexts, we used 3 age clocks: standard chronological age, age relative to PHV, and age relative to menarche, to evaluate timing of peak growth velocities and peak young adult values for radius bone mass, geometry, and density, in US females with diverse organized physical activity and forearm mechanical loading exposures.Methods: We collected longitudinal data (1997-2023) via annual DXA scans for 1/3 and ultradistal (UD) radius bone mass (BMC, g), projected area (AREA, cm2), and areal bone mineral density (BMD, g/cm2), contemporaneous with height (cm) & body mass (Wt, kg). We used SuperImposition by Translation And Rotation (SITAR package, R) to model growth curves using 3 age clocks (years, y), centered at birth (chronological age, CAGE), individual age at PHV (PHVAGE), and individual age at menarche (gynecological age, GYNAGE). For each DXA outcome and age clock, we report ages at peak velocity (AGEPkV; PkV), ages at peak value (AGEPEAK), and model R2.Results: We included data for 124 white non-Hispanic females, median 11 annual observations [IQR 7-13, range 3-23; CAGE 8y to 36y; GYNAGE -8y to +24y; PHVAGE -5y to +25y; CAGE<10y n=45; CAGE>18y n=96]. Grand means by CAGE were: AGE@PHV=12.4y; AGE@MENARCHE=13.2y; AGE@WtPkV=13.4y. Radius AGEPkVs ranged from: CAGE 12y to 14y; PHVAGE -1y to +3y; GYNAGE -0.5y to +1y (Table 1). All Radius AGEPkVs and AGE@WtPkV lagged after PHV, except 1/3AREA, for which AGEPkV preceded PHV by 1 year. All 1/3 AGEPkVs & AGE@WtPkV were well-centered around menarche, but UD AGEPkVs lagged. All model R2 exceeded 90%.Conclusion: Ultradistal AGEPkVs lag relative to PHV, weight PkV, and 1/3 diaphysis PkVs, suggesting an extended period of metaphysis fracture risk. Ultradistal lags may be due to growth plate proximity and trabecular sensitivity to loading/unloading, estrogen, and metabolic factors. Failure to detect 1/3 BMC & BMD AGEPEAKs suggests diaphysis bone accrual/remodeling may extend into adulthood. Future work will detail nutrient intakes, physical activity, and mechanical loading as time-varying factors for tissue-specific bone mass, geometry, and density growth.

Wide Range of Calcium-Sensing Receptor Response to Small Pediatric Burns *Gordon Klein[1] [1]University of Texas Medical Branch, United States

Severe burns in children up-regulate the parathyroid calcium-sensing receptor (CaSR) but the CaSR response to small burns remains unclear. The aim of the study was to review data on smaller pediatric burns and compare circulating ionized calcium (iCa) and parathyroid hormone (iPTH) to those seen in previously published pediatric patients with severe burns (Klein et al J Pediatr 1997). We examined previously published data from 37 anonymized pediatric patients, ages 1-15 yr, with total body surface area burns <20% with known age and length of stay as an index of severity of burn. Admission intact PTH and iCa data were available and correlated with age and length of stay. Findings: No correlation was found between length of stay and iCa, r2=0.22, p- 0.38, or between length of stay and iPTH, r2=0.07, p=0.016. Similarly, no correlation was observed between patient age and admission iCa (r2=0.094, p=0.065) or iPTH (r2=0.04, p=0.21) . Of interest, circulating iCa was low in 34 of 37 of the patients (95%), similar to the published findings in severely burned patients (J Pediatr 1997), However, the distribution of iPTH values, in contrast to values previously published in severely burned pediatric patients, 19 of the 37 patients (51%), were in the normal range (10-65 pg/ml), 10 of the 37 patients (27%) had iPTH in the low range, and 8 of the 37 patients (22%) had iPTH levels above normal despite low circulating iCa. The variability of the iPTH response to small burns compared to large burns (>40% total body surface area) in the presence of low circulating iCa suggests that CaSR gene expression may be affected by severity of burn and the attendant inflammatory and stress responses.

Self-Reported Sleep Duration and Timing and Bone Mineral Density in Adolescents *Jessica Decker[1] Kimberly Yolton[2] Joseph Braun[3] Heidi Kalkwarf[4] Jessie Buckley[5] Bruce Lanphear[6] Aimin Chen[7] Kim M. Cecil[2] Babette Zemel[8] Jonathan Mitchell[9] [1]CHOP, United States [2]CCHMC, United States [3]Brown University, United States [4]Cincinnati Children's Hospital Medical Center, United States [5]Johns Hopkins, United States [6]Simon Fraser University, Canada [7]UPenn , United States [8]Children s Hospital of Philadelphia, United States [9]Children's Hospital of Philadelphia, United States

Background: Bone accretion can be optimized to maximize peak bone mass during childhood to prevent or delay the onset of osteoporosis in adulthood. Emerging evidence indicates that impaired sleep may be associated with lower bone mineral density. We aimed to determine if an association exists between sleep duration and timing with bone mineral density in adolescents.Methods: We analyzed cross-sectional data from the Health Outcomes and Measures of the Environment (HOME) Study collected in early adolescence. Dual-energy X-ray absorptiometry (DXA) scans yielded the following bone mineral density content (BMC) or areal bone mineral density (aBMD) traits as outcome variables: total body less head (TBLH) BMC, spine aBMD, total hip aBMD, femoral neck aBMD, and distal radius aBMD. All BMC and aBMD variables were converted to age and sex specific Z-scores and adjusted for height-for-age Z-score. Sleep duration (hours) and sleep onset times (hours from 00:00) on week and weekend nights were self-reported. Linear regression models were constructed to examine the association between sleep variables and bone Z-scores, adjusted for sex, race, household income, calcium intake, physical activity, and Tanner stage.Results: The study participants were 229 adolescents, aged 11-14 years; 56% were female and 57.2% non-Hispanic White. Average sleep onset time was 21:30 on weeknights and 00:42 on weekend nights and average sleep duration was 9.1 [standard deviation (SD): 1.1] hours on weeknights and 10.1 (SD: 1.8) hours on weekend nights. We observed no associations between sleep duration on weeknights or weekend nights and the bone outcomes. Similarly, we observed no associations between the timing of going to bed on weeknights or weekend nights and bone outcomes, with one exception. Later time in bed on weekend nights was associated with higher femoral neck aBMD (1 SD later time in bed on weekend nights: b=0.18; 95% CI: 0.02, 0.34; P=0.030). No sex or Tanner stage differences were detected with respect to the association between sleep exposures and the bone Z-score outcomes. Conclusion: Self-reported sleep duration and timing were not associated with TBLH-BMC or aBMD in this study. Future studies using actigraphy to assess sleep patterns are needed to advance this area of research.

Circulating preosteoclasts and mesenchymal stem cells are decreased in adolescents with Duchenne muscular dystrophy on chronic glucocorticoids whom have a significant fracture history *Angela Sadlowski[1] Julia See[1] Weixin Zhang[2] Arryn Otte[1] Emely Loscalzo[1] Sisir Barik[1] Janet Crane[3] [1]Johns Hopkins University, Department of Pediatrics, Division of Endocrinology, United States [2]Johns Hopkins University, Department of Orthopedic Surgery, Center for Musculoskeletal Research, United States [3]Johns Hopkins University, Department of Pediatrics, Division of Endocrinology and Department of Orthopedic Surgery, Center for Musculoskeletal Research, United States

By adolescence, 80% of people with Duchenne muscular dystrophy (DMD) on chronic glucocorticoids (GCs) have sustained a vertebral compression fracture. We have previously shown in a young GC-induced osteoporosis (GIO) mouse model that GCs decrease preosteoclast platelet-derived growth factor type BB (PDGF-BB), ultimately impairing bone angiogenesis and osteogenesis. As PDGF-BB stimulates the migration of endothelial precursor cells (EPCs) and mesenchymal stem cells (MSCs) to support angiogenesis and osteogenesis, we conducted a case-control study to determine if there is an association between serum PDGF-BB concentrations or peripheral blood mononuclear cell (PBMC) subpopulations representative of circulating bone precursor cells with DMD-GIO. Cases included 8-20-year-old DMD patients with GIO as defined by a significant fracture history (DMD-GIO, n=14); two control groups included disease controls, defined as DMD patients on chronic GCs without a significant fracture history (DMD-control, n=10) and healthy controls (n=9) whom were age- and sex-matched people not on any prescription medications and without a significant fracture history. The mean GC duration was 12.8 years for the DMD-GIO group and 9.0 years for the DMD-control group (P=0.06), partially explained by the DMD-GIO group being slightly older (16.5 years vs 14.4 years, P=0.3). Preliminarily, mean serum PDGF-BB concentration in DMD-control (n=6) was significantly lower relative to DMD-GIO (n=9) and healthy controls (n=9) ($P < 0.05$). PBMC percentage of preosteoclasts (CD14+, Stro-1-, CD105-) was significantly decreased in both DMD groups (DMD-GIO, n=11; DMD-control, n=4) relative to healthy controls (n=8). The percent of EPCs (CD34+, CD14-, Stro-1-, CD105-) was similar between DMD-GIO and healthy controls but increased significantly in DMD controls. The percent of MSCs (Stro-1+, CD105+, CD14-, CD45-) was lowest in DMD-GIO, intermediate in DMD controls, and highest in healthy controls. (P=0.05). In prospective follow-up, 8 of the DMD controls have sustained at least one vertebral compression fracture, such that additional analyses are underway to determine if a specific biomarker correlates with the probability of future fracture. Overall, a low circulating percent of preosteoclasts and MSCs was observed in patients with DMD-GIO,

whereas DMD-controls had low concentrations of PDGF-BB, low circulating preosteoclasts and MSCs, but high EPCs relative to age- and sex-matched healthy controls

Saphenous Nerve Transection Results in Sensory and Sympathetic Denervation of the Mouse Tibia *Talia Lizotte[1,] Gesele Henderson[1,] Jacob Hickey[1,] Peter Caradonna[1,] Victoria Eaton[1,] Gabriel DeOliveira[1,] Derek Molliver[1,] TAMARA KING[1,] Kathleen Becker[1,] [1]University of New England, United States

The saphenous nerve is a sensory nerve that is commonly injured during ACL repair, varicose vein surgery, and other procedures, resulting in numbness or pain. Retrograde labeling studies have suggested that the tibia is innervated by the saphenous nerve, but this has not been confirmed with nerve transection. While sensory and sympathetic input to bone impacts bone metabolism, little is known about the specific consequences of saphenous nerve injury on tibial innervation and bone mineral density (BMD). We hypothesize that saphenous nerve transection will result in a decrease in sensory nerve fibers in the tibia. A greater understanding of elements regulating tibial innervation will help identify risk factors influencing tibial BMD.To demonstrate that the saphenous nerve innervates the tibia, fast blue dye was injected into the proximal tibia of saphenous nerve transected or sham 8-week-old female C57BL/6J mice. The L2-L5 dorsal root ganglia (DRG) were isolated one week post-injection and fast blue positive cells were quantified in the DRG. The highest level of retrograde labeling was observed in the L2 and L3 DRG of sham surgery mice. To determine if transection of the saphenous nerve resulted in tibial denervation, the saphenous nerve was unilaterally transected in 8-week-old female C57BL/6J mice and the ipsilateral and contralateral control tibiae were isolated 2 weeks post-nerve transection. Retrograde labeling from the tibia to the L2 DRG was reduced by 75% in mice with saphenous nerve transection, consistent with the paradigm that the saphenous nerve is the primary source of tibial innervation. Immunohistochemical analysis of sensory and sympathetic innervation was performed using immunofluorescent staining for calcitonin gene-related peptide (CGRP, sensory fiber), tyrosine hydroxylase (TH, sympathetic fiber) and ?III-tubulin (?3T, pan-neuron). CGRP, TH, and ?3T positive fibers were reduced by 40-60% in the proximal, lateral-most periosteum of the tibia ipsilateral to the saphenous nerve transection. Longitudinal analysis of saphenous nerve transected animals indicated no long-term hindlimb unloading. These data show that saphenous nerve denervation reduces sensory and sympathetic innervation of the tibia. Our findings demonstrate that the saphenous nerve is a critical source of tibial innervation making transection of the saphenous nerve a versatile model to study the impact of innervation on bone.

Chronic kidney injury induced bone loss through downregulation of the runt-related transcription factor 2-alkaline phosphatase signaling pathway *Yu-Pin Chen[1,] Tso-Hsiao Chen[1,] Ruei-Ming Chen[2,] [1]Wan Fang Hospital, Taiwan, Province of China, [2]Taipei Medical University, Taiwan, Province of China

In Taiwan, the population density of kidney dialysis is the highest in the world. Unfortunately, the patients suffering from end-stage renal disease (ESRD) usually also raise the risk of bone disorders. This study was aimed to investigate the effects of chronic kidney injury (CKI) on loss of bone mass and the possible mechanisms. Administration of male ICR mice with 0.2% adenine for 4 weeks significantly elevated levels of serum creatinine, blood urea nitrogen, and urea, finally resulting in server insults to the kidneys. In parallel, our results by micro-computed tomography (?CT) displayed that administration of mice with CKI significantly decreased trabecular bone numbers, bone volumes, and trabecular thickness, but caused an elevation in trabecular separation. As to the mechanisms, exposure of female ICR mice to 0.2% adenine for 4 weeks diminished levels of runt-related transcription factor 2 (Runx2), a critical transcription factor of osteogenesis, in the femur. Alkaline phosphatase (ALP) is a typical biomarker of osteoblasts. A bioinformatics search revealed that there are 3 Runx2-specific DNA-binding elements existing in the 5'-promoter of the alp gene. Treatment of mice with CKI meaningfully inhibited ALP mRNA and protein expressions. Furthermore, our in vitro analysis also confirmed that exposure of MC3T3-E1 cells to indoxyl sulfate, a uremic toxin, significantly inhibited runx2 and alp gene expressions and consequently suppressed cell mineralization. Therefore, this study has shown that CKI could induce loss of bone bass through downregulating the Runx2-ALP signaling events.

SAT-049

The Time Course of Bone Resorption Following Muscle Paralysis is Sex-Dependent *Leah Worton[3,] Phillipe Huber[3,] Brandon Ausk[3,] Steven Bain[3,] Adrian Piliponsky[2,] Edith M. Gardiner[3,] Ted Gross[3,] [3]University of Washington, United States, [2]Seattle Children's Research Institute, United States, [3]University of Washington,

Transient calf paralysis in female mice rapidly initiates osteoclast mediated trabecular bone resorption in the ipsilateral proximal tibia metaphysis. In this study, we explored whether: 1) transient muscle paralysis induces acute bone resorption in male mice as it does in female mice, and 2) if elevated Substance P (SP), a neuropeptide precursor to neurogenic inflammation, precedes the initiation of trabecular bone resorption in female and male mice. First, 8 female and 8 male C57BL/6 mice underwent right calf paralysis and serial microCT imaging of the proximal tibia and tibia midshaft (d-1, d6, d13, and d21). Standard trabecular and cortical bone morphology outcome measures were determined as a percentage of d-1. Second, 41 female and 25 male C57BL/6 mice were randomly assigned to a naïve group (F:11; M:5) or right calf paralysis (F:30; M:20). Right tibia bone marrow was removed on d1, d3, d7, and d14 post-paralysis and SP was quantified via ELISA (F: > n=6/timepoint, 3 independent experiments; M: n=5/timepoint, 1 experiment). For each experiment, data were expressed as a percentage of mean naïve group SP. Consistent with the literature, female mice demonstrated significant proximal tibia trabecular bone loss by d6 vs baseline (BV/TV, mean +/- SE: -45.0 +/- 5.9%, $p<0.01$) that progressed through d13 (-73.1 +/- 2.0%, $p<0.001$) and then plateaued (d21: -77.1 +/- 2.6%, $p<0.001$). In contrast, trabecular bone loss was not observed in male mice at d6 vs d-1 (BV/TV: 1.3 +/- 9.9%, $p=0.33$), but it was evident by d13 (-50.6 +/- 7.5%, $p=0.002$) and was similar in magnitude to female mice by d21 (-72.8 +/- 3.6%, $p<0.001$). Midshaft endocortical expansion (a surrogate for osteoclastic resorption) demonstrated the same pattern of delayed initiation but a similar endpoint (F v M: d6 3.9 +/- 1.6 % vs -0.4 +/- 0.5%, $p=0.02$; d21: 10.4 +/- 2.0% vs 8.1 +/- 2.0%, $p=0.43$). SP expression in female mice was rapidly elevated vs naïve (d1: 48.0 +/- 10.9%, $p<0.01$) and returned to normal levels by d14 (-17.1 +/- 19.0%). SP expression in male mice was not elevated at any time point vs naïve mice. In summary, trabecular and cortical bone loss induced by transient muscle paralysis was delayed in male vs female mice. Further, acute upregulation of SP in female mice, but not male mice, suggests sex-based differences in neurogenic signaling following transient muscle paralysis. As a result, successful interventions to mitigate paralysis induced bone loss may require sex-specific targeting.

Morphine-induced Bone Loss is Associated with Altered Bone miRNA Expression in Male C57BL/6J Mice *Audrie Langlais[1,] Claire Morrow[1,] Katherine Motyl[1,] [1]MaineHealth Institute for Research, United States

Opioids pose a serious risk to bone health by reducing bone mineral density and increasing fracture risk. Previously, we identified morphine-induced bone loss was due to reduced bone formation in male but not female mice. This was associated with differentially expressed circulating micro RNAs (miRNA) in serum and altered target gene expression in bone. However, miRNA changes in bone have not yet been assessed. We delivered morphine (17 mg/kg) or vehicle (0.9% saline) subcutaneously via osmotic minipumps to 8-week-old C57BL/6J male mice (N = 12/group) for four weeks. Femur and vertebrae were isolated for micro-computed tomography and mRNA/miRNA was extracted from tibia for qPCR. Consistent with our previous study, trabecular bone volume fraction was reduced by 10% in the L5 vertebrae ($p<0.05$) and cortical area fraction was reduced by 5% in the femur midshaft. We confirmed that the top differentially expressed miRNAs from serum were also expressed in tibia bone marrow and cortical bone. miR-223-3p was significantly elevated in serum but downregulated in bone marrow and not altered in cortical bone. Interestingly, miR-223-3p has been previously associated with opioid use in humans and shown to regulate osteogenesis through its targets, including Foxo3 and Igf1r. Alternately, miR-28a-3p was downregulated in serum and cortical bone. Although the function of this miRNA has not been previously investigated within bone, several predicted and validated targets (e.g., Tgif1, Sox2) suggest an influence on osteoblast function. Furthermore, within bone marrow, expression of all six miRNAs examined were significantly lower, which is consistent with morphine causing a negative skew in miRNA expression in serum in our previous study. Due to the robust suppression of miRNA levels in marrow, we assessed expression of miRNA biogenesis genes (Dicer1, Drosha, Ago2 and Xpo5), but none were altered by morphine. Future studies will test whether the nervous system, the major target of morphine, is the source of suppressed miRNA levels in marrow and serum. Furthermore, we will test how opioids and miRNA gene targets collectively impact osteoblast function to cause bone loss. This

work will critically expand our understanding of how opioids impair bone and may influence future clinical treatment and prevention strategies.

Osteoclast and neuronal crosstalk as a mechanism for chest wall pain in lung cancer patients receiving thoracic radiosurgery *Sun Park[1], Joseph Moore[1], Kaitlyn Reno[1], Michael Farris[1], Christopher Peters[2], Jeffery Willey[1]. [1]Department of Radiation Oncology, Wake Forest University School of Medicine, United States. [2]Department of Anesthesiology, Wake Forest University School of Medicine , United States

Purpose: Thoracic stereotactic body radiation therapy (SBRT) for the treatment of lung tumors near the chest wall unavoidably delivers high doses of radiation to the surrounding normal tissues. This predisposes patients to debilitating radiation-induced chest wall pain (CWP). CWP may present and resolve acutely or may develop and persist chronically over years with or without bone fractures. The underlying mechanisms of CWP are unclear, but could involve damage to intercostal peripheral nerves, and or RT induced osteoclast mediated bone degradation. While RT induced nerve damage has typically been thought of as a separate process from RT induced bone damage, we describe here evidence of potential crosstalk between factors released from irradiated osteoclasts and nerves.Methods: We utilized an in vitro culture system involving a pre-osteoclast mouse cell line (Raw264.7) and primary mouse thoracic dorsal root ganglion (DRG) neuron cultures. Mature osteoclast cells were plated on Osteoassay plates to measure resorption of a bone proxy surface. Osteoclasts were irradiated with a single fraction of 10Gy using Cs137 ?-rays, and conditioned media (CM) from these cells was collected at 24h and applied to non-irradiated neurons. Changes in neurite growth was assessed with immunohistochemistry and alterations in gene expression of pain-associated molecular markers, including substance P (SP), calcitonin gene-related peptide (CGRP),and nerve growth factor (NGF) were measured using quantitative real time PCR. Unpaired t-tests were used for statistical analyses (?=0.05).Results: Radiation induced osteoclast activity at 24h as measured with Osteoassay disks. Non-irradiated neurons treated with CM, demonstrated no change in total nerve length. However, neurons exposed to CM expressed a higher level of CGRP (+38.5%), substance P (+29.5%), and NGF (+14.5%) compared to control media.Conclusions: RT induced damage to intercostal nerves may be influenced by the release of factors from nearby resident osteoclasts within ribs or vertebrae, triggering expression and release of pain related neuropeptides. This osteoclast mediated elevation in neuropeptides could contribute to debilitating radiation related CWP. Understanding the crosstalk between osteoclasts and peripheral nerves may identify potential targets for preventating CWP, and provide clinicians an opportunity to achieve higher tumor dosing with reduced toxicity.

3D Genomic features across >50 diverse cell types reveal insights into the differing genomic architectures of BMD determination and osteoporotic fracture pathogenesis *Khanh B. Trang[1], Matthew C. Pahl[1], James A. Pippin[1], Alessandra Chesi[2], Yadav Wagley[3], Babette Zemel[4], Kurt Hankenson[5], Andrew D. Wells[6], Struan Grant[6]. [1]Children's Hospital of Philadelphia, United States. [2]University of Pennsylvania, United States. [3], , [4]Children s Hospital of Philadelphia, United States. [5]University of Michigan, United States. [6]Children s Hospital of Philadelphia / University of Pennsylvania, United States

The incomplete correlation between bone mineral density (BMD) determination and the pathogenesis of osteoporotic fracture suggests a degree of difference in underlying biological processes. Genome-wide association studies (GWAS) have identified numerous genetic variants associated with either BMD or osteoporotic fracture, where indeed the genetic overlap is also only partial. There is much that remains to be characterized for such loci, including cellular context, underlying causal variants and corresponding effector genes. Leveraging our existing 3D genomic datasets across >50 diverse human cell types consisting of high-resolution promoter-focused Capture-C/Hi-C, ATAC-seq and RNA-seq, enables us to contrast both the causal variants and the corresponding effector genes for these two orthogonal traits. These cell types include those closely relevant to bone biology, such as human mesenchymal stem cell (hMSC)-derived osteoblasts, plus those spanning more broadly across metabolic, neuronal and immune cell types. Using stratified LD regression, we calculated the proportion of genome-wide SNP heritability attributable to our derived cell type specific features via the integration of the most recent adult BMD and osteoporosis fracture GWAS summary statistics. These analyses revealed a statistically significant enrichment ($P<0.05$) for osteoporotic fracture across multiple immune cell types (plasmacytoid and classical CD1c+ dendritic cells, along with several classes of T-cells), pancreatic ?-cells and adipocytes; while in contrast, the features related to BMD were more enriched for bone-related cell types (hMCS-derived osteoblasts, the human fetal osteoblasts hFOB cell line), as well as several derived neuron and neural progenitor cell lines. Subsequent application of our chromatin contact-based 'variant-to-gene' mapping of these loci identified key "hub" genes, functional pathways, and biological processes, including regulation of extracellular matrix remodeling and immune response. These observations further reinforce the prevailing hypothesis that GWAS-implicated variants confer their effects via complex polygenetic regulatory mechanisms involving key signaling pathways. In conclusion, our comprehensive appraisal of 3D genomic datasets in a myriad of different cell types drives greater genomic understanding of both the similarities and the differences across BMD determination and osteoporotic fracture pathogenesis.

Secoisolariciresinol exerted bone protective effects via inhibiting intestinal tryptophan hydroxylase 1 (Tph-1) and altering circulating serotonin *Yu-Xin Zhu[1], Hong-Yu Peng[1], Man Sau Wong[2], Hui-Hui Xiao[1]. [1]The Hong Kong Polytechnic University Shenzhen Research Institute, China. [2] The Hong Kong Polytechnic University, Hong Kong

We previously demonstrated that the lignan-rich fraction from Sambucus williamsii Hance could exert bone protective effects indirectly by suppressing serotonin synthesis via inhibiting the intestinal tryptophan hydroxylase 1 (TPH-1) protein, a rate-limiting enzyme of serotonin synthesis, and modulating gut microbiota composition. However, there was no direct evidence for the modulating actions of lignans on TPH-1 protein. This study aims to verify the direct actions of a major lignan Secoisolariciresinol (SECO) from S. williamsii on TPH-1 protein, and its mechanism on bone protection via modulating circulating serotonin. The molecular docking, surface plasmon resonance (SPR), TPH-1 protein activity, TPH-1 protein expression, mRNA expression as well as mice serum serotonin level and bone properties upon SECO treatment were determined. Molecular docking study and SPR analysis revealed that SECO exhibited high binding affinities to Tph-1 protein. SECO significantly inhibited the TPH-1 activity and protein expressions in RBL 2H3 cells. It also decreased the serotonin level, inhibited intestinal TPH-1 protein expressions, and improved bone properties in OVX mice. Our results indicated that SECO is a new TPH-1 inhibitor and it induced decreased circulating serotonin level may account for its bone protective effects.

The Impact of Zoledronic Acid on Bone health and Fracture Risk in Intestinal Transplant Patients *Ayat ElSherif[1], LEILA KHAN[2], Krupa Doshi[3], James Bena[4], Kareem Abu-Elmagd[1]. [1]Center of Gut Rehabilitation and Transplantation, Cleveland Clinic Foundation, OH, USA, United States. [2]CLEVELAND CLINIC FOUNDATION, United States. [3]Mayo Clinic Arizona, , [4]Department of Quantitative Health Sciences, Cleveland Clinic Foundation, OH, USA, United States

BACKGROUND: Intestinal transplant is the standard of care for patients with gut failure (GF) who can no longer be maintained on total parenteral nutrition (TPN). The intestinal transplant recipients are at increased risk of osteoporosis and deleterious metabolic effects of TPN than their solid organ counterparts. However, existing literature about bone health in intestinal transplant recipients is sparse. The use of alendronate in solid organ and intestinal transplantation was shown to be associated with a reduction in bone loss. However, the use of oral bisphosphonates (only 1-4% of which are absorbed from the gut) may not be the ideal answer for intestinal transplant recipients. This is the first study to examine pre-surgical use of one or more doses of zoledronic acid in intestinal transplant recipients and to evaluate its impact on the fracture risk post-transplantation.METHODS: An institutional review board-approved prospective database was reviewed of patients with total parenteral nutrition-dependent catastrophic and chronic GF who were referred for surgical

intervention particularly transplantation from 2013-2019 and had received at least one dose of zoledronic acid. Patient demographics, status of digestive health, total parenteral nutrition details, type of allograft received and mineral data were collected. Date of zoledronic acid, number of doses received and incidence of fragility fractures post- transplant were analyzed. RESULTS: A total of 28 patients were identified. Fifty-seven percent of the patients (n=16) were females. Median age was 47 years (IQR 33, 55) and median BMI was 24.7 (IQR 21.7, 27.9). The incidence of post-transplant fragility fracture in the cohort was 14% (n=4). The time between first pre-transplant zoledronic acid injection and surgery was the only significant risk factor for fragility fracture (p=0.024). Age, sex, BMI, duration of gut disease, and TPN duration were not associated with increased fracture risk. A significant increase in vitamin D levels was noted from pre-transplant to post-transplant (Median 25 [IQR 20, 30] vs 54 [37, 61], p=0.009).CONCLUSION: Pre-transplant zoledronic acid has a protective effect against fragility fracture in patient undergoing transplant patients.

Association between bone mineral density and body composition among Mongolian adult women *Narantsetseg Jargalsaikhan[1], Giimel Ajnai[1], Sarnai Gunsenkhorloo[1]. [1]Research and Development Office, Fourth Hospital, Mongolia

Background: Maintaining bone health is an important public health issue and challenge (concern) in women for preventing a determinant of the risk of developing osteoporosis later in life. The aim of the present study is to investigate the relationship between bone mineral density (BMD) analysis, and body composition in a female population in Mongolia. Methods: A sample of 309 women aged between 20 and 39 underwent scans between January and December 2022 by dual x-ray absorptiometry (DXA) in Fourth Hospital, Ulaanbaatar City. The correlation between bone mineral density analysis and total fat mass, lean mass, and bone mass was analyzed by Pearson correlation and multiple linear regression analysis. Results: According to the DXA results, 76.4% of women had normal bone mineral density, and 20.1% and 3.6% were diagnosed with osteopenia and osteoporosis, respectively. Multiple linear regression analysis indicated BMD was positively associated with total fat mass (?: 0.042, p<0.001), total lean mass (?: 0.083, p<0.001), and bone mass (?: 0.857, p<0.001). The positive correlation of BMD and lean and bone mass was significant in younger women aged <30 years, whereas women over 30 were positively associated with lean mass and fat mass. There were no significant relationships between BMD and body weight, percentage of body fat, and android/gynoid ratio parameters. Conclusions: Our results indicate that women younger than 30 were associated with BMD, lean, and bone mass. Emphasizing lean mass and bone mass in young Mongolian women may be valuable for improving bone health.

Injectable Levonorgestrel Butanoate Does Not Result in a Decline in Z-Scores in Reproductive-Age Women *Jeffrey Kroopnick[1], Min Lee[1], David Archer[2], Mitchell Creinin[3], Jeffrey Jensen[4], Aaron Lazorwitz[5], Lori Gawron[6], Carolyn Westhoff[7], Katharine White[8], Diana Blithe[1]. [1]Contraceptive Development Program, Eunice Kennedy Shriver National Institute of Child Health and Human Development, NIH, United States. [2]Clinical Research Center, Department of Obstetrics and Gynecology, Eastern Virginia Medical School, United States. [3]Department of Obstetrics and Gynecology, University of California, Davis, United States. [4]Department of Obstetrics and Gynecology, Oregon Health & Science University, United States. [5]Department of Obstetrics and Gynecology, University of Colorado Anschutz Medical Campus, United States. [6]Department of Obstetrics and Gynecology, University of Utah, United States. [7]Department of Obstetrics and Gynecology, Columbia University, United States. [8]Department of Obstetrics and Gynecology, Boston University, United States

Purpose: The NICHD Contraceptive Development Program has developed levonorgestrel butanoate (LB) as an injectable contraceptive that will inhibit ovulation for 3 or more months, with the goal of reducing side effects, such as weight gain and mood issues, compared to depot medroxyprogesterone acetate (DMPA), the only marketed injectable progestin available in the U.S. The FDA has issued a warning to DMPA users of significant decreases in bone mineral density (BMD) and possible increased fracture risk with long-term use. Levonorgestrel has a well-established history of clinical use in a variety of contraceptives, including pills, intrauterine devices, and implants. Its efficacy and safety are well-recognized, particularly for obese women or women with other risk factors for which estrogen is contraindicated. Here, we report the change in Z-scores pre- and post- treatment in subjects receiving escalating LB doses.Methods: Participants received one dose of LB intramuscularly or subcutaneously and were followed until return to ovulation occurred. Subjects received LB 40 mg (20 mg/mL) intramuscularly (Group A) or subcutaneously (Group B). Group B2 received LB 40 mg (70 mg/mL) subcutaneously. Baseline and post-treatment Dual Energy X-ray Absorptiometry (DXA) scans were obtained. Two subjects were excluded from analysis due to a baseline Z-score of <= -2.0. We compared pre- and post-treatment Z-scores at the lumbar spine (LS) and total hip (TH) using a two-tailed t-test for two independent means and considered a post-treatment Z-score <= -2.0 as clinically significant.Results: We enrolled 86 participants into Groups A (n=24), B (n=31), and B2 (n=31) with median duration from baseline to post-treatment DXA scans of 129, 185, and 205 days. In Group A, mean pre- and post-treatment Z-scores at the LS were 0.04 and 0.00, respectively (p=0.58) and at the TH were 0.00 and -0.05, respectively (p=0.90). In Group B, LS scores were 0.28 and 0.25, respectively (p=0.91) and TH scores were 0.24 and 0.18, respectively (p=0.84). In Group B2, LS scores were 0.47 and 0.29, respectively (p=0.57) at TH scores were 0.36 and 0.45, respectively (p=0.76). No subject had a post-treatment Z-score <= -2.0.Conclusion: We found no clinically significant decline in Z-scores among participants receiving injectable LB over the treatment period in our study. Once a treatment dose is identified, larger, long-term studies are needed to assess bone density with prolonged use.

Prevalence of Low Vitamin D Level among Older US Asian and Pacific Islander Women *Joan Lo[1], Malini Chandra[1], Jennifer Park-Sigal[1], Jeanne Darbinian[1], Catherine Lee[1], Wendy Yang[1]. [1]Kaiser Permanente Northern California, United States

Asian women are at higher risk for low Vitamin D level compared to non-Hispanic White (NHW) women, but differences may exist among subgroups. Large population studies among US Asian subgroups remain lacking. PURPOSE: We compared the prevalence of low vitamin D among Asian and Pacific Islander (PI) and NHW women aged 50-89y. METHODS: Data from Asian/PI and NHW women in a Northern California health plan who had body mass index (BMI) assessed at a clinical encounter in 2010-2019 and measurement of 25-hydroxy-vitamin D (25OHD) within 1 year of the visit were examined. The earliest BMI and 25OHD level in the specified time frame was ascertained. Prevalence of low vitamin D (25OHD <20 ng/mL) was examined by race and ethnicity, reported with 95% confidence intervals [CI]. Modified Poisson regression was used to calculate prevalence ratios (PRs), adjusting for age and BMI. RESULTS: Among 50,728 Asian/PI women (average age 60.0+/-9.8y; 13,865 Chinese, 12,629 Filipina, 3902 South Asian, 3238 Japanese, 2170 Vietnamese, 1320 Korean, 1212 Native Hawaiian/Pacific Islander (NHPI), 807 other Southeast Asian, and 11,585 unspecified or other Asian/PI) and 181,862 NHW women (average age 63.2+/-10.8y), prevalence of low 25OHD was 19.4% [19.0-19.7%] for Asian/PI women and 14.8% [14.7-15.0%] for NHW women. Among Asian/PI women, prevalence ranged from 15.7% [14.4-16.9%] for Japanese, 17.4% [16.7-18.1%] for Filipina, 19.2% [18.6-19.9%] for Chinese, 20.4% [18.2-22.6%] for Korean, 23.6% [21.9-25.4%] for Vietnamese, 22.7% [19.8-25.6%] for other Southeast Asian, 23.9% [22.5-25.2%] for South Asian, and 30.9% [28.3-33.5%] for NHPI women. Adjusted PRs for low 25OHD (NHW as reference) were 1.29 [1.19-1.40] for Japanese, 1.33 [1.28-1.39] for Filipina, 1.65 [1.59-1.71] for Chinese, 1.74 [1.56-1.93] for Korean, 1.75 [1.65-1.85] for South Asian, 1.96 [1.80-2.13] for NHPI, 2.06 [1.91-2.22] for Vietnamese, and 1.79 [1.58-2.04] for other Southeast Asian women. CONCLUSION: In a community-based population of older Asian/PI women receiving healthcare, low Vitamin D prevalence was higher than NHW women but varied widely by Asian/PI ethnicity, ranging from 30% higher for Japanese and Filipina women, to 65-75% higher for Chinese, Korean, and South Asian women, and twofold higher for NHPI and Vietnamese women, accounting for age and BMI. While these findings are limited by lack of data on Vitamin D intake or treatment, they emphasize the much higher risk of low vitamin D among selected Asian/PI subgroups.

SAT-068

Low bone density screening rate in patients treated with long term glucocorticoid therapy *Tasma Harindhanavudhi[1], Rebecca Freese[2], Nolawit Tesfaye[1], Susanne Trost[1]. [1]Division of Endocrinology, Diabetes and Metabolism, Department of Medicine, University of Minnesota, United States. [2]Clinical and Translational Science Institute, University of Minnesota, United States

Glucocorticoid is the most common cause of secondary osteoporosis. Approximately 10% of patients who receive long-term glucocorticoid treatment sustain a fracture. Previous data derived from U.S. health maintenance organizations in 2000-2001 found only 9.8% of the total population received a bone density measurement. However, no recent data are available. Our aim is to understand the clinical practice pattern of bone density screening (DXA) in patients who are prescribed long-term glucocorticoid therapy (for 3 months or longer).

This retrospective cohort study (n=8924) used the electronic medical record's databases to identify patients who were dispensed 2.5 mg of prednisone or equivalent per day for at least 3 months between 2017 to 2022. Approximately half of the patients (51%) were women and the majority of participants were Caucasian (88.6%). Overall, 15% of the patients (n=1378) had at least one DXA measurement within 2 years prior and 1 year after the index glucocorticoid prescription. Among patients who received bone density screening, 17% had more than one DXA measurement. Among DXA measurements performed, 62.4% (n=1041) were performed within 2 years before the glucocorticoid initiation, while 21.9% (n=366) and 15.7% (n=262) were performed within 6 months and between 6 months to 1 year after glucocorticoid initiation, respectively. Our study found suboptimal bone density screening in patients receiving long-term glucocorticoid therapy as recommended in the clinical practice guideline. Future efforts should focus on quality improvement to understand the barriers and improve the frequency of bone density screening to facilitate osteoporosis management.

The association of muscle (amount and function) with bone mass in women diagnosed with anorexia nervosa followed up by a multidisciplinary team
*Iana Mizumukai de Araujo[1], Carlos Ernesto Garrido Salmon[2], Francisco Jose De Paula[3]. [1]Ribeirão Preto Medical School - University of São Paulo, Brazil, [2]University of São Paulo, Brazil, [3]Ribeirao Preto Medical School- USP, Brazil

Introduction: Anorexia nervosa (AN) is a psychiatric disorder in which the individual presents extreme aversion to weight gain, leading to self-imposed fasting. The catabolism in muscle and adipose tissues is accompanied by bone loss and marrow adipose tissue (MAT) expansion. The present study was designed to evaluate the association of muscle mass and metabolism with bone properties and MAT composition in AN patients.Methods: The study comprised 13 women with AN and 25 healthy women (C). A multidisciplinary team is treating the AN group. BMD was measured by DXA in several regions, while MAT composition (saturated/unsaturated/total) were assessed by 1H-MR Spectroscopy in proximal tibia. Phosphocreatine (PCr) and inorganic phosphorus (Pi) were measured by 31P-MR Spectroscopy in rest in the soleus muscle. Trabecular bone score (TBS) was assessed via the software TBS iNsight v.3.0. Lean mass index (LMI) was calculated as appendicular skeletal muscle mass adjusted by height squared and Fat mass index (FMI) calculated as body fat mass dividing by height squared. p-value<0,05 was considered as statistical threshold.Results: We present the medians of the results. The groups were matched by age (Median: C=24, A=21y) and height (C:1.63; AN=1.60m). The BMI was higher in C than in AN (C=21.1; AN=19.1). AN showed lower BMD and Z-score in lumbar spine, total hip, and femoral neck than C. TBS was also lower in AN than in C (C=1.462, AN=1.302). The total (C=93.4, AN=94.85%), saturated (C=39.49, AN=36.3%), and unsaturated (C=7.69, AN=7.98%) MAT were similar between the groups. Lean mass index was similar between the groups (C=6.1, AN=5,4 kg/m²). FMI was lower in AN than in C group (C=7.3, AN=5.5 kg/m²). OC, albumin, PTH, and 25-hydroxyvitamin D were similar between the groups. Rest PCr and Pi were similar between the groups. There was a positive correlation between FMI and TBS (r=0.58). LMI was positively associated with L1-L4, TH, and FN BMD (respectively r=0.45, 0.44, 0.38). Conclusion: Our data reaffirms that bone loss is a long-lasting complication for women with AN. In addition, our results contribute to this line of investigation by showing that muscle mass is positively associated with bone mass. People with AN have bone mass and quality loss. In addition, the AN group showed lower adipose tissue but similar LMI in comparison to controls. An adequate nutritional approach can mitigate muscle mass loss and limit the expansion of MAT in anorexia nervosa.

Bone Mineral Density and Body Composition in Postmenopausal Primary Hypothyroid Females on Replacement Dose of Levothyroxin and its Correlation with TSH and Duration of Hypothyroidism
*Eram Nahid[1], Parth Jethwani[2], Kamla Kant Shukla[3], Madhukar Mittal[4], M K Garg[5], Ravindra Shukla[4]. [1]Resident, Department of Endocrinology and Metabolism, All India Institute of Medical Sciences(AIIMS),Jodhpur, India. [2]Resident, Department of Endocrinology and Metabolism, All India Institute of Medical Sciences, Jodhpur, India. [3]Associate professor, Department of Biochemistry, All India Institute of Medical Sciences(AIIMS), Jodhpur, India. [4]Additional Professor, Department of Endocrinology and Metabolism, All India Institute of Medical Sciences, Jodhpur, India. [5]Professor, Department of Endocrinology and Metabolism, All India Institute of Medical Sciences, Jodhpur, India

Background:Long term use of Levothyroxin (LT4) is known to increase the risk of fracture,but there is limited knowledge on Bone mineral density (BMD) and body composition in postmenopausal primary hypothyroid female patients. Body composition measures such as Visceral adipose tissue (VAT) and Total body fat (TBF%) are important determinants of cardiometabolic diseases.Aim/Purpose:To assess BMD and body composition in postmenopausal primary hypothyroid female patients on replacement dose of LT4 by Horizon-A DXA scanner and to explore association of BMD with dose of LT4,duration of hypothyroidism & level of serum TSH.Methodology:This is single-centre cross-sectional study conducted among 104 postmenopausal primary hypothyroid females on replacement dose of LT4. The outcome included BMD of femur neck, total hip, lumbar spine, distal forearm and whole body, along with body composition. Furthermore, effect on BMD was analysed with respect to age, duration of the disease and treatment, physical activity, and thyroid status. The analyses were performed using Spearman's correlation.ResultA total of 104 postmenopausal women who were taking LT4 for mean duration of 5.83 years were analysed. 50(48.8%) patients were found to have osteopenia and 36 (34.62%) were found to have osteoporosis. A comparison of BMD showed that neither TSH nor LT4 dose and duration of hypothyroidism was correlated with BMD at various sites. The number of years post-menopause, as well as age were inversely correlated with BMC at all the sites (p-value<0.05). Physical activity (METs/week) was strongly correlated with BMC at all the sites (P value<0.001). On subgroup analysis patients who has suppressed TSH (5IU/L.63 females (60.57%) were obese based on Southeast Asia specific BMI cut offs. However 102 females (98%) were having TBF > 30%. Critical VAT (VAT area > 100 cm2) present in 73 (70.1%) and VAT area >160cm2 was present in 24 (23%) patients. Metabolically obese normal weight (MONW) defined as a VAT area >100 cm2 with a normal BMI (<25kg/m2) constituted a total of 19.2% (n=20). 49 females (47%) had appendicular lean mass index (ALM/height2) <6 kg/m2.ConclusionThis study found no significant correlation between BMD and serum TSH, duration of hypothyroidism or LT4 dose.98% patients were obese according to TBF% and 70% had significantly high VAT suggesting high cardiometabolic risks.

SAT-072

Artificial Neural Network (ANN) model employing Immunometabolic factors is better than FRAX for predicting fragility fractures (FF) in postmenopausal women with autoimmune hypothyroidism
*ravindra shukla[1], eram nahid[1], Ayan Roy[2], kamalakant shukla[1], MK Garg[1], divyangi mishra[3]. [1]AIIMS Jodhpur, India. [2]AIIMS Kalyani, India. [3]SNMC Jodhpur, India

Introduction: Various observational studies have shown conflicting evidence between primary hypothyroidism and fragility fracture risk in postmenopausal women. Unlike autoimmune diseases like SLE, RA (which have FF risk) , systemic manifestations of autoimmune hypothyroidism have been poorly understood. In this study we explore veritability immunometabolic factors Versus traditional FRAX score in predicting fragility fractures in autoimmune hypothyroidism Methods: In this single center cross-sectional study , consecutive subjects of post menopausal women with primary hypothyroidism on stable levothyroxine and positive anti TPO antibody were evaluated for symptoms, metabolic (HbA1C,lipid, visceral adipose tissue,hypertension,thyroid hormones),inflammatory(vit D,IL6,hsCRP, DHEAS, antiTPO Ab, N/L ratio) and Bone (BMD indices,TBS,Ca,Phosphorus,parathormone) profile.Those with rheumatological disease,diabetes mellitus or any other endocrine disorder, recent (<2 months) viral illness or hospitalization were excluded.Of 243 screened 104 were included in the study. The subjects were divided into two groups: those who had fragility fractures & those who did not. FRAX for major osteoporotic fracture (MOF)calculated online. Discriminant analysis was done to find out factors associated with metabolic inflammation. Levothyroxine dose (?g/kg/day) , dose-duration exposure (?g.months), neutrophil to lymphocyte(NL) ratio, 25 (OH)Vit D,Parathormone, anti TPO Ab, Free T4, freeT3, DHEAS , LDL,Triglycerides,IL-6, HbA1c ,Visceral Adipose tissue index, hypothyroidism duration(in yrs), Presence or absence of Hypertension or any musculoskeletal symptoms was used to construct Multilayer perceptron (MLP) using artificial neural networking

(ANN). ROC analysis of FRAX MOF & MLP in predicting FF was done and Area Under Curve (AUC) compared. SPSS ver21 used Results: Comparison of FRAX based risk (Fig1a) versus MLP based immunometabolism model (Figure 1b) in predicting Fragility fracture in primary hypothyroidism showed MLP to be better than FRAX (AUC 0.67 Vs 0.754). ANN with 18 immunometabolic parameters shown in fig2 Conclusion: ANN algorithm employing immunometabolic factors is more effective than traditional FRAX MOF scores in predicting fragility fracture. Future studies defining fracture risk in primary autoimmune hypothyroidism should focus on disease specific immunometabolic factors.

Bone Deficits in Ambulatory Children and Adults with Cerebral Palsy Are Not Severe or Progressive *Tishya Wren[1], Adriana Liang[1], Veronica Beltran[1], Robert Kay[1]. [1]Children's Hospital Los Angeles, United States

Children with severe cerebral palsy (CP) are known to have low bone mass, with dual-energy x-ray absorptiometry (DXA) areal bone mineral density (BMD) Z-scores several standard deviations below normal. Less is known, however, about bone mass in adults and more functional persons with CP. The purpose of this study was to measure DXA Z-scores in ambulatory children and adults with CP to determine the effects of age and severity level. We hypothesized that Z-scores would be lower in less functional subjects and would decrease with age. 83 subjects (52 male) with CP ages 6-46 years (mean 19.0, SD 9.4) underwent DXA imaging (Hologic Horizon A) of the spine and bilateral hips following standard clinical procedures. CP severity was classified using the Gross Motor Function Classification System (GMFCS). All subjects were ambulatory (using assistive devices if needed) with 28 (34%) in GMFCS I, 36 (43%) in GMFCS II, and 19 (23%) in GMFCS III. The relationship of DXA BMD Z-scores from the lumbar spine, right femoral neck, and right total hip to age and GMFCS level was examined using univariate, followed by multivariate, linear regression. Surprisingly, DXA Z-scores showed no relationship to GMFCS level or age in univariate and multivariate analysis ($p>0.45$). Z-scores were slightly below normal, averaging -0.67 (SE 0.15) for the lumbar spine ($p<0.0001$), -0.83 (SE 0.14) for the femoral neck ($p<0.0001$), and -0.58 (SE 0.14) for the total hip ($p=0.0001$). In contrast to more severely involved children with CP in GMFCS levels IV and V, who are non-ambulatory or minimally ambulatory and have very large deficits in BMD, ambulatory children and adults with CP appear to have much smaller bone deficits through middle age with average Z-scores between -0.5 and -0.9. In addition, bone deficits did not worsen with age or disease severity, contrary to expectations. These results suggest that most ambulatory persons with CP generate enough mechanical loading to build and maintain bone mass close to peers of the same age. While modest bone deficits are present and age-related bone loss is still a concern, osteopenia and osteoporosis may not be as severe a problem as feared for more functional and ambulatory persons with CP.

Significant bone loss in bone marrow transplant patients over 3884 person-years of follow up *Joanna Gong[1], Cherie Chiang[2], John Wark[3], David Ritchie[4], Yvonne Panek-Hudson[5], Minh Le[1], Lydia Limbri[6], Nicolo Fabila[6], Spiros Fourlanos[7], Christopher Yates[8]. [1]The Royal Melbourne Hospital, Australia. [2]Head of Chemical Pathology, The Royal Melbourne Hospital, and The Peter MacCallum Cancer Centre, Australia. [3]Previous Head of Bone & Mineral Medicine, The Royal Melbourne Hospital, and Professor of Medicine, The University of Melbourne, Australia. [4]Head of Allogeneic Stem Cell Transplantation, The Royal Melbourne Hospital & The Peter MacCallum Cancer Centre, Australia. [5]The Peter MacCallum Cancer Centre, Australia. [6]The University of Melbourne, Australia. [7]Director of the Department of Diabetes & Endocrinology, The Royal Melbourne Hospital, Australia. [8]Head of Bone & Mineral Medicine and Head of the Bone Densitometry Unit, The Royal Melbourne Hospital, and Co-director of Research, Department of Endocrinology & Diabetes, Western Health, Australia

As outcomes from allogeneic bone marrow transplantation (BMT) continue to improve, monitoring for longer-term complications becomes increasingly important. Decline in bone health post BMT is well-established, although the pathophysiology is multifactorial and unique. Currently available fracture risk calculators do not adequately predict fracture risk in these patients.We aimed to evaluate the fracture risk and decline in areal bone mineral density (aBMD) and trabecular bone score (TBS) post BMT.Patients who attended Royal Melbourne Hospital BMT clinic from 2005-2018 and responded to a patient questionnaire, and those who underwent BMT and had a DXA scan with TBS between 2019-2021, were included. Patient characteristics and DXA values were collected from the electronic medical record and questionnaires. TBS iNsight was used to calculate TBS and FRAX® was used to calculate probability of fracture.337 patients were eligible for inclusion. Patients were primarily male (60%) and mean age was 45.6+/-13.4 years. Baseline DXA T-scores for aBMD were relatively preserved: median (IQR) T-score -0.56 (-1.40?0.48) at the lumbar spine, -1.00 (-1.79?0.02) at the femoral neck, and -0.59 (-1.39?0.39) at the total hip. The annualised decline in aBMD was greater at the femoral neck (4.6%; 3.2g/cm2 (0.18?8.2)) and total hip (4.7%; 4.6g/cm2 (0.64?9.5)), compared to the spine (3.2%; 2.4g/cm2 (-0.16?7.6)). BMD loss occurred most rapidly in the first year post BMT, after which the rate of decline slowed. Post BMT, 18 patients (5.3%) had 19 fractures over 3884 person-years of follow-up (median 11 years (8.2?15)). This corresponds to a 4.9% fracture prevalence over 10 years, significantly higher than FRAX estimates. For the 50 patients with TBS data, the FRAX risk of major osteoporotic fracture was 2.7%. There was no association between fracture post BMT and graft-versus-host disease, total body irradiation or annualised decline in aBMD at any site. Twenty-one (6.2%) patients received antiresorptive therapy; among fracture patients, only 8 (44%) received treatment. In the subgroup of 50 patients with TBS and sequential DXA data, TBS declined independently of aBMD T-scores at all sites.There is significant bone loss post BMT, with a higher fracture rate than predicted by FRAX®. Novel tools such as TBS may help to assess bone fragility in this group. Adjustments to existing fracture risk calculators may be required to guide the use of antiresorptive therapy.

Western Diet Alters Gut-bone Axis in IL-10 KO Mice in a Sex Dependent Manner *Pelumi A. Adedigba[1], Sanmi E. Alake[2], Bethany H. Hatter[2], Islam Proapa[2], Leo Perez[2], John A. Ice[2], Trina A. Knotts[3], Edralin A. Lucas[2], Brenda J. Smith[4]. [1]Indiana Center for Musculoskeletal Health, Indiana University-Purdue University Indianapolis, United States. [2]Department of Nutritional Sciences, Oklahoma State University., United States. [3]Department of Surgery, Center for Alimentary Metabolic Sciences, UC Davis Health, United States. [4]Department of Obstetrics and Gynecology and Indiana Center for Musculoskeletal Health, Indiana University-Purdue University Indianapolis, United States

Loss of interleukin (IL)-10, an anti-inflammatory cytokine, has been associated with gut inflammation and bone loss in animal models and patients with inflammatory bowel diseases. A high fat, high sugar western diet (WD) contributes to gut dysbiosis and bone loss. This study aimed to determine if the absence of IL-10 exacerbates the impact of a WD on the gut-bone axis in male and female mice. 8-wk-old B6.129P2-Il10tm1Cgn/J (KO) and C57BL/6 (WT) were assigned to 4 groups in 2x2 factorial with diet (Control [CO] or WD) and strain (WT or KO). After 3 mo, bone mineral density (BMD) and trabecular and cortical bone microarchitecture, serum biomarkers, gene expression, and the gut microbiota profile were assessed. Data were analyzed using 2-way ANOVA. Both the female and male KO mice exhibited reduced (P<0.001) whole body BMD and trabecular bone volume (BV/TV) in the femur compared to WT mice. In WT mice on WD, BMD was unaltered in either sex, but BV/TV was decreased in the females. Only the female KO mice on WD exhibited an unexpected increase (P<0.001) in BMD and BV/TV compared to KO-CO. WD increased (P<0.05) femoral cortical thickness and cortical area in both strains and sexes. In females, the expression of bone morphogenetic protein 2 (BMP2), osteocalcin (BGALP-2), and collagen, type 1, (COL1A1), genes involved in osteoblast differentiation and activity, as well as genes expressed by osteocytes (i.e., dentin matrix acidic phosphoprotein 1 (DMP1), SOST, phosphate-regulating endopeptidase homolog X-linked (PHEX)) were increased (P<0.05) in KO-WD vs. KO-CO, but not in WT mice. However, there were no changes in gene expression in male mice. In females, WT-WD increased (p<0.05) serum intact FGF-23 (iFGF-23) compared to WT-CO. In contrast, WD normalized the KO-induced increase in iFGF-23. In male mice, WD reduced (P<0.01) iFGF-23, irrespective of strain. Intestinal activity of ?-glucuronidase (bGUS), which deconjugates estrogens, was reduced (P<0.01) in the male and female KO mice, and WD increased (P<0.01) bGUS in both strains and sexes. The microbiota analysis revealed the relative abundance of lactobacillus and bifidobacterium was suppressed (P=0.05) by WD. Our findings indicate that WD does not exacerbate the bone phenotype in IL-10 KO mice. However, in the absence of IL-10, WD consumption restored bone in female but not male mice, a response potentially mediated through gut-derived estrogens and Fgf23 signaling.

SAT-079

LSD1 is Important for Physiological, but not Inflammatory Induced Osteoclast Differentiation *Kristina Astleford-Hopper[1], Jennifer Auger[2], Bryce Binstadt[2], Elizabeth Bradley[3], Kim Mansky[4]. [1]University of Minnesota School of Dentistry, United States. [2]University of Minnesota Medical School, United States. [3]University of Minnesota , United States. [4]University of Minnesota, United States

Receptor activator of NF-kB ligand (RANKL) is the only known physiological inducer of osteoclast differentiation; however, we understand much less about the mechanisms driving osteoclast differentiation during inflammatory conditions. Therapies that block TNF-? successfully inhibit bone erosion in RA; however, we still do not understand why inflammatory cytokines such as TNF-? do not induce osteoclastogensis independent of RANKL. A recent study demonstrated that TGF-? reprograms TNF-? stimulation of macrophages towards inflammatory osteoclast differentiation by downregulating interferon regulated genes. Lysine-specific demethylase 1 (LSD1, KDM1A) functions as a transcriptional co-repressor/co-activator and histone demethylase catalyzing the removal of mono- and di-methyl groups from histone 3 lysine 4 (H3K4) and histone 3 lysine 9 (H3K9). To determine the role LSD1 plays in regulating cells of the myeloid lineage including osteoclasts, we bred Lsd1fl/fl mice with mice expressing LysM-driven Cre. Our previous data demonstrated that conditional deletion of LSD1 (Lsd1cKO) reduced osteoclast differentiation leading to osteopenia in female mice. Additionally, increased expression of IFN-? stimulated genes resulted in decreased osteoclast differentiation of Lsd1cKO mice. To better understand the role of LSD1 in osteoclasts under inflammatory conditions, we sequentially primed Lsd1WT and Lsd1cKO bone marrow macrophages (BMMs) with TGF-? for two days before stimulating with TNF-? in the absence of RANKL. Additionally, we used a rheumatoid arthritis model (K/BxN serum transfer) to determine if loss of LSD1 mitigates bone loss in inflammatory diseases. We found that treating Lsd1cKO BMMs with TGF-? followed by TNF-? did not impact the size and number of TRAP+ multinuclear cells as compared to Lsd1WT. These results contrast with our previous data where Lsd1cKO monocytes were stimulated with RANKL and M-CSF. Additionally, we found that Lsd1WT and Lsd1cKO mice given K/BxN serum have statistically similar clinical scores and ankle thickness, supporting that under inflammatory conditions, the loss of LSD1 does not significantly affect osteoclast differentiation. These data demonstrate that ablation of LSD1 reduces bone loss mediated by physiological osteoclast activity, but other LSD1-independent pathways promoting inflammatory-induced osteoclastogenesis.

Impact of FasL deficiency on osteoblastic cells with focus on intramembranous bones *Adela Kratochvilova[1], Martina Zapletalova[1], Janka Gregorkova[1], Reinhard Gruber[2], Eva Matalova[1]. [1]Institute of Animal Physiology and Genetics CAS, Czech Republic. [2]University Clinic of Dentistry, Medical University of Vienna, Austria

FasL is a key molecule in the immune system participating in regulation of cell number via apoptosis, however the spectrum of its functions appears much broader. This applies also for the bone. Recently, FasL was demonstrated to impact expression of sclerostin (Sost), the major osteocytic marker, and also to be required for osseous healing in extraction sockets. The latter finding was shown in gld (FasL deficient) mice.To further follow these observations, the transcriptomic profile (based on RNA Sequencing) of primary gld osteoblastic cells with potential to differentiate into osteocytes (Sost-positive cells) was compared with corresponding wild type samples (intramembranous bone origin). To this type of bones belongs also the alveolar bone being a component of the periodontal apparatus necessary for functional dentition.The majority of affected genes have been involved in formation and mineralization of the extracellular matrix (ECM). The alterations were morphologically visible also in the cell cultures and based on activity of alkaline phosphatase. Along with these core groups of genes, those known from regulation of vasculature development (angiogenesis), cell migration and morphogenesis were identified. Notably, some genes associated with tooth mineralization were also impacted. In more details, Tgfb ligands were investigated to follow possible interactions within cytokine networks and metalloproteinases (Mmps) as the key proteases within the ECM. While Tgfb ligands were upregulated, the majority of Mmps was downregulated in the gld cells. The reactome analysis pointed to several additional groups of genes being recently investigated to provide a more complex evaluation of the data.In general, there was obtained a robust dataset which can be used for further analyses of non-apoptotic functions of FasL in tooth and bone related cells, including tooth-bone interface.

SAT-082

Deletion of Vhl in Dmp1-expressing cells induces splenic stress erythropoiesis *Janna Emery[1], Betsabel Chicana[1], Hanna Taglinao[1], Citlaly Ponce[1], Cristine Donham[1], Aimy Sebastian[2], Scott Trasti[3], Jennifer Manilay[1]. [1]University of California, Merced, United States. [2]Lawrence Livermore National Laboratory, United States. [3]Texas Tech University Health Sciences Center, United States

In recent years, several hypoxia-inducible factor (HIF)-prolyl hydroxylase (PHD) enzyme inhibitors have been developed for the treatment of anemia of renal disease and more recently, for osteoporosis. However, it remains a challenge to target the HIF signaling pathway without dysregulating the skeletal and hematopoietic system and causing off target metabolic, hormonal, and renal effects. Previous work in Dmp1-Cre; Vhl conditional knockout (VhlcKO) mice, where Vhl is deleted in subsets of mesenchymal stem cells, late osteoblasts, and osteocytes, indicated drastic defects in B lymphocyte development in the bone marrow (BM), which could be a potential side effect in HIF-PHD inhibitor-treated patients. Here, we examined the effects of Vhl deletion in bone by performing longitudinal analyses of VhlcKO mice at 3, 6, 10, and 24 weeks of age, where at 10 and 24 weeks of age, high bone mass and splenomegaly are present. Using flow cytometry, we observed increased frequency (%) of CD71-TER119+ orthochromatophilic erythroblasts in 10- and 24-week-old VhlcKO BM, which correlated with the elevated erythropoietin (EPO) levels in the BM, and our complete blood count analysis, where we found increased number of red blood cells (RBC) in circulation. The absolute numbers of myeloerythroid progenitors (MEPs) in the BM were significantly reduced. Bulk RNA-Seq of the MEPs showed upregulation of Hif1a and Hif2a in VhlcKO MEPs, consistent with a response to hypoxia, and genes involved in erythrocyte development, actin filament organization, and response to glucose. Vhl expression was similar in control and VhlcKO MEPs, ruling out aberrant activity of Dmp1-Cre in MEPs. WT?VhlcKO chimeras confirmed a cell-extrinsic effect on erythroblast development. We also observed a polycythemic phenotype and marked hypoglycemia in VhlcKO mice, which may reflect increased glucose uptake in both RBC and bone. Additionally, histological analysis of VhlcKO spleens revealed red pulp hyperplasia and the presence of megakaryocytes, both of which are features of extramedullary hematopoiesis (EMH). EMH in the spleen was correlated with the presence of mature stress erythroid progenitors, suggesting that stress erythropoiesis is occurring to compensate for the BM microenvironmental irregularities. Our studies implicate HIF-driven alterations in skeletal homeostasis with BM microenvironmental changes that accelerate erythropoiesis.

Effects of Systemic PPAR? Inhibition on Bone and Immune Cells in Aged Female Mice *Xingming Shi[1], Kehong Ding[1], Raysa Rosario[1], Ashwin Ajith[1], Yun Su[1], Sean Shaw[1], Meghan McGee-Lawrence[2], Xin-Yun Lu[1], Anatolij Horuzsko[1], Carlos Isales[1]. This study investigates the effects of peroxisome proliferator-activated receptor gamma (PPAR?) inhibition on bone and immune cell profile in aged female mice, as well as in vitro MSC osteogenic differentiation and inflammation gene expression. The hypothesis was that inhibition of PPAR? would increase bone mass and alter immune and other cellular functions. Our results showed that treatment with PPAR? antagonist GW9662 for six weeks reduced bone volume and trabecular number and increased trabecular spacing. However, inhibition of PPAR? had no significant effect on marrow and spleen immune cell composition in aged female mice. In vitro experiments indicated that GW9662 treatment increased the expression of osteogenic genes but did not affect adipogenic genes. Additionally, GW9662 treatment decreased the expression of several inflammation related genes. Overall, these findings suggest that PPAR? inhibition may have adverse effects on bone in aged female mice.

C. acnes Related Bone Prothesis Infection: How Osteoblasts May Rule the Innate Immune Response *Léa Thoraval[1], Min Tang-Fichaux[1], Jennifer Varin-Simon[1], Christine Guillaume[1], Sophie C. Gangloff[1], Céline Mongaret[1], Fany Reffuveille[1], Frédéric Velard[1]. [1]URCA, EA 4691 BIOS, France

Purpose: Cutibacterium acnes is a commensal skin bacterium, involved in bone prosthesis infections (BPI) [Boisrenoult, 2018]. C. acnes infections mainly present low-grade clinical symptoms that delay the diagnosis [Portillo, 2013]. This led us to hypothesize that C. acnes could escape immune system in bone site. This work aims to study the ability of osteoblasts (OB) infected with clinical and non-clinical strains of C. acnes to trigger innate immune cells response.Methods: Human primary OB (n=4), cultured on titanium alloy, were infected with two C. acnes strains (a reference and a BPI-related strain) for 3h (MOI 20:1 and 200:1). After 24h, human primary neutrophils (PMN) (n=16) were put into contact with infected OB for 4h. Pro-inflammatory mediators' production (IL-8, TNF-?, MCP-1, IL-6, MIP-1?) by OB, infected or not with C. acnes, and then by the PMN/OB/C. acnes trio or PMN challenged with infected OB conditioned supernatants, was determined by ELISA. Confocal fluorescence microscopy and scanning electron microscopy allowed to visualize these complex interactions.Results: We demonstrated a C. acnes-induced increased secretion of IL-8, IL-6 and MCP-1 by OB ($p<0.05$ vs uninfected OB) only at MOI 200:1. Conditioned supernatants from infected OB did not trigger PMN response, whereas PMN/infected OB contact elicited a MOI-dependent production of IL-8, TNF-? and MIP-1? ($p<0.05$ vs uninfected OB/PMN interaction) by PMN. OB-mediated IL-6 and MCP-1 production was also noticed but only in the triple interaction thanks to cell/cell contact with PMN. Previous data evidenced a more sustained inflammatory response with BPI strain in direct contact with PMN or in mice air pouch model in vivo, conversely, no differences were found here between both strains. Fluorescence microscopy showed the presence of C. acnes in both OB and PMN, while scanning electron microscopy highlighted an absence of bacteria at the cell surface, indicating an effective clearance by PMN, and a real ability of OB to hide C. acnes from PMN.Conclusion: This work suggests that C. acnes could escape immune system by at least partial internalization within the OB. The immune response elicited in this model appeared to be reduced for the clinical strain compared to that observed without OB in our previous work. Even if precise mechanisms remain to be elucidated, these results show for the first time that OB may temper the immune response to C. acnes despite production of inflammatory mediators.

Compromised Bone Microarchitecture and Fragility in Ovariectomized Mice is Reversed by a Novel Immunotherapy *Di Wu[2], Anna Cline-Smith[2], Deborah Veis[3], Rajeev Aurora[2]. [2]Saint Louis University School of Medicine, . [2]Saint Louis University School of Medicine, United States. [3]Washington University in St. Louis School of Medicine, United States

Patients with low bone mineral density (BMD) are at high risk of fragility fractures. However, accumulating clinical data demonstrates that ~ 15% of people with normal BMD experience fragility fractures, indicating that bone mass and bone quality are independent parameters. The osteolineage, which includes osteoblasts and the osteocytes, plays a key role in maintaining the microarchitecture. Bone quality is reflected by the microarchitecture, and its contribution to fracture resistance is less well understood than bone mass. Over the past three decades, studies revealed that T-cell produced cytokines, particularly TNF? and IL-17A, play a role in the pathogenesis of postmenopausal osteoporosis (PMOP) by stimulating osteoclasts to favor bone resorption. Our lab has described a pathway in which TNF? and IL-17A produced by memory T cells in the bone marrow is necessary for bone erosion in ovariectomized (OVX) mice. We hypothesize that inflammation post estrogen loss targets the osteolineage to degrade bone quality. In this study, we evaluated bone quality by four parameters: collagen organization by picrosirius red staining and CT-FIRE analysis; lacunar-canalicular network (LCN) integrity by rhodamine staining; osteocyte network connectivity by phalloidin staining; and biomechanical strength normalized to bone mass. We show that OVX of 12-week-old C57BL/6 (n = 5 in each group) leads to diminished fracture resistance, disorganized collagen matrix, disrupted LCN and decreased osteocyte connectivity. To determine whether these alterations are dependent on T-cell produced TNF? and IL-17A, we are comparing C57BL/6, TCR?KO, and IL-15RA?TKO mice. We expect this comparison to illuminate the different contributions of estrogen loss, T cells and cytokines. In addition, our lab has also shown that pulsed low dose RANKL (pRL) induces CD8+ FoxP3+ regulatory T cells (TcREG). TcREG induction in OVX mice is anti-resorptive, bone anabolic, and limits production of TNF? and IL-17A. Here, we show that pRL treatment improves the biomechanical properties of the bone post OVX in WT mice. We also show that the anabolic effects of pRL is IL-10 dependent, as treatment in IL-10KO mice post OVX had no effect on bone quality. Taken together, our data demonstrates that the compromised microarchitecture observed in PMOP can be modeled using OVX in mice and that pRL is a promising immunotherapy that improves bone quality in addition to bone mass.

In vitro effects of Tanshinone and Ligustrazine promoting the differentiation of primary endothelial cells into type H vascular endothelial cells *Xiaohui Hu[1], Kanghui Sun[1], Liqiang Guo[1], Ziyu Huang[1], Jing Wang[2], Yongjian Zhao[1], Dongfeng Zhao[1], Yongjun Wang[1], Bing Shu[2]. [1]Longhua Hospital, Shanghai University of TCM, China. [2]Shanghai University of TCM, China

Background: type H blood vessels play an important role in the process of osteogenesis, and Tanshinone and Ligustrazine can protect vascular endothelial cells and promote angiogenesis. Objective: to observe the effects of Tanshinone and Ligustrazine on primary endothelial cells differentiation into type H vascular endothelial cells. Methods: primary endothelial cells were obtained from bone tissue of mice, and were treated with different concentrations of Tanshinone or Ligustrazine solutions respectively for 7 days. The cell survival rate was assessed using the CCK-8 kit, and the generation of CD31+ EMCN+ type H vascular endothelial cells and their proportion in the total cells were detected by immunofluorescence staining and flow cytometry, respectively. Results: no significant effects on cell survival of different concentrations of Tanshinone and Ligustrazine were observed. Tanshinone and Ligustrazine dose-dependently promoted the differentiation of primary endothelial cells into type H vascular endothelial cells. Ligustrazine solution of 100 ?M could increase the percentage of type H vascular endothelial cells in primary endothelial cells to nearly 20%. Conclusion: Both Lanshinone and Ligustrazine can promote the differentiation of primary endothelial cells into type H vascular endothelial cells, which may contributed inthe process of bone repair.

Real Life Use of Bone-Targeting Agents for Bone Metastases in France: the OPTIMOS Study *Cyrille Confavreux[1], Béatrice Bouvard[2], Nicolas Girard[3], Pauline Bosco-Levy[4], Clarisse Marchal[5], Manon Walter[5], Eric Lehmann[6], Gaelle Desamericq[6], Manon Belhassen[5]. [1]INSERM UMR1033-University of Lyon-Hospices Civils de Lyon, France. [2]CHU d'Angers-Univ Angers, Nantes Université, Oniris, UMR 1229 RMeS, France. [3]Institut Curie - Paris Saclay, UVSQ, France. [4]Bordeaux PharmacoEpi-INSERM CIC-P 1401-Université de Bordeaux, France. [5]Pharmaco-Epidémiologie Lyon (PELyon), France. [6]Amgen, France, France

Purpose. Progress in oncology improved survival of bone metastatic (BM) patients highlighting bone health issue. We aimed to describe recent use of bone-targeting agents (BTA) in BM patients in France.Methods. We accessed EGB, a French National Health Insurance database corresponding to 1/97 of the whole population. The algorithm identified adult BM patients either through BM ICD-10 hospitalization code or through the onset of a skeletal-related event (SRE): pathologic fracture, cimentoplasty, spondyloplasty, spinal cord compression, palliative radiotherapy, orthopaedic surgery and malignant hypercalcemia. Inclusion period covered the years 2009-2018. Patients not affiliated to the general health system and patients with primary sarcoma or with prevalent BM during the 3 years preceding inclusion date, have been excluded. Dispensations of clodronate, IV bisphosphonates (zoledronate, pamidronate- IVBP) and denosumab (Dmab), the BTA marketed in France, were recorded. Discontinuation was defined as absence of dispensation of more than 30 days after the end of coverage period.Results. We identified 6663 new BM patients. Mean (SD) age was 69.7 yrs (13.2). Charlson comorbidity index was >= 5 in 5532 (83.0%) of cases. Major primary cancer sites were breast (15.8%), prostate (13.4%), lung (12.6%) and digestive (10.6%). Among BM patients, 4300 (64.5%) had SRE at inclusion. The median [Q1-Q3] follow-up was 1.3 yrs [0.3-3.4] mainly interrupted by death (63.5%) or end of study (35.6%).After inclusion, only 621 (9.3%) patients initiated BTA (327 received Dmab). Median initiation delay was 99 days [37-241] similar in Dmab and IVBP. Patients initiating BTA decreased by two-fold overtime. Proportion of BM patients who discontinued was lower with Dmab than IVBP (43% vs 56%). Treatment persistence lasted longer with Dmab than IVBP (302 days [152-616] vs 180 [90-427]). Among patients included with SRE, the ones with early (<100 days) BTA initiation (N=118 vs 125) had a reduced incidence rate of 2nd SRE (12.9% pers-yrs [8.4-18.9] vs 20.7% [15.7-26.7]) corresponding to a cumulative incidence at 12 months of 13.6% [8.1-20.4] vs 21.6% [14.8-29.2]. Conclusion. Proportion of BM patients treated with BTA in France is low even in secondary prevention. Early BTA treatment is efficient to reduce second SRE. This highlights the need for optimizing BM management in France in accordance to the ESMO guidelines.

Osteosarcoma growth in Fos-transgenic mice is limited by Rsk2 and Lrp5 deficiency via different mechanisms *Armelle Carreau[1], Christina Baldauf[1], Mona Neven[2], Olga Winter[1], Julia Luther[1], Michael Amling[1], Jean-Pierre David[1], Thosten Schinke[1]. [1]Department of Osteology and Biomechanics University Medical Center Hamburg-Eppendorf, Germany. [2] Department of osteology and Biomechanics University Medical Center Hamburg-Eppendorf, Germany

Since specific treatment options for osteosarcoma are still limited, it is required to better understand the molecular mechanisms that control proliferation and/or differentiation of the transformed bone-forming osteoblasts. Using a Fos-transgenic mouse model spontaneously developing osteosarcomas, we have previously shown that inactivation of the ribosomal S6 kinase 2 (Rsk2) strongly impairs osteosarcoma growth.Using cell lines derived from FosTg;Rsk2-/- tumors we observed that Rsk2 deficiency impaired the growth advantage of FosTg cells, which was explained by aberrant nuclei number due to impaired cytokinesis suggesting the induction of "mitotic catastrophe". A similar influence was observed by treatment of FosTg cells with a pharmacological Rsk inhibitor (BI-D1870). Moreover, since BI-D1870 administration to FosTg cell lines reduced expression of aurora kinase B, the influence of a pharmacological aurora kinase B inhibitor (Hesperadin) was also tested. Similar to BI-D1870, Hesperadin caused impaired cytokinesis, resulting in the accumulation of polynuclear cells, an effect that was not only observed in FosTg cell lines, but also in the human osteosarcoma cell line U2OS.We next focused on targeting a more osteoblast-specific pathway involving the transmembrane protein Lrp5, which acts as a co-receptor of Wnt ligands. To analyze the role of Lrp5 in osteosarcoma growth, FosTg mice were crossed with Lrp5-deficient mice or with mice carrying a high bone mass mutation of Lrp5 (Lrp5A213V/+). It was found that Lrp5 deficiency drastically reduced the osteosarcoma volume in FosTg mice, which was explained by a decreased number of active osteoblasts at the tumor surfaces associated with the appearance of large unmineralized areas. Cell lines were established from the three FosTg mouse models with different Lrp5 genotypes, however growth curve and mineralization analyses did not reveal significant differences, thereby suggesting a non-cell-autonomous mechanism.Taken together, this study identified the relevance of both, the Rsk2 and the Lrp5 pathway, for osteosarcoma formation, yet the impairment of osteosarcoma growth by Rsk2 or Lrp5 deficiency are explained by different mechanisms.

Population Dynamics-Based Model to Predict Tumor Cell Interactions with Bone Resident Cells *Natalie Bennett[1], Alexandra Gutierrez Vega[2], Leonard Harris[2], Julie Rhoades[1]. [1]Vanderbilt University, United States. [2]University of Arkansas, United States

Tumor-induced bone disease (TIBD) is the result of signaling between tumor cells and bone resident cells, such as osteoclasts and osteoblasts, that ultimately results in osteolysis. This leads to severe clinical manifestations such as pain and pathologic fractures. Standard-of-care cancer therapies such as chemotherapy and immunotherapy are not curative for bone metastases, and the unique physical and cellular characteristics of the bone microenvironment can lead to drug resistance and immune exclusion. Computational models are a valuable tool to better understand how cell-cell interactions can lead to disease progression. There are several published mathematical models that demonstrate the process of homeostatic bone remodeling via interactions between osteoclasts and osteoblasts, including some that incorporate key signaling components such as the receptor activator of nuclear factor kappa-B (RANK) - RANK ligand axis. While some models of the bone microenvironment include malignant cells, there are none to our knowledge that specifically model the interactions between bone resident cells and metastatic breast cancer cells. We aim to develop a population dynamics-based mathematical model that can demonstrate how signaling between breast cancer cells, osteoclasts, and osteoblasts drives bone destruction. While many other models are based on theoretical data, our analyses will be based on tumor growth and bone destruction measurements in experimental murine models of TIBD. Our preliminary model is able to recreate experimental data of tumor growth and resultant bone loss. Furthermore, our model will incorporate tumor-secreted parathyroid hormone-related protein (PTHrP), a downstream target of the transcription factor Gli2, which is an essential driver of bone metastases. The outputs of this model can then be verified with in vitro co-culture experiments and in vivo tumor models with modified Gli2 and PTHrP activity. Overall, capturing the critical cell-cell interactions in TIBD via this novel computational model will enhance our understanding of the bone metastatic microenvironment and can eventually be expanded by incorporating additional cell populations. Computational modeling is a robust technique to evaluate the potential clinical impacts of targeting pathways that drive disease, which is an essential step toward overcoming drug resistance in TIBD.

The role of SWAP-70 in bone formation and osteosarcoma progression *Laura Di Giuseppe[1], Jacopo Di Gregorio[2], Sara Terreri[2], Madalina Maftei[2], Giulia Battafarano[2], Salvatore Minisola[1], Andrea Del Fattore[2], Michela Rossi[2]. [1]Department of Clinical, Internal, Anaesthesiology and Cardiovascular Sciences, Policlinico Umberto I, "Sapienza" University of Rome, Rome, Italy, Italy. [2]Bone Physiopathology Unit, Genetics and Rare Diseases Research Area, Bambino Gesù Children's Hospital, IRCCS, Rome, Italy, Italy

Introduction: Osteosarcoma is the most common primary bone tumour, particularly prominent among adolescents and young adults. The therapeutic strategies for osteosarcoma involve both surgery and chemotherapy, but the identification of new therapeutic targets is needed in patients with chemo-resistance, recurrence and metastases. Our study aims to investigate the mechanisms by which the phosphatodylinotsitol trisphophate (PIP3) binding protein SWAP-70 controls osteosarcoma progression. SWAP-70 is involved in actin rearrangement, phagocytosis and cell migration. It also plays an important role in the oncogenesis of many malignant tumors. However, the role of SWAP-70 in osteosarcoma has not been previously investigated.Methods: Gene and protein expression, proliferation, cell migration, invasion, apoptosis, ALP activity and mineralization were evaluated by in vitro assays.Results: To understand the role of SWAP-70 in tumour progression, we analysed its expression in mesenchymal stem cells (MSC), osteoblasts and Saos-2 osteosarcoma cells. Our data evidenced that SWAP-70 increases during osteoblast differentiation from MSC to osteoblasts and its expression is not detected in Saos-2. To further study the role of SWAP-70 in osteosarcoma, we transfected Saos-2 cells with vector overexpressing SWAP-70 (pSWAP-70) or empty plasmid (pEmpty). The overexpression of SWAP-70 in Saos-2 increased the expression of RUNX2, SP7, ALP, DMP1 and MEPE. SWAP-70 overexpressing Saos-2 cells showed reduced proliferation rate [Proliferative rate; pEmpty: 1.000+/-0.007, pSWAP-70: 0.815+/-0.119. **p<0.01], decreased migration [Wound closure (%); pEmpty: 100.000+/-1.000, pSWAP-70: 52.110+/-20.760. *p<0.05] and invasion abilities [Absorbance (%); pEmpty: 100.000+/-1.000, pSWAP-70: 62.540+/-11.260. **p<0.01] compared to empty vector transfected cells. No substantial changes between pEmpty- and pSWAP-70-transfected cells were detected in the apoptosis induced by H2O2 treatment. Moreover, increased ALP [ALP intensity; pEmpty: 1.000+/-0.008, pSWAP-70: 1.386+/-0.157. **p<0.01] and 2-fold higher ability to form mineralized nodules were revealed in SWAP-70 overexpressing cells.Conclusion: Our results showed that the overexpression of SWAP-70 in Saos-2 induced osteoblast differentiation of osteosarcoma cells, suggesting that SWAP-70 could act as an onco-suppressor and represent a novel therapeutic target for this rare paediatric tumour.

SAT-099

High dose melphalan induces senescence features in multiple myeloma cells

*ANGELO GUILATCO[1], GABRIEL ALVARES BORGES[1], Tamar Tchkonia[2], James L Kirkland[2], Taxiarchis Kourelis[3], Matthew Drake[4], Megan Weivoda[5]
[1], , [2]Robert and Arlene Kogod Center on Aging, Mayo Clinic, United States, [3]Division of Hematology, Mayo Clinic, United States, [4]College of Medicine, Mayo Clinic, United States, [5]Mayo Clinic, United States

Multiple myeloma (MM) is a clonal plasma cell malignancy. MM cells can persist after treatment, where they exhibit growth arrest and chemotherapy resistance: features consistent with tumor dormancy. These cells may regain proliferative capacity to drive relapse. Thus, understanding these cells is key to achieving durable response in MM. Cytotoxic chemotherapies, including those used in MM (e.g., high dose melphalan, HDM), drive senescence in many tissues. Senescence shares many features with dormancy, including growth arrest and apoptosis resistance. Therefore, we hypothesize that MM cells persisting after HDM exhibit therapy-induced senescence.5TGM1 mouse MM cells were treated with vehicle (Veh) or HDM (10uM, IC90) for 6 hours. Cells were washed and plated in the presence/absence of wildtype C57BL/6 bone marrow stromal cells (BMSCs) in normal media for 2 weeks. Cells were counted during media changes to track proliferation. HDM-5TGM1 cells exhibited substantial cell death following treatment; HDM-5TGM1 cultured alone did not survive past 48 hours. Co-culture with BMSCs maintained survival of a portion of HDM-5TGM1 cells. This was not reproduced with BMSC conditioned media, suggesting that direct cell interactions are required. HDM-5TGM1 with BMSCs exhibited a significant growth arrest and increased size compared to Veh-5TGM1 for at least 10 days. To validate senescence features, Day 10 HDM-5TGM1 cells were stained for telomere-associated DNA damage foci (TAFs) and assessed for gene expression. HDM-5TGM1 had significantly more TAFs than Veh-5TGM1, reflecting persistent DNA damage signaling in senescence. HDM-5TGM1 demonstrated upregulation of myeloid/dormancy markers (Axl, Fcer1g, Csf1r, Mpeg1) as well as significantly increased senescence markers (Cdkn1a, Cdkn1c, Glb1), anti-apoptosis (Bcl2l1), and senescence associated secretory phenotype genes (Ccl5, Icam1, Mmp13). Further, HDM-5TGM1 were more sensitive to navitoclax senolysis. After 14 days, clusters of HDM-5TGM1 that regained proliferative capacity were detectable, suggesting escape from senescence-like growth arrest.Our findings demonstrate that direct interactions with BMSCs facilitate survival of HDM MM cells, which go on to develop features of therapy-induced senescence. However, this is a temporary response. These data suggest that targeting senescence anti-apoptosis pathways following HDM may be a viable therapeutic strategy to eliminate surviving MM cells and prevent disease relapse.

Abnormal Structures in Prostate Cancer Metastatic Bone Lesions as a Fracture Risk Factor

*Naomi Jung[1], Qiong Wang[2], Felipe Eltit Guersetti[1], Danmei Liu[3], Samuel Xu[1], Sheryl Munshan[1], Eva Corey[4], Colm Morrissey[4], Lawrence True[5], Rizhi Wang[6], Michael Cox[1], [1]Department of Urologic Sciences, University of British Columbia; Vancouver Prostate Centre, Canada, [2]Department of Materials Engineering, University of British Columbia, Canada, [3]Centre for Aging SMART at VCH, Canada, [4]Department of Urology, University of Washington, United States, [5]Department of Pathology and Laboratory Medicine, University of Washington, United States, [6]Department of Materials Engineering, University of British Columbia; School of Biomedical Engineering, University of British Columbia , Canada

Prostate cancer (PC) is the most frequently diagnosed male cancer. Improved treatments have dramatically improved survival rates, but 20% of patients will develop metastatic disease, ~70% of whom will suffer from PC bone metastases (PCBM). PCBM reduces quality of life due to intractable pain and high risk of fracture. PCBM lesions are defined as being predominantly osteoblastic/sclerotic. We hypothesize that pain and fracture risk are caused by aberrant matrix deposition in the sclerotic lesions. This study aims to characterize the structure of PCBM-involved bone and the connection between structural changes and increased risk of fracture.We evaluated the bone macrostructure and trabecular properties of 13 PCBM, and 12 control, cadaveric vertebral specimens using micro computed tomography (microCT, Scanco µCT35) at 10 µm voxel size. We performed quantitative backscattered electron scanning electron microscopy (QBSE-SEM) to observe microstructural details. A custom MATLAB script was used to identify lacunae density and properties in osteoblastic bone and control trabeculae.We observed 3 qualitative phenotypes by microCT imaging: mixed-osteolytic with thinned trabeculae and patches of sclerosis (n=4), osteosclerotic with residual trabeculae where new bone deposits on the surface of trabeculae and medullar spaces (n=7), and osteosclerotic with minimal residual trabeculae (n=2). PCBM samples had significantly higher trabecular number, bone volume/total volume, and connectivity density, and significantly lower trabecular separation and tissue mineral density compared to controls. PC sclerotic bone had a greater lacunae density and lacunae area/bone area compared to residual trabeculae by QBSE-SEM. Lacunae in PC sclerotic bone have significantly increased area, circularity, and minor axis length, and decreased major-to-minor axis ratio and eccentricity. Lacunae in sclerotic lesions exhibited a significant loss of anisotropy relative to their strongly aligned organization in trabecular bone.PCBM lesions have altered trabecular bone architecture with a predominantly osteoblastic presentation, and abnormal lacunae density and lacunar characteristics. This macrostructural analysis demonstrates distinct qualitative and quantitative differences between control vertebrae and PCBM lesions. These multiple pathologic structural details indicate that PCBM lesions are subjected to irregular loading of the bone that can elevate fracture risk.

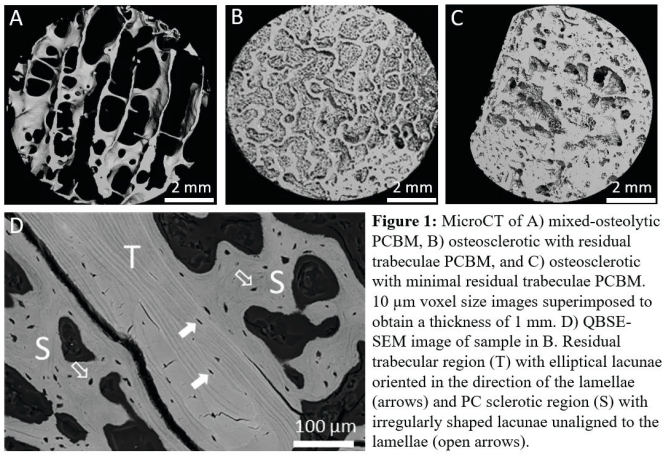

Figure 1: MicroCT of A) mixed-osteolytic PCBM, B) osteosclerotic with residual trabeculae PCBM, and C) osteosclerotic with minimal residual trabeculae PCBM. 10 µm voxel size images superimposed to obtain a thickness of 1 mm. D) QBSE-SEM image of sample in B. Residual trabecular region (T) with elliptical lacunae oriented in the direction of the lamellae (arrows) and PC sclerotic region (S) with irregularly shaped lacunae unaligned to the lamellae (open arrows).

Role of Advanced Glycation End Product in Malignancy on Chondrosarcoma via the Activation of Cancer Stemness

*Rong-Sen Yang[1], Shing-Hwa Liu[2], Ting-Yu Chang[2], [1]National Taiwan University Hospital, Taiwan, Province of China, [2]National Taiwan University, Taiwan, Province of China

Despite epidemiologic evidence suggests that diabetes mellitus is a risk factor for cancer, the link between diabetes mellitus and primary bone cancer is rarely discussed. Chondrosarcomas are primary malignant cartilage tumors with poor prognosis and high metastatic potential. N?-(1-Carboxymethyl)-L-lysine (CML), an advanced glycation end product (AGE), is the major AGE immunological epitope detected in the tissue proteins of diabetes patients. It remains unclear whether AGE affects the stemness and malignancy of chondrosarcoma cells. This study aimed to clarify the role of CML/AGE in the stemness and malignancy of chondrosarcoma. A commercial human chondrosarcoma tissue microarray was used to test the expression of CML and receptor for AGE (RAGE). Human chondrosarcoma cell lines JJ012 and SW1353 cells were cultured. The concentrations at 5-100 ?M of CML were used for in vitro experiments. Male non-obese diabetic (NOD)/severe combined immunodeficiency (SCID) mice with or without streptozotocin (STZ)-induced diabetes with high AGE levels were used for in vivo tumor xenograft experiments (n=10/group) (IACUC approval has been obtained). CML and RAGE were highly expressed in patients' chondrosarcoma tissues with advanced grade (Fig. 1A: representative images; total samples: 80, $p<0.0001$). CML at the concentrations of 25 and 50 ?M enhanced tumor sphere formation (a) and cancer stem cell marker expression (b) (Figure 1B) in both JJ012 and SW1353 cells ($n >= 3$, $p<0.05$). The epithelial-mesenchymal transition (EMT) process and the migration and invasion (Figure 1C) abilities were also induced with CML treatment in both JJ012 and SW1353 cells ($n>=3$, $p<0.05$). Moreover, CML increased the expression levels of RAGE and phosphorylated NF?B-p65 protein in both JJ012 and SW1353 cells (Figure 1D; $n>=3$, $p<0.05$). We also found that diabetic hyperglycemia decreased the body weights (a), facilitated the tumor metastasis (increased lung tissue weights and nodules) (b), and increased blood CML levels (c) in a STZ-treated NOD/SCID mouse model (Figure 1E; $n=10$, $p<0.05$). Our findings revealed the role of CML in chondrosarcoma stemness and metastasis, leading to tumorigenesis and malignancy. CML induced cancer stemness properties, cell migration/invasion, and EMT process in chondrosarcoma cells. These results figure out the importance of CML in chondrosarcoma progression, and may provide a potential prognostic strategy for chondrosarcoma patients, especially in diabetic conditions.

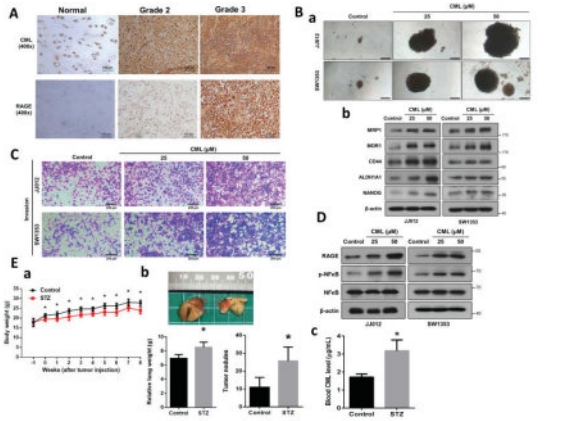

Figure 1. Role of CML in malignancy on chondrosarcoma via the activation of cancer stemness. (A) The CML and RAGE stains in patients' tumor tissues were shown. (B-D) The in vitro sphere formation (B-a) and cancer stem cell marker expression (B-b), transwell invasion (C), and RAGE/NFκB expression (D) were shown. (E) The in vivo xenograft mouse model for body weight (a), tumor lung metastasis (b), and blood CML level (c) were shown. In vitro: results are shown as mean±SD of three independent experiments. In vivo: Tumor nodules were counted in lung tissue. Results are shown as mean±SD (n=10 mice/group). *, $p < 0.05$, compared to the control.

SAT-103

CD36-Sphingosine 1-Phosphate Axis in Non-Malignant Osteoblasts Contributes to Osteosarcoma Progression *InHong kang[1], Uday Baliga[2], Zachariah Hedley[2], Besim Ogretmen[2], Meenal Mehrotra[2]. [1]Medical university of South Carolina, United States. [2]Medical University of South Carolina, United States

Osteosarcoma (OS) is a primary malignant bone sarcoma and main cause of cancer-related mortality in adolescents/young adults, characterized by abnormal osteoid formation. Despite wide-margin surgery and intensification of chemotherapy, overall survival rates have plateaued at 60%. Novel treatment modalities are therefore needed, but mechanisms underlying its spread/metastasis are still largely unclear. Role of tumor microenvironment in tumor progression has recently gained attention. OS develops in a complex/dynamic milieu made up of calcified extracellular matrix as well as bone, stromal, vascular, and immune cells. Although the contribution of other cells has been characterized, very little is known about the contribution of bone cells, particularly osteoblasts. Our findings show that non-malignant osteoblasts (nmObs) significantly increase OS cell invasion in vitro and their metastatic potential in vivo, suggesting a role for nmObs itself in OS progression. RNA sequencing of nmObs showed enhanced accumulation of components of the sphingolipid signaling pathway ($p<0.003$). Increased sphingosine-kinase (SphK1) levels were observed in nmObs in presence of OS cells which co-related with increased Sphingosine-1-phosphate (S1P) levels in the microenvironment in nmObs. S1P significantly increased OS invasion. No increase in OS invasion was seen in the presence of SphK1-/- nmObs, which was restored when S1P was added. Importantly, nmObs-mediated OS cell invasion was prevented by the functional S1P antagonist FTY720. Also, presence of OS cells greatly elevated expression of the fatty acid transporter, CD36, in nmObs. Moreover, CD36-/- nmObs as well as blocking CD36 expression in wild type nmObs by the specific inhibitor SSO or with shRNA, significantly decreased SphK1 expression, S1P secretion into the microenvironment and OS cell invasion. Additionally, OS invasion was significantly increased when S1P was added to CD36-/- nmObs. Furthermore, simultaneous inhibition of CD36 and SphK1 has an additive effect on the decrease in OS progression in vitro and in vivo. We, thus, hypothesize that SphK1 activity is elevated by CD36 mediated lipid intake and increases S1P which in turn is exported to the tumor microenvironment, where it promotes OS development and metastasis. Thus, inhibiting this interaction between CD36-SphK1-S1P and in turn between nmObs and OS cells in the tumor microenvironment, will aid in the development of novel therapeutics to halt OS progression.

Vertebral Osteosclerotic Bone Metastasis Lesions of Prostate Cancer Acquire Altered Extracellular Matrix Characteristics *Bita Mojtahedzadeh[1], Dennis Xie[1], Hans Adomat[1], Felipe Eltit[2], Raphaële Charest-Morin[3], Colm Morrissey[4], Eva Corey[4], Lawrence True[4], Michael Cox[2]. [1]Vancouver Prostate Centre, Canada. [2]Department of Urologic Sciences, University of British Columbia, Canada. [3]Department of Orthopedics, University of British Columbia, Canada. [4]Department of Urology, University of Washington, Seattle, United States

Prostate cancer (PC) bone metastases (BM) is a debilitating disease morbidity that primarily affects the axial skeleton. PCBMs are mixed blastic/lytic with increased, irregular, bone density and deposition, loss of collagen alignment and increased porosity. Under pathological conditions or repair, bone matrix composition is altered and can include cartilage-associated proteins. We hypothesize that PCBMs induce dysregulated repair-like bone remodeling activity resulting in differential deposition and organization of extracellular matrix (ECM) factors relative to residual trabecular bone.We analyzed lumbar vertebrae specimens from 13 cadaveric PCBMs, 6 biopsies from patients undergoing decompression surgery, and 4 age-matched cancer-free donors. We used mass spectrometry (MS) to compare the protein content of sclerotic and lytic vertebral PCBMs vs. cancer-free controls. We performed Goldner's trichrome staining to compare bone matrix organization among specimens. We performed immunohistochemistry (IHC) using antibodies against collagens (COL-I, -II, -III), osteocalcin (OSC), osteopontin (OSP), aggrecan, bone morphogenic protein 2 (BMP2), and alkaline phosphatase (ALP) to evaluate the composition of irregular and residual trabecular PC-associated bone matrix. MS analysis differentially segregated sclerotic and lytic PCBMs from control specimens (Fig. 1A). Differential Goldner's staining of irregular PC-associated bone and lamellar bone under brightfield, and loss of collagen alignment under polarized light in the PCBM specimens confirmed irregular bone interspersed with lamellar (residual trabeculae) bone (Fig. 1B,C). Stronger COL-III (Fig. 1D), OSC and OSP (Fig 1F), and ALP and BMP2 staining in sclerotic regions of PCBMs validated noted MS findings from the sclerotic PCBM specimens. Aggrecan and COL-I levels were indistinguishable between specimen groups, and COL-II was not detected in sclerotic, PC-associated bone. We did not observe evidence of a collagenous matrix switch based on the absence of COL-II and aggrecan. High COL-III content suggests that a process akin to bone repair occurs in the PCBM, while elevated levels of polyanionic proteins, such as OSP, suggest an accelerated process of mineralization. Our observations demonstrate structural and biochemical alterations in irregular PC-associated bone consistent with a hyperblastic dysregulation of matrix deposition that results in a disorganized sclerotic matrix distinct from healing physiology.

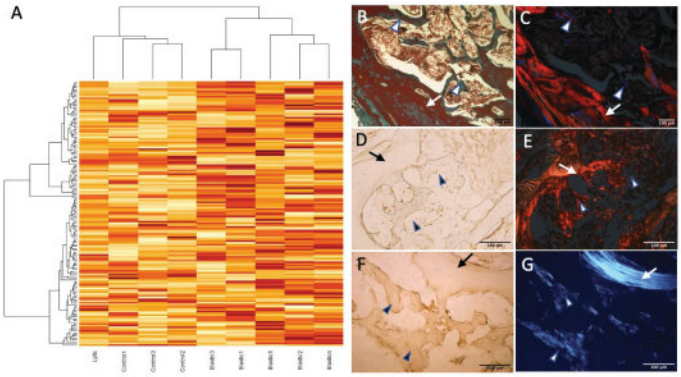

Figure 1. Bone matrix composition and collagen alignment differences between irregular PC-associated bone and lamellar bone. **A)** Differential expression of proteins in sclerotic bone (label: blastic1-5) compared to lytic bone (label: lytic) and cancer-free control bone (label: control1-3) seen via Mass Spectrometry. Protein expression shows higher similarity within groups. **B)** Goldner's trichrome stain shows lamellar bone stained red (arrow) while irregular PC-associated bone stains green (arrowhead). **C,E,G)** Polarized light imaging shows collagen alignment in lamellar bone and non-organized alignment in the irregular PC-associated bone. **D)** Increased staining of collagen-III in irregular PC-associated bone (arrowhead) compared to lamellar bone (arrow). **E)** Increased staining of osteopontin in irregular PC-associated bone (arrowhead), compared to lamellar bone (arrow). Recombinant Adeno-associated Viruses Designed to Target Pediatric Osteosarcoma and Bone Stromal Cells *Patrick Mulcrone[1], Anh K. Lam[1], Erika A. Dobrota[1], Dylan A. Frabutt[1], Pankita H. Pandya[1], Karen E. Pollok[1], Weidong Xiao[1]. [1]Indiana University School of Medicine, United States

As new first-line therapies for primary bone cancers have not been developed for decades, the need for effective, genomically-guided treatments for these tumors is warranted. The viral-based gene therapy, recombinant adeno-associated virus (rAAV), is a powerful biological tool making a positive clinical impact on various diseases, yet it is an underexplored treatment strategy for cancers, including pediatric osteosarcoma (OS). The AAV3 serotype is known to transduce various tumor cells, and AAV9 is being researching for various bone pathologies. In this exploratory project, we hypothesize that rAAV3 and 9 serotype construct designs can be assembled to transduce human OS cells for therapeutic means. We prioritized the p16INK4a cell cycle regulator as aggressive OS typically harbors loss of the CDKN2A gene encoding p16. As high levels of p16 may be a favorable prognostic factor in OS progression, AAV gene therapy could restore proper function of this tumor suppressor. We observed in vitro transduction of the OS cell lines U2OS and Saos2, and the patient-derived xenoline TT2, developed at IUSM, with AAV serotypes 2, 3, and 9. Transduction with rAAV2 or rAAV9 driving expression of the tumor suppressor p16INK4a resulted in elevated levels of p16 protein and significant decreases in proliferation and cell number in vitro. In 3D cultures, a decrease in U2OS tumor spheroid volume transduced with rAAV2-p16INK4a compared to the control rAAV2-eGFP was evident. Additionally, chemical modification of rAAV9 protein capsid with the organic compound N-ethylmaleimide (NEM) led to a greater increase in transduction in U2OS and Saos2 cell lines via luciferase activity. To determine if

this NEM modification also altered rAAV9 transduction of non-transformed bone cells, we transduced murine bone marrow stromal cells, or their derivative osteoblasts and adipocytes with the NEM-modified rAAV9 or the WT rAAV9. Only primary osteoblasts were effectively transduced by rAAV9-NEM, suggesting that NEM alters AAV's trafficking and/or interaction of surface membranes or receptors on bone and OS cells. Overall, our data demonstrates that rAAVs efficiently transduce bone and OS cells, and that specific designs and modification can be used to dictate their tropism in vitro. More research, including in vivo OS cancer models, is underway to characterize the translational efficacy of our rAAV designs.

Evaluating Changes in Estrogen Receptor Signaling in Breast Cancer at Stiffnesses Related to the Bone Marrow *LOGAN NORTHCUTT[1], Marjan Rafat[2], Julie Rhoades (Sterling)[3]. [1], . [2]Vanderbilt University, United States. [3]Vanderbilt University Medical Center, United States

Estrogen receptor (ER) status is a primary marker used to predict breast cancer (BC) outcomes and metastatic disease. Clinical studies have indicated that ER+ patients often have bone-only metastatic disease. However, previous studies have indicated that ER+ cells lack factors for osteoclast-mediated bone destruction. It is well-established that tumors are heterogenous in ER expression and studies in primary tumor sites suggest that changes in stiffness can alter ER signaling. However, it remains unclear how ER may change through the stiffnesses of the bone microenvironment, which can be 20 times stiffer than the breast. We reasoned that the stiffness of the bone and bone marrow may drive changes in ER signaling that alters epithelial-to-mesenchymal transition (EMT). Understanding how the bone environment may alter ER signaling leading to changes in EMT and osteolytic factors may lead to a better understanding of how ER+ BC may be able to induce osteoclast-mediated bone destruction.We hypothesize that higher stiffnesses of the bone marrow and bone decrease estrogen receptor sensitivity of ER+ BC cells which increases the expression of genes that can drive osteoclast-mediated bone destruction. To evaluate this, we seeded ER+ (MCF7s) and ER- (MDAs) cells on CytoSoft® Rigidity Plates that mimicked the stiffness of the bone marrow (0.5 - 32 kPa). After 2 days in culture, RNA and protein were extracted to analyze factors associated with osteolysis (ITGB3, TGFB-RII, Gli2, and PTHLH). Additionally, we probed the expression of ER and phosphorylated ER (pS118ERa) to evaluate estrogen activity. Preliminary results show that gene expression of osteolytic factors PTHLH and Gli2 were changed at various stiffnesses. We predict that increased other osteolytic factors will be altered at these stiffnesses.Overall, this work gives insight into how estrogen signaling is changed in the bone marrow compared to the primary site. For our next steps, we plan to re-evaluate the expression of osteolytic genes when given aromatase inhibitors at varying stiffnesses and perform RNA-sequencing to gain an understanding of what other signaling pathways change in ER+/ER- bone metastatic tumors. These studies may lead to more targeted therapies in ER+ breast cancer patients that no longer respond to hormone-targeted therapies, which may help reduce the negative effects of therapies and better predict which patients may develop bone metastatic disease.

SAT-111

Investigating the Role of EphA2 in Breast Cancer-Mediated Osteoclast Expansion and Function *Dominique Parker[2], Verra Nwga[2], Jin Chen[2], Julie Rhoades (Sterling)[3]. [2]Vanderbilt University, . [2]Vanderbilt University, United States. [3]Vanderbilt University Medical Center, United States

Bone metastases are present in over 70% of metastatic breast cancer patients and are complicated by the development of tumor-induced bone disease (TIBD). Frequently, TIBD is characterized by an increase in osteoclast proliferation and bone-resorbing activity, and patients often experience pain and increased fractures. Additionally, bone metastatic patients are often resistant to first- and second-line therapies highlighting an importance for research in this area. Moreover, the receptor tyrosine kinase, Ephrin-type-A 2 receptor (EphA2), is highly expressed in bone metastases, and previous evidence suggests its involvement in TIBD and anti-tumor immunity. EphA2 participates in both forward and reverse signaling during receptor/ligand engagement and is known for its role in inflammation and bone homoeostasis. Previous data shows a reduction in osteoclast number and bone lesions following EphA2 knockout. However, the mechanism by which EphA2 mediates the expansion of osteoclasts is not well understood. We therefore hypothesize that increased expression of EphA2 in breast cancer cells at the site of bone metastasis promotes osteoclast expansion, leading to TIBD. In agreement with previous work, our data shows that EphA2 deletion in murine breast cancer (BC) cell line, 4T1, reduces bone lesion area and number and reduces the presence of bone metastasis-associated macrophages, which are important in tumor establishment and expansion in the bone. To assess the effects of EphA2 deletion on the behavior of 4T1 cells, we conducted a wound healing assay. We observed a reduction in wound healing capacity in 4T1 cells following EphA2 deletion. This suggests that EphA2 expression in BC cells may increase their metastatic potential. Our future studies will investigate EphA2 signaling and reverse signaling in BC cell lines, myeloid progenitor cells, osteoclasts, and bone metastasis-associated macrophages. We will utilize murine and human BC cell lines to elucidate the effects of EphA2 deletion on immune cell populations, bone metastasis, and tumor progression. Additionally, we will investigate how EphA2 reverse signaling impacts osteoclasts' ability to modulate immune cells. We aim to reduce TIBD and tumor burden by reducing the expansion of osteoclasts and shifting the immune cells to an anti-tumorigenic phenotype. Our studies will provide additional insight into the underlying mechanisms of TIBD which will offer new treatment strategies for osteolytic breast cancer.

68Ga-PSMA-11 (Gozetotide) PET Radiomic Features of Prostate Gland Related to Osseous Metastatic Disease. *Orhan Oz[1], Jin Qi[2]. [1]University of Texas Southwestern Medical Center, Dallas, United States. [2]Parkland Heath System & UTSW Medical Center, United States

Purpose:To test the hypothesis whole prostate 68Ga-PSMA-11 (Gozetotide) PET radiomic features can be identified that are predictive of/portend a higher probability for osseous metastasis.Materials & Methods:One hundred three subjects with available preoperative PET imaging were included in this IRB-approved retrospective study. Two radiologists, with 30 years (OKÖ) and 15 years (JQ) experience, jointly interpreted the PET/CT scans and agreed on the presence of metastatic disease. The study cohorts were established based on the location of the metastases on the scans: Bone only ("osseous metastases" (OM)), nodes only ("nodal metastases", (NM)), both bone and nodal metastases, (OM+NM), and "non-osseous metastases (NOM)", or "both nodal and osseous metastases" designation for each scan. Whole prostate semi-automated segmentation and feature extraction were performed on axial PET/CT images using public domain 3D slicer software (V5.2.1). The Pyradiomic features were compared between "osseous metastases" (OM), "non-metastases (NOM)" via Mann Whitney U test. Features with P values < 0.05 were considered to build the multivariable model. Logistic regression analysis was performed to discriminate two groups using GraphPad Prism 9.Results:To explore the radiomic features that only related to osseous metastasis in this initial study, 44 of the 103 pre-operative subjects were excluded- 12 subjects with both nodal and osseous metastases, and 32 subjects with only nodal metastases were excluded. The study cohort consisted of 59 subjects with pre-operative Gozetotide PET/CT and intact prostate glands. Scans of 37 subjects constituted the NOM cohort, 22 the OM cohort. Among 108 features, the most statistically predictive features differentiating OM from NOM on PET images were: the Maximum2DDiameterRow (p= 0.0275), JointEnergy (p=0.0001), JointEntropy entropy (p=0.0001), SmallAreaLowGrayLevelEmphasis (p=0.0001), DependenceNonUniformityphase (p= 0.0464), Coarseness (p=0.0420), wavelet-LHH_ Coarseness (p= 0.0109) (Table 1). Multivariable analysis of radiomics achieved an AUC (95%CI) of osseous metastatic predictive power of 0.85 Figure 1.Conclusions:To our knowledge, this is the first study to determine that there are radiomic features of the primary prostate that have predictive power for osseous metastases. 68Ga-PSMA-11 PET radiomic features of the whole prostate were identified that could play a role in improving predictive capability in diagnosing osseous metastasis in prostate cancer. This information could inform follow-up periods after initial scanning. Future larger studies may help determine the clinical significance of our findings. Features will be tested for the ability to predict nodal metastases and the feature sets will be expanded to include the other 1000 or more other features available to test.

Aging of the bone marrow niche awakens dormant breast cancer cells and promotes overt bone metastasis *Alexander Scaeffer[1], Ioanna Tsoukala[1], Mohammed Mosa[1], Devona Soetopo[2], Maresa Weitmann[3], Wadim Kisel[4], Sophia Thevissen[5], Jennifer Beavarlet[6], bernhard drotleff[7], theodore alexandrov[7], Lisa Sevenich[3], Thomas Broggini[8], Marcus Czabanka[8], Halvard Boenig[9], Katharina goetze[6], Aline Bozec[10], Klaus Pantel[11], Lorenz Hofbauer[12], Martina Rauner[13], Hind Medyouf[1]. [1]Georg-Speyer-Haus, Germany, [2]Georg-Speyer-Haus-haus, Germany, [3]Georg-speyer-haus, Germany, [4]TU Dresden, Germany, [5]Georg-Speyer-haus, Germany, [6]TUM, Germany, [7]Embl, Germany, [8]Goethe University Frankfurt, Germany, [9]German Red Cross, Germany, [10]UK Erlangen, Germany, [11]UKE Hamburg-Eppendorf, Germany, [12]TU Dresden University Medical Center, Germany, [13]Medical Faculty of the TU Dresden, Germany

Background: Despite substantial advances in the treatment of primary tumors, metastases are associated with poor outcome and remain the major source of cancer-related deaths. In breast cancer (BCa), bone is one of the major sites of metastasis, with autopsy studies showing occurrence in up to 70% of BCa patients. In patients with hormone receptor positive BCa, bone metastatic manifestations frequently follow an indolent disease course, where disseminated tumor cells (DTCs) remain initially dormant for years up to a decade before overt outgrowth and symptomatic disease manifestation. Notably, besides the hormone receptor status, advanced age is the second most significant predictor of overt bone metastasis occurrence in BCa. However, the molecular mechanisms that underpin this association, remain largely unknown. Methods and Results: Here, we used a newly generated immunocompromised model that recapitulates bona-fide features reminiscent of physiological aging, to demonstrate that age-related alterations in the bone marrow niche, dictate growth dynamics of human breast cancer DTCs in the bone. More specifically, our data point to a prominent tumor-extrinsic control of dormancy that is linked to aging of specific structural niche cell types. To confirm this in a fully human setting and dissect the cellular origin of the observed phenotype, we used bone metastatic cell lines and patient-derived circulating tumor cells (CTCs) in a newly established 3D human organotypic marrow environment (3D-HOME). We demonstrate that age-related alterations in the cell-fate decision of mesenchymal niche cells towards adipocytes, generates an adipo-rich local microenvironment that drives the awakening of quiescent DTCs. Metabolomic analysis revealed specific dependencies, targeting of which, effectively reverted the outgrowth phenotype. Current work is additionally exploring whether these new metabolic dependencies could be exploited to sensitize the DTCs to a specific form of programmed cells death, to enable disease eradication. Conclusion: This work shows that DTC-niche dependencies dynamically evolve with age. The findings will enhance our ability to propose disease-stage and age-adapted therapeutic interventions and inform the rational design of new treatment strategies for patients with bone metastasis.

Mechano-activation of Osteocytic Connexin Hemichannels Prime Microenvironment in Suppressing Breast Cancer Bone Metastasis *Xuewei Wang[1], Rui Hua[2], Manuel Riquelme[2], Jingruo Zhang[2], Francisca Acosta[2], Jean Jiang[2]. [1]University of Texas Health Science Center at SAn Antonio; University of Texas at San Antonio, , [2]University of Texas Health Science Center at San Antonio, United States

Previous studies have shown that moderate mechanical stress prevents the growth of metastatic breast cancer (BC) and bone destruction by transducing mechanical stimulation into downstream cellular signals. Connexin 43 (Cx43) is abundantly expressed on the plasma membrane of osteocytes and forms both gap junctions (GJs) and hemichannels (HCs, unpaired GJs), which enable communication between neighboring cells or intra-extracellular microenvironment, respectively. Our recent study demonstrated that Cx43 HCs activation in osteocytes, induced by mechanical stress, inhibited the migration of triple-negative BC cells and HC-released factors such as ATP and PGE2 were involved in this process. To investigate if activation of osteocytic Cx43 HCs cultivates bone microenvironment that is BC suppressive, we examined the ER+ BC cells that have a greater potential to metastasize to the bone. We adopted a 3D tumor spheroid model for human ER+ BT-474 cells that closely mimics tumor growth in situ and cultured cells with conditioned medium (CM) collected from osteocytes after treated with fluid shear stress (FSS). The results showed that the FSS-CM significantly reduced BC cell growth and increased numbers of apoptotic cells; however, this inhibitory effect was attenuated with the CM collected from osteocytes treated with a specific HC-blocking antibody (Panel A). To further investigate the impact of activation of osteocytic Cx43 HCs by mechanical stress on bone microenvironment and BC metastasis in vivo, we applied mechanical loading to the left tibia for two weeks (5 minutes/day, 5days/week, peak strain: 1000 ??). After loading, murine Py8119 BC cells were implanted in both loaded and unloaded tibiae of wild type (WT) and two osteocyte-specific transgenic mice expressing dominant negative mutants: R76W (impaired GJs) and ?130-136 (impaired both HCs and GJs). The unloaded right tibia had greater cancer cell proliferation, tumor growth, and bone damage than pre-loaded left tibia in WT and R76W mice with functional HCs. However, no significant differences were observed in ?130-136 mice with impaired HCs (Panel B). ATP and PGE2 released by Cx43 HCs were elevated in loaded tibiae of WT and R76W mice but not ?130-136 mice. This study suggests that activation of Cx43 HCs by mechanical stress associated with the release of the factors changes the bone from tumor-supportive to suppressive microenvironment that inhibits BC metastasis (Panel C).

SAT-118

Prostate Cancer Engages Osteoblasts and Osteocytes via Soluble Signals *Kristina Wells[1,] Stephen Wilson[2,] Aimy Sebastian[2,] Gabriela Loots[1,] Damian Genetos[3,] [1]University of California, Davis, United States, [2]Lawrence Livermore National Laboratory, United States, [3]University of California, Room 1020 VM3B, United States

Prostate cancer (PCa) is the fifth leading cause of death worldwide. PCa's preferential metastasis to bone bodes terribly for survival, where 5-year survival rates plummet from 56% to <1%. Thus, mitigating bone metastasis is critical for improving the health- and lifespan of PCa patients. How PCa metastasizes to bone or engages bone cells to promote its survival are incompletely understood. Previous research established that PCa engages bone-building osteoblasts (OB) and bone-resorbing osteoclasts to promote PCa growth and survival; less is known about PCa interactions with osteocytes (OCY), the long-living cells in bone that orchestrate remodeling. We sought how PCa indirectly engaged OBs and OCYs as well as common and distinct transcriptional responses.We created PCa conditioned media (CM) by culturing C4-2B PCa cells to 80% confluence, adding fresh RPMI1640, then growing cells for 24 hours. We treated MC3T3-E1 pre-OBs or OCY-like OCY454 cells with PCa CM or naïve media for 24 hours. PCa CM dose-dependently increased MC3T3-E1 apoptosis without affecting OCY454. Bulk RNA sequencing was performed to establish PCa impact on transcription vs. naïve media. PCa CM impacted OBs more than OCYs, affecting 1536 MC3T3-E1 transcripts vs 423 OCY454 transcripts. Only 38 differentially expressed genes (DEGs) affected in both cell types when treated with PCa CM. Gene ontology analysis revealed changes in expected and novel pathways. In MC3T3-E1 cells, 'cholesterol biosynthetic process,' 'regulation of endothelial cell differentiation,' and 'regulation of nitric oxide biosynthetic process' were among enriched processes. In OCY454 cells, 'regulation of nitric oxide synthase biosynthetic process' and 'regulation of wnt signaling pathway' were enriched. In both MC3T3-E1 and OCY454 cells, 'epithelial to mesenchymal transition' and 'cell junction assembly' were enriched by PCa CM. Overall, MC3T3-E1 cells were more strongly impacted by treatment with PCa CM compared to OCY454 cells, in terms of apoptosis, total DEGs, and gene ontology analysis. Few genes or pathways were differentially expressed in response to PCa CM in both MC3T3-E1 and OCY454 cells. Thus, MC3T3-E1 cells, a pre-OB cell line, appear to be more strongly impacted by the presence of PCa than the OCY-like cell line OCY454. This suggests that PCa may more effectively engage OBs than OCYs, despite their common origin.AS and GGL conducted work under the auspices of the USDOE by LLNL (DE-AC52-07NA27344).

Assessing Effects Of Immune Checkpoint Inhibitors On Bone Using Opportunistic Computerized Tomography Bone Densitometry: A Translational Pilot Study In Oncology *Carrie Ye[1,] Jacob Jaremko[1,] John Walker[1,] Jasmine Gill[1,] Bryn Matheson[2,] Cassandra Gallant[1,] William Leslie[3,] Michael Kolinsky[1,] Steven Boyd[2,] [1]University of Alberta, Canada, [2]University of Calgary, Canada, [3]University of Manitoba, Canada

Many therapies in oncology are associated with decline in bone mineral density (BMD) and increased risk of fragility fractures. The newest class of cancer drugs, immune checkpoint inhibitors (ICIs), have become standard of care for treatment of several types of cancer. ICIs work by activating T-cells to attack cancer cells, but T-cell activation is known to activate osteoclast maturation, leading to increased bone resorption. Increased fracture rate has been reported after ICI initiation, but the direct effects of ICI on BMD have never been studied.AIM: To investigate the effects of ICI on BMD using clinical computed tomography scans (CT).METHODS: We performed a retrospective cohort study of patients treated at the Cross Cancer Institute or Kaye Edmonton Clinic in Edmonton, Canada. The study cohort included individuals with stage III melanoma, treated with at least 6 months of ICI and the control cohort included individuals with stage II melanoma, not treated with ICIs. Inclusion criteria required that each individual have a baseline and 12-month follow-up CT that included the lumbar spine. Using an automated segmentation algorithm and internal calibration, lumbar spine BMD obtained from CT images will be compared between baseline and follow-up using a mixed-effects regression model. Glucocorticoid exposure between the baseline and follow-up CT was ascertained and stratified analysis will be completed for those exposed to long-term glucocorticoids.PRELIMINARY RESULTS: 42 study patients and 49 control patients have been identified with available baseline and follow-up CT images. All CT images have been collected and are undergoing analysis including automated segmentation of lumbar spine vertebrae and BMD measurement. Preliminary results demonstrated approximately 7% decline in lumbar spine (L1-5) BMD 12-months after ICI initiation (Figure).CONCLUSION: It is feasible to obtain BMD from clinical CT using machine learning and internal calibration. Full longitudinal BMD results for all study participants is ongoing.

Bone	Baseline BMD (mg/cc)	Follow-up BMD (mg/cc)	Percent Difference
L5	349.3	322.9	-8.2
L4	348.6	316	-10.3
L3	330.5	312	-5.9

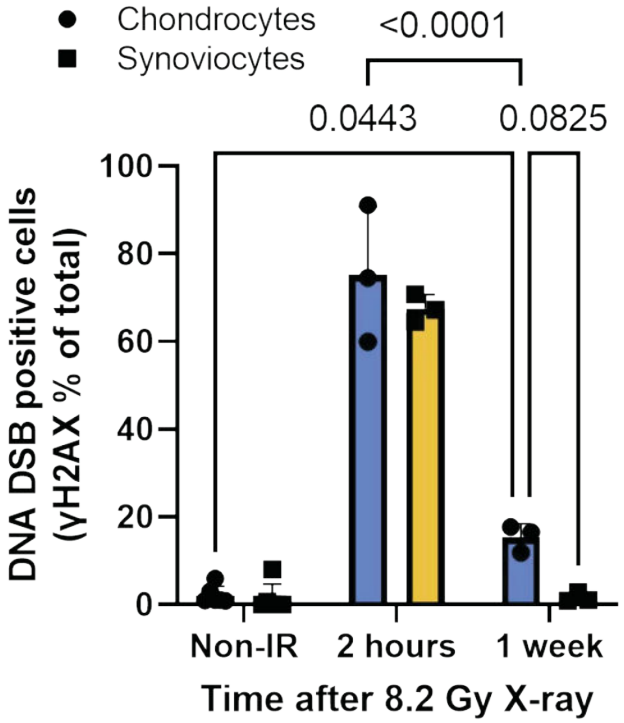
Persistent DNA Damage in Chondrocytes May Contribute to Osteoarthritis Onset *Mark James[2], Eduardo Peralta-Herrera[2], Danielle Benoit[3], Jennifer Jonason[4]. [2]University of Rochester, . [2]University of Rochester, United States. [3]Phil and Penny Knight Campus to Accelerate Scientific Impact, University of Oregon, United States. [4]UNIVERSITY OF ROCHESTER, United States

Background: Osteoarthritis (OA) is the most common form of arthritis and is characterized by progressive loss of articular cartilage which can cause pain and loss of mobility. Aging is a significant risk factor for OA and while DNA damage is associated with aging, the role of DNA damage in chondrocyte aging and OA remains unclear. It was recently shown that aged and OA human knee chondrocytes contain more damaged DNA relative to young healthy chondrocytes. In response to DNA double-strand breaks (DSBs), stimulator of interferon gene (STING) activates the nuclear factor ?B (NF-?B) pathway. We previously showed increased NF-?B activity in aged chondrocytes and chondrocyte-specific induction of NF-?B activity promotes early OA onset in mice. We hypothesize that accumulating DNA damage leads to chronic proinflammatory signaling in aging chondrocytes, ultimately resulting in OA onset.Design: To investigate the role of DNA damage in chondrocytes and OA, we induced DNA DSBs in cultured chondrocyte-like cells using etoposide and modulated STING activity using siRNA or a small molecule STING agonist before collecting protein and RNA for respective immunoblot and RT-qPCR analyses. We also induced DNA damage using targeted X-rays in the knee joints of young and aged adult mice and assessed DNA damage, proinflammatory signaling, and cell senescence by histology at 2 hours, 2 days, and 1 week after irradiation. We also included a separate cohort of mice to assess histology, pain and mobility 6 months after irradiation.Results: We found that inducing DNA DSBs in cultured, chondrocyte-like cells led to proinflammatory signaling, as evidenced by increased NF-?B activity. We also showed that knockdown of STING by siRNA partially reduced this proinflammatory response while STING agonist treatment elevated NF-?B target gene expression. In vivo, we found that chondrocytes contained more persistent DNA damage a week after irradiation compared to synoviocytes. Histology and behavioral studies on mice 6 months after irradiation are currently in progress.Conclusions: We learned that chondrocytes contained more persistent DNA damage compared to synoviocytes after irradiation. Our future work will determine whether radiation-induced DNA damage may cause OA using histological and behavioral techniques. Understanding how DNA damage impacts articular cartilage could inform future clinical radiation therapies as well as provide new pathways to inhibit inflammation and prevent OA.



Quantification of tibial articular cartilage (blue) and synovium (yellow) of γH2AX IHC which marks DNA DSBs in non-irradiated (non-IR) and at time-points after 8.2 Gy X-irradiation.

Single-cell Transcriptomic Analysis supports GP stem cell hierarchy and reveals FoxA2+ long-term skeletal stem cells (LTSSC) and PTHrP+ short-term stem cells (STSSC) clusters are independent of each other. *Yiwei Kong[1], Yu Zhou[2], Shreya Kumar[1], Shanmugam Muruganandan[1], Shobana Sekar[1], Rachel Pierce[1], Hannah Alberico[1], Dori Woods[1], Andreia Ionescu[3]. [1]NORTHEASTERN UNIVERSITY, United States. [2]Boston Children's Hospital Harvard Medical School, United States. [3]Northeastern University,

We recently discovered a FoxA2+LTSSCs population at the top of growth plate (GP) resting zone (RZ), with higher clonogenicity and longevity than the previously identified PTHrP+STSSCs. To validate the newly discovered GP stem cell hierarchy, we performed 10x genomics single-cell RNA sequencing on GP cells isolated from P18 C57B6 mice (Fig.1A). We separated clusters positive for chondrocyte markers (Acan, col2a1) from erythroid cells, B cells, neutrophils, osteoblasts, macrophages, endothelial cells, NK cells and monocytes. We performed Seurat-based specific sub-clustering of the chondrocytes, yielding 1444 cells separated in 9 independent clusters (0-8). High expression level of Col2a1 was observed in all clusters (A1). Cluster 6 was enriched for proliferation markers Mki67 and Cdk1 (A2-3). Clusters 2, 3, 6 showed enrichment for columnar chondrocytes marker Gdf10 and hypoxia-associated gene Cox4i2 (A4-5). Cluster 4 has high levels of hypertrophic chondrocytes markers Col10a1 and Ihh (A6-7). Cluster 5 was enriched for S100a7a (A8) and Cdkn1c (p57), expressed in pre/hypertrophic chondrocytes. Cluster 1 expressed markers of late hypertrophic chondrocytes Mmp13 and Bmp7 (A10-11). The remaining clusters (0, 8, 7) were annotated as RZ cells positive for skeletal stem cell markers Pdpn, Xrcc2 and Srpx2 (A12-14). In line our previous studies, FoxA2 marks two distinct populations, the FoxA2+col.10-LTSSC group in the RZ (cluster 8), and the FoxA2+col.10+ HZ chondrocytes (cluster 4) (A16). Consistent with GP geography, hypoxia-induced gene, Mif was highly expressed in all clusters except for Cluster 8 (RZ FoxA2+ layer - at the top of the GP) and Cluster 1 (late hypertrophic chondrocytes - at the bottom of the GP) (A15). Lastly, PTHrP expression is mapped to RZ cluster 0, consistent with specific localization of PTHrP+ cells at the bottom of the RZ. Future investigations need to determine whether RZ cluster 7 are progenitor cells. These results confirm a distinct separation of FoxA2+LTSSC and PTHrP+STSSC in the GP RZ. To further validate cluster hierarchy, we performed Monocle 3 pseudotime cell trajectory analysis, assigning cluster 8 (FoxA2+LTSSC) as a starting point. This analysis showed a continuous trajectory linking RZ chondrocytes (clusters 8, 0, 7), going through columnar chondrocytes (clusters 2, 3, 6), to terminal differentiated hypertrophic chondrocytes (clusters 5, 4, 1) (Fig.1B) supporting previously identified GP stem cell hierarchy.

SAT-126

Nutrition-dependent stunted growth in neonatal mice is associated with decreased chondrocyte proliferation but not the activity of skeletal stem cells within the growth plate. *Daniela Schnyder[1], Anna Usanova[1], Baoyi Zhou[1], Jussi Heinonen[1], Jose M Lopez-Pedrosa[2], Ricardo Rueda[2], Andrei S Chagin[1]. [1]Department of Physiology and Pharmacology, Karolinska Institutet, Stockholm, Sweden, Sweden. [2]Abbott Nutrition R&D, Granada, Spain, Spain

Introduction: One of the leading causes of stunted and/or retarded longitudinal growth in children and adolescents is nutrient depletion. In the year 2020, 149.2 million children under the age of five were affected by stunted growth worldwide. Recently, it was shown that catch-up growth after nutrition-dependent growth retardation is associated with the regulation of skeletal stem and progenitor cells (SSPCs) in the growth plate1. However, the effect of stunted growth retardation on SSPCs is unknown.Method: Extensive nutrition deprivation was induced by litter size expansion to 15-16 pups per dam at postnatal day 7 (P7). Restriction lasted until pups were starting to eat by themselves between P17 and P21. SSPCs were assessed by employing the PTHrP-mCherry mouse strain and their ability to form progeny by PTHrP-CreERT2:tdTomato mice as described2.Results: Body weight was significantly reduced in nutrition-deprived mice as early as P14 and was not restored until the end of the study period, 2 months of age. At the same time, decreased tibia and femur length were restored to control values at day P35. Systemically, the malnourishment caused a dramatic reduction of serum levels of insulin and IGF1 and while insulin levels were restored to control at P21, levels of IGF1 remained low at P21. Locally, a profound decrease in proliferation (28.8% of control, normal-fed pups) was observed throughout the growth

plate including PTHrP-mCherry SSPCs (33.3% of control). However, the number of SSPCs normalized to the length of the growth plate was not significantly changed by malnourishment. The formation of committed progeny was not affected by malnourishment as assessed in PTHrP-CreERT2:tdTomato mice pulsed with tamoxifen one day prior to the initiation of malnourishment. We also noticed a mild reduction in the number of hypertrophic chondrocytes during malnourishment (86% of control), which was restored to normal at P21, but not their size.Conclusion: We concluded that malnourishment-caused growth retardation in neonatal and early postnatal periods is not associated with SSPCs behavior in the growth plate, but instead all chondrocytes respond by dramatic reduction of their proliferation. The effect is probably regulated by insulin/IGF1 serum levels.References:1. Oichi T, et al. Nutrient-regulated dynamics of chondroprogenitors in the postnatal murine growth plate. SAT-128

Runx2 activity in hypertrophic chondrocytes regulates postnatal cartilage and bone turnover *Caris Smith[1], Harunur Rashid[2], Vashti Convers[3], Katelynn Clark[3], Amjad Javed[4]. [1]The University of Alabama at Birmingham, United States, [2]University of Alabama Birmingham, United States, [3]The University of Alabama at Birmingham School of Dentistry, United States, [4]University of Alabama at Birmingham, United States

Resting chondrocyte specific deletion of Runx2 gene blocks chondrocyte differentiation and endochondral ossification resulting in perinatal lethality. Importantly, expression of Runx2 increases progressively from resting to hypertrophic chondrocytes (HCs). HCs regulate endochondral ossification by secreting matrix resorbing enzymes and angiogenic factors. However, HCs specific role of Runx2 during postnatal chondrogenesis remains unknown. We deleted Runx2 gene specifically in HCs using the type-X collagen-Cre mice. Endochondral ossification was assessed from birth to adulthood using molecular, biochemical, and histological approaches. Homozygous (Runx2HC/HC) mice survive but show limb dwarfism and enlarged growth plates. A significant decrease in apoptosis of Runx2-defecient HCs resulted in doubling of the HC zone in the growth plate. Consistent with this observation, expression of HC marker type-X collagen was increased in Runx2HC/HC littermates. Evaluation of 10-weeks-old mice revealed a significant increase in the articular and growth plate cartilage. Interestingly, the expression of collagen type 2 and major proteoglycans was unchanged. In sharp contrast, expression of collagenases and aggrecanases was markedly decreased during both embryonic and postnatal chondrogenesis. Cartilage islands were extended into the mid-diaphysis of the Runx2HC/HC mice indicating impaired resorption of the cartilage matrix. Histomorphometry and ?CT analyses revealed a significant increase in trabecular BV/TV, trabecular number, thickness, and a concomitant decrease in trabecular space in Runx2HC/HC mice. Osteoblast number and the expression of early and late osteoblast markers were comparable among the littermates. Furthermore, dynamic bone synthesis showed no differences in mineral apposition or bone formation rates. Despite an increased trabecular bone mass 3-point-bending test revealed bone fragility in Runx2HC/HC mice. TRAP staining showed a significant decrease in number and surface of osteoclasts in Runx2HC/HC mice. Runx2 deficient HCs showed a significant decrease in the expression of Rankl and IL-17. Bone marrow culture from Runx2HC/HC mice showed few, smaller osteoclasts. Impaired osteoclast differentiation was evident by a marked decrease in expression levels of mature osteoclast markers. Thus, Runx2 controls endochondral ossification by regulating the expression of cartilage resorbing enzymes and osteoclast differentiation factors in hypertrophic chondrocytes.

Observer-independent Identification of the Cellular Zone and Rates of Mineral Deposition in the Mouse Growth Plate Using Image Analysis Algorithms *Seung-Hyun Hong[1], Li Chen[2], Xiaonan Xin[2], Zhihua Wu[2], David Rowe[2]. [1]University of Connecticut, United States, [2]University of Connecticut Health, United States

Previously we have demonstrated the use of multimodal fluorescent and chromogenic imaging of single cryosectioned mouse growth plate section of a 4 week old mouse that was injected with EdU and alizarine complexone (AC) one day prior to sacrifice. Captured in the imaging process is the deposited mineral, the surfaces of active mineral deposition, TRAP positive cells (osteoclasts and columnar chondrocytes), EdU positive columnar chondrocytes and marrow cells, and AP positive osteoblasts and chondrocytes, all of which are aligned to an aqueous DAPI and Safranin O/ Fast Green image taken in color and Cy5 autofluorescence. In this abstract we describe how the individual image files from each round of scanning (11 files) are vertically aligned utilizing registration beads and how specific layer combinations are used to assign a line that separates specific zones. The imaging algorithms were designed to replicate the cellular and structural features that the human observers use as criteria of distinguishing each zone. In most cases, more than one criteria for a border line was generated from the multiple images from which the computer averaged the subtle differences into a final dividing line. Distinguishing features of the germinal, proliferative, prehypertrophic and hypertrophic zones of the growth plate and the metaphyseal and diaphyseal zone of the invading bone allowed the calculation of the width/area (absolute and relative) of each zone. Comparison of the zonal level of the accumulated mineral, deposited AC and expressed AP allow the calculation of the 1 day mineralization rate of cartilage and bone component of the growth plate. Other features of the columnar zone that can be computed is the proliferation index and the relative alignment of the columnar stacks. The images also capture the activity of the zone of Ranvier which is EdU and AP positive with a mineralizing front. We believe that this imaging and analysis workflow will be useful for high throughput screening of knockout mouse lines for cartilage abnormalities and a baseline for histological spatial localization of specific cell types identified by either CODEX or MERFISH technologies.

Modified Periodic Acid-Schiff (PAS) is an alternative to Safranin O for discriminating bone-cartilage interfaces *Maria A Serrat[1], Kelsey M Kjosness[2], Philip L Reno[2]. [1]Marshall University School of Medicine, United States, [2]Philadelphia College of Osteopathic Medicine, United States

Safranin O is a cationic dye that binds to proteoglycans in cartilage and is routinely used to assess growth plate dynamics and/or fracture repair at bone-cartilage interfaces. When used with a counterstain such as fast green, Safranin O can offer exquisite differentiation of cartilage from surrounding bone. However, various decalcification and processing methods can deplete proteoglycans, rendering inconsistent, weak, or absent Safranin O staining with indiscriminate bone-cartilage boundaries. We sought to develop an alternative staining method that preserves the contrast of bone and cartilage in cases of proteoglycan depletion. Periodic acid-Schiff (PAS) is a carbohydrate-specific stain used to demonstrate glycogen and other polysaccharides, such as the mucopolysaccharides in cartilage. This two-step reaction involves exposure to periodic acid, which oxidizes glycol groups to aldehydes, followed by Schiff's reagent, which turns the aldehydes a rose-violet color. PAS preferentially targets glycol groups with a neutral charge, making this reaction more sensitive than Safranin O for staining cartilage matrix. We developed a simple and novel modification of a standard PAS protocol using Weigert's iron hematoxylin and light green stains that produces a contrast between bone (blue-green) and cartilage (purple).Juvenile mouse fore- and hindlimb bones (N=87) were fixed in formalin, decalcified in 10% EDTA and processed for routine paraffin histology. Modified PAS staining was performed using a commercially available kit (Sigma-Aldrich) with several modifications to the manufacturer's protocol: sections were exposed to periodic acid for 5 minutes, rinsed, immersed in Schiff's reagent for 10 minutes, rinsed and counterstained with Weigert's iron hematoxylin, after which they were "blued" in PBS, rinsed, and stained with 1% light green.In all samples tested, this modified PAS method consistently rendered purple staining in cartilage and blue-green staining in bone. Importantly, our technique provided a clear distinction of the bone-cartilage interface even when Safranin O staining did not (Figure 1). This modified PAS protocol provides a practical solution for differentiating bone and cartilage when Safranin O staining is not detected following decalcification and paraffin processing. This method can be a useful alternative for studies in which identification of the bone-cartilage interface is essential but may not be preserved with standard staining approaches.

A Crucial Role For microRNA-433-3p in Endochondral Ossification: suppressing miR-433-3p in the osteochondral lineage alters growth plate morphology and bone growth *Prachi Thakore[1], Sangita Karki[2], Anne Delany[2]. [1]University of Connecticut Health Center, United States. [2]UConn Health, United States

Spatiotemporal regulation of gene expression is critical for establishing the cartilaginous scaffold needed for endochondral ossification, and there is little understanding of how small non-coding microRNAs (miRNAs) regulate growth plate biology. Mutation of a miR-433 binding site in human HDAC6 leads to X-linked chondrodysplasia, suggesting its clinical relevance. In vitro, miR-433 was induced >10 fold during chondrogenic differentiation of primary mouse mesenchymal cells. Decreasing miR-433 activity increased the expression of chondrogenic marker genes Sox9, Col2a1, and ColXa1, suggesting that miR-433 restrains chondrogenesis.To study the function of miR-433 in vivo, a miR-433 tough decoy (TuD) inhibitor was knocked into the Rosa26 locus; its expression is activated in cre expressing cells and their progeny. To suppress miR-433 activity in the osteochondral lineage RosamiR-433TuD/+ mice were crossed with Prrx1-cre, targeting limb bud mesenchyme. Femurs of both male and female miR-433 decoy (Prx-RosamiR433TuD/+) were shorter than littermate controls at 3, 6 and 12 weeks of age, with males more severely affected. Histology of tibias from 6 week males showed that miR-433 decoy mice exhibited disordered chondrocyte columns and reduced column length, indicating a critical role for miR-433 in growth plate organization.microCT analysis revealed that femurs from 6 week miR-433 decoy mice were narrower, with a 35% decrease in total cortical area. miR-433 decoy mice also had a 40% decrease in trabecular bone volume fraction, driven by decreased trabecular thickness. While trabecular bone volume increased from 6 to 12 weeks of age for both control and miR-433 decoy mice, the percent change in bone volume in this interval was 5 fold higher in decoy mice compared with controls. Thus, by 12 weeks, trabecular parameters in miR-433 decoy mice were similar to controls, supporting the concept that miR-433 dampens osteoblast function. In contrast, 12 week miR-433 decoy bones remained narrower and shorter, highlighting the impact of miR-433 on growth.Some validated miR-433 targets include Runx2 and Hdac6, which are known to regulate chondrocyte proliferation and maturation; we are currently examining how genes associated with chondrogenesis are affected by miR-433. Our study demonstrates that suppressing miR-433 in the osteochondral lineage significantly impacts growth plate morphology and bone accrual, indicating a crucial role of miR-433 in endochondral bone formation.

Piezo1 activation accelerates osteoarthritis progression and the targeted intervention effect of artemisinin *Donghao Gan[1], Guozhi Xiao[2], Qinnan Yan[1], Xiaowan Jin[1], Chu Tao[1], Yiming Zhong[1], Qingyun Jia[3]. [1]Southern University of Science and Technology of China, China. [2]Southern University of Science and Technology, China. [3]Linyi People's Hospital, China

Purpose: Osteoarthritis (OA) is a devastating whole-joint disease affecting a large population worldwide with no cure, its mechanism remains poorly defined. Abnormal mechanical stress is the main pathological factor of OA. Here we investigate the effects of Piezo1 activation on osteoarthritis (OA) development and progression and to explore Piezo1-targeting OA treatment.Methods:The expression levels of Piezo1 were determined in human OA cartilage and experimental OA mice. Mice with genetic Piezo1 deletion in chondrocytes or intra-articular injection of the Piezo1 activator Yoda1 were utilized to determine the effects on DMM-induced OA progression. In an effort to define PIEZO1-targeting drugs for potential OA treatment, via virtual docking technology in the constructed small molecule compound library, we found that artemisinin (ART), a potent antimalarial drug, may be a PIEZO1-targeting drug. Effects of ART, on Piezo1 activation, chondrocyte metabolism and OA lesions were determined.Results: Piezo1 expression is up-regulated in articular chondrocytes in human OA and destabilization of medial meniscus (DMM)-induced mouse OA cartilage. Inducible deletion of Piezo1 in articular chondrocytes in adult mice largely attenuates DMM-induced OA lesions. In contrast, intra-articular injection of Yoda1, a selective activator of Piezo1, aggravates the knee joint OA lesions induced by DMM in adult mice, while Yoda1 treatment did not cause marked OA lesions in sham mice. PIEZO1 activation increases, while PIEZO1 siRNA knockdown decreases, expression levels of RUNX2 and catabolic enzymes MMP13 and ADAMTS5 in primary OA-human articular chondrocytes (HACs) in a PI3K-AKT dependent manner. Similar results were observed in DMM mice articular cartilage. Of potential translational significance, we find that ART may have strong binding ability with several amino acid residues near the ion channel pore of Piezo1 molecule through computer protein-ligand docking simulation. We have provided strong evidence supporting that ART is a novel and potent inhibitor of Piezo1 activation in primary OA-HACs and all cell lines examined, including human endothelial HUVEC cells, ATDC5 chondrocyte-like cells and MLO-Y4 osteocytes-like cells. Results from in vitro experiments confirmed that ART decreases the Yoda1-induced increases in the levels of OA-related genes and p-PI3K and p-AKT proteins in OA-HACs and alleviates DMM-induced OA lesions in mice.Conclusions: We establish a critical role of Piezo1 in promoting OA development and progression and define ART as a potential OA treatment.

Falsely Elevated Lumbar Spine BMD Due to Overlying Calcified Fibroid *Jovan Milosavljevic[1], Vafa Tabatabaie[2], Priyanka Mathias[1], Jenna Le[3]. [1]Division of Endocrinology, Department of Medicine, Montefiore Medical Center, Albert Einstein College of Medicine, United States. [2]Division of Endocrinology, Department of Medicine, and Department of Orthopedic Surgery, Montefiore Medical Center, Albert Einstein College of Medicine, United States. [3]Department of Radiology, Montefiore Medical Center, Albert Einstein College of Medicine, United States

Introduction: Dual-energy X-ray absorptiometry (DXA) is widely recognized as the gold standard for evaluating bone mineral density (BMD). However, approximately one-third of patients have artifactual findings on lumbar spine (LS) DXA imaging, resulting in the exclusion of at least one vertebral level. Identifying the presence of artifacts is crucial, as they can substantially influence BMD measurements. We present a case of falsely elevated LS BMD due to overlapping calcified uterine fibroma.Clinical Case: A 51-year-old woman was referred to endocrinology for evaluation of primary hyperparathyroidism (PHPT). Laboratory tests showed a serum calcium level of 10.6 mg/dL (normal 8.5 - 10.5 mg/dL) and an

inappropriately elevated serum PTH level of 163 pg/mL (normal 20.0 - 80.0 pg/mL) establishing diagnosis of PHPT. She denied history of prior fragility fractures. Bone densitometry was performed using a Hologic DXA scan and showed a total lumbar BMD of 1.701 g/cm2 and a T-score of 5.9. Individual lumbar T-scores were as follows: L1 = 1, L2 = 3.7, L3 = 8.3, and L4 = 8.7. The total hip BMD was 1.225 g/cm2 with a T-score of 2.3, femoral neck BMD was 1.159 g/cm2 with a T-score of 2.8, and the distal third of the left forearm BMD was 0.787 g/cm2 with a T-score of 1.8. An artifact overlying L2-L4 levels of the spine was identified, corresponding to a calcified uterine fibroid, measuring 18.3 x 14.9 x 14.2 cm, previously observed on a CT scan of the pelvis. Taking into account the measurements hip, and forearm, it was determined that the patient had normal bone mineral density. Due to the artifact obscuring 3 vertebral bodies, spine was excluded from the analysis.Conclusion: This case report emphasizes the significant influence of artifacts, in this case presence of a calcified uterine fibroma, on the evaluation of lumbar spine BMD. Providers interpreting DXA scans should routinely examine the images and be aware of various artifacts that can falsely alter interpretation of BMD values.

SAT-141

Regional citrate anticoagulation with continuous renal replacement therapy: a rare cause of hypercalcemia *Leor Needleman[1,] Michael S. Hughes[1,] Ralph Mohammed Mohty[2,] Pedram Fatehi[2,] Deborah Sellmeyer[3.] [1]Division of Endocrinology, Stanford University School of Medicine, United States. [2]Division of Nephrology, Stanford University School of Medicine, United States. [3]Stanford University, School of Medicine, United States

Introduction: Regional citrate anticoagulation is used to prevent clotting in continuous renal replacement therapy (CRRT) circuits by chelating ionized calcium. On CRRT, patients with impaired citrate clearance can develop hypercalcemia due to citrate toxicity manifest as an elevated total calcium and low ionized calcium (a high "calcium ratio") and high anion gap metabolic acidosis. A calcium ratio (tCa:iCa) above 10 is considered high. We present three cases of citrate toxicity that resulted in significant total hypercalcemia. Clinical Case 1: A 61-year-old female with cirrhosis was admitted 11 months after liver transplantation with septic shock and renal failure. Serum calcium on admission was 9.6 mg/dL (8.4-10.5 mg/dL), albumin 2.4 g/dL (3.5-5.2 g/dL). She was placed on CRRT and underwent combined liver and kidney transplantation. Serum calcium increased to 13.1 mg/dL with ionized calcium 0.70 mmol/L (1.12-1.32 mmol/L) and calcium ratio 18.7. CRRT was discontinued and total and ionized calcium levels normalized. Case 2: An 80-year-old female was admitted with heart failure from carcinoid heart disease and AKI due to cardiorenal syndrome. Calcium on admission was 8.0 mg/dL, albumin 2.7 g/dL. Three days after starting CRRT serum calcium rose to 11.9 mg/dL with ionized calcium 0.91 mmol/L (calcium ratio 13.1). Rate of citrate infusion was reduced and within two days the serum calcium panel normalized. Case 3: A 41-year-old female with cirrhosis was admitted with AKI due to hepatorenal syndrome; admission calcium was 9.4 mg/dL. Within two days of starting CRRT, serum calcium increased to 11.9 mg/dL with ionized calcium 0.96 mmol/L (calcium ratio 12.4). She was transitioned to hemodialysis and the serum calcium levels normalized within two days. Conclusion: Because the clearance of exogenous citrate relies heavily on hepatocyte mitochondrial metabolism, citrate accumulation correlates inversely with residual hepatic function. This case series illustrates the importance of recognizing citrate toxicity as a cause of total hypercalcemia in patients on CRRT. An important diagnostic clue is an elevated total to ionized calcium ratio. Citrate toxicity is associated with high mortality although occurs in a critically ill patient population with a high underlying mortality. Endocrinologists should be aware of citrate accumulation and toxicity as causes of hypercalcemia and work closely with nephrologists to minimize the risk of hypercalcemia in patients on CRRT.

SAT-142

The Use of Ketoconazole for Hypercalcemia Resulting from Lymphoma *Katlyn Sawyer[1,] Monique Maher[1,] Micol Rothman[2,] Lisa Kosmiski[1.] [1]University of Colorado, United States. [2]University of Colorado- Denver, United States

Introduction: 1,25- dihydroxyvitamin D mediated hypercalcemia is associated with lymphoma, granulomatous infections, or autoimmune disease. This is a case of severe hypercalcemia from 1,25-dihydroxyvitamin D excess treated with ketoconazole. Case presentation: A 79-year-old male with history of elevated prostate-specific antigen (PSA) and monoclonal gammopathy of undetermined significance (MGUS) was brought in by family for altered mental status. On admission, corrected calcium was 19.1 mg/dL (ref range: 8.1-10.5 mg/dL). Subsequent labs revealed a low parathyroid hormone (PTH) of 8.1 pg/mL (ref range: 9.0-55.0 pg/mL), mildly elevated parathyroid hormone-related protein (PTHrP) of 4.4 pmol/L (ref range: 0.0-2.3 pmol/L), phosphorus of 3.5 mg/dL (ref range: 2.7-4.8 mg/dL), eGFR of 24 mL/min/1.73m2, elevated PSA of 27.19 ng/mL (ref range: 20 ng/mL for years and a nuclear medicine whole body bone scan without evidence of osseous metastatic disease. He was treated with aggressive intravenous fluids, one dose of pamidronate 60 mg, and four doses of calcitonin at 4 U/kg. Corrected calcium improved to 16.1 mg/dL along with mild improvement in mental status. The presence of diffuse lymphadenopathy raised suspicion for lymphoma or granulomatous disease, prompting lymph node biopsy. Steroid therapy was not initiated to ensure accurate pathological diagnosis. Hypercalcemia persisted and he received a 3.3 mg dose of zoledronic acid with only a mild calcium reduction. Another 48 hour treatment of calcitonin was given simultaneously with ketoconazole 200 mg PO three times daily. Corrected calcium level went from 12.2 mg/dL to 10.5 mg/dL after four days of ketoconazole treatment. The calcium nadir on ketoconazole therapy was 9.9 mg/dL. Ultimately, lymph node pathology confirmed large B-cell lymphoma. Clinical Conclusions: Ketoconazole can be used for 1,25-dihydroxyvitamin D mediated hypercalcemia when steroids are contraindicated or ineffective. 1 alpha-hydroxylase can become autonomously active in the macrophages of granulomas and in malignant lymphocytes, increasing conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D. Both glucocorticoids and ketoconazole inhibit 1-alpha hydroxylase.

SAT-144

Successful management of sarcoid-mediated hypercalcemia with anti-TNF-alpha antibody adalimumab. *Aidar Gosmanov[1.] [1]Stratton VAMC,

Background: Glucocorticosteroids is therapy of choice in the management of sarcoid-mediated hypercalcemia. Rarely, some patients may require high doses of steroids which result in spectrum of side effects. It is unknown if alternative approaches may be offered to these patients to control hypercalcemia in attempt to mitigate burden of adverse effects from high-dose steroid therapy. Clinical Case: A 54-year old Caucasian male with a history of type 2 diabetes treated with oral hypoglycemia agents, psoriatic arthritis (PA) and recent diagnosis of biopsy-proven pulmonary and hepatic sarcoidosis was admitted to hospital in March 2020 with newly-diagnosed hypercalcemia. On admission his serum albumin-adjusted calcium was 14.0mg/dL (8.3-10.4), 25-OH vitamin D level 14.8ng/mL (20-50), phosphorus 3.0mg/dL (2.5-4.5) and undetectable parathyroid hormone (PTH) level (14-72pg/mL). His 1,25-dyhydorxy vitamin D was inappropriately high-normal at 59pg/mL (18-72) and ACE level was elevated at 177U/L (9-67). Based on clinical and biochemical evaluation, sarcoid-induced hypercalcemia diagnosis was made and prednisone 10mg daily initiated. During follow up, his hypercalcemia persisted and prednisone regimen was gradually intensified to 40mg daily. This however led to marked deterioration of glycemic control resulting in initiation and then intensification of insulin therapy reaching regimen of 1.5 units/kg/day. As part of PA care, his rheumatologist in December 2021 has initiated weekly injections of 40mg adalimumab, an anti-tumor necrosis factor (TNF)-alpha antibody. One month after adalimumab commencement, routine biochemical evaluation incidentally showed marked improvement of calcium levels allowing to gradually reduce and then stop prednisone over 2-month period while maintaining eucalcemia. Nine months after stopping prednisone, he remains eucalcemic and PTH level is now normal associated with marked reduction in insulin requirement. Discussion: This case report for the first time demonstrated robust hypocalcemic effect of adalimumab in a patient with sarcoid-induced hypercalcemia who was failing intensive prednisone regimen. TNF-alpha inhibition in patients with extra-pulmonary manifestations of sarcoidosis is poorly studied and considered to be a third-line therapy for these patients. Our case report illustrates that TNF-alpha blockade can prove to be a rescue agent in cases of sarcoid-induced hypercalcemia that are difficult to control with glucocorticosteroids.

Acute decompensated heart failure from hypocalcaemia induced cardiomyopathy due to osteoblastic bone metastases only reversed after correction of hypocalcaemia *Ariel Woo[1,] Donovan Tay[2.] [1]Department of Endocrinology, Sengkang General Hospital, Singhealth, Singapore. [2]Sengkang General Hospital, United States

Calcium is essential for physiologic excitation-contraction coupling in cardiac myocyte and severe hypocalcaemia leads to reduced cardiac contractility and dilated cardiomyopathy. Failure of response to standard heart failure therapy has been reported unless calcium has been sufficiently repleted. Loop diuretics increase urinary calcium excretion and further worsen hypocalcemia. We share our experience in treating a patient with acute decompensated heart failure from hypocalcaemic induced cardiomyopathy due to disseminated osteoblastic bone metastases from prostatic malignancy with resolution of heart failure following the correction of serum calcium.An elderly Chinese man with no history of cardiac disease presents after a fall complicated by right humeral and left pubic ramus fracture with dyspnea and pedal edema. He did not complain of muscle cramp, perioral numbness, and peripheral paraesthesia.Clinical examination revealed elevated jugular venous pressure, bilateral crepitations and left sided reduced breath sounds with stony dull percussion. There were no audible cardiac murmurs.Investigations showed high pro-BNP (23681 pg/mL; NR<99). Serial cardiac enzymes were normal. ECG showed sinus rhythm, T-wave inversion in the anterior leads and prolonged QTc (470ms). CXR showed left pleural effusion, cardiomegaly, and pulmonary edema. Echocardiogram showed low ejection fraction of 34%.Hypocalcaemia was noted on Day 4 (Ca 1.86 mmol/L; NR 2.1-2.6), normal PO4 (1.05 mmol/L; NR 0.8-1.5), secondary hyperparathyroidism (PTH 31.7 pmol/L; NR 1.6-6.9), low 25OHD (7 ug/L), high ALP (1762 U/L; NR 40-129) and renal impairment (Cr 156umol/L; NR 59-104). CTAP showed diffuse patchy sclerosis in the skeleton and an unenlarged prostate. Bone scan showed a "super scan" appearance from extensive osteoblastic bone metastases. TRUS prostate biopsy confirmed prostatic acinar adenocarcinoma.He was treated with oxygen, fluid restriction and IV frusemide but pulmonary edema persisted. A calcium gluconate infusion was started with oral calcium and vitamin D supplementation and titrated till an eventual

dose of CaCO3 1.25g qds, calcitriol 0.25mcg bd, and cholecalciferol 1000IU/day. There was a clear positive response to diuretics once his serum hypocalcaemia was corrected. He was started on androgen-deprivation therapy, Bicalutamide.Severe hypocalcaemia can induce heart failure that may be resistant to diuretic treatment but responds only when normocalcemia is achieved.

SAT-146

Marked phenotype of the Dentin-Enamel Junction in murine model of Dentinogenesis Imperfecta Type 1 *Kai Clarke[1], Sobhan Katebifar[2], Roland Kröger[3], Alix Deymier[2]. [1]Department of Biomedical Science, UConn Health Center, United States. [2]Department of Biomedical Engineering, UConn Health Center, United States. [3]School of Physics, Engineering and Technology, United Kingdom

Dentinogenesis Imperfecta (DGI) is an inherited autosomal dominant disorder characterized by abnormal dentin mineralization that affects 1 in 6,000-8,000 people worldwide. DGI type I is caused by mutations in the collagen 1 gene, which are also associated with Osteogenesis Imperfecta (OI), resulting in dentin hypertrophy and enamel attrition. The loss of enamel predominantly occurs near the Dentin-Enamel Junction (DEJ), the interfacial tissue that connects these two mechanically dissimilar materials, suggesting that DGI may negatively affect the DEJ. However, due to its small hierarchical organization the structural and mechanical changes of the DEJ caused by DGI remain unknown. It has been shown that compositional and structural gradients cross the DEJ provide it with mechanical robustness in healthy dentition; therefore, we hypothesize that DGI type I affects the graded structure of the DEJ causing increased fracture risk.Incisors (n=6) were collected from 12-week-old DGI type 1 mice (Col1a2oim) and their wildtype littermate controls (WT) according to UConn Health Institutional Animal Care and Use Committee. Incisors were embedded in EpoKwick FC, polished, and data was collected using a WiTec Alpha 300 Raman Spectrometer. Spectra were collected across DEJ to obtain compositional information in the dentin and enamel. The 960 cm-1 phosphate peak was fit to obtain peak intensity, peak position, and full width half max (FWHM) as a function of location. Gradients width of these values were calculated.The position of the phosphate peak in the dentin trended (p=0.086) towards higher wavenumbers compared to WT. This was not seen in the enamel. Peak FWHM, which is inversely correlated to atomic order, was unchanged between DGI and WT for both dentin and enamel near the DEJ. The ratio of peak intensities between the tissues was unchanged for DGI vs. WT. Gradients in peak intensity, position, and fwhm were present for all samples but their width did not vary between DGI and WT.These results suggest that DGI does not affect mineral content or atomic order of the dentin near the DEJ; however, it does cause the mineral to be more hydroxyapatite-like. This may point to a reduction in substitutions in the DGI mineral which affects mineral stiffness. An increase in mineral modulus near the DEJ could cause stiffening of the interface and changes to the DEJ mechanics. This may explain in part the increase in fracture risk with DGI.

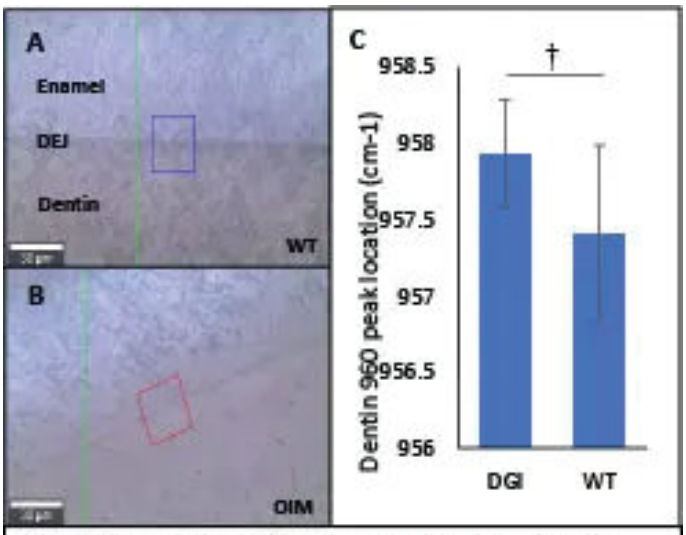

Figure 1: The effect of DGI on the phosphate peak position in dentin. (A-B) Image of the DEJ for WT and OIM incisor showing area of interest (C) Plot of the 960 peak location for the Dentin. † indicates p<0.1.

Impact of Dental Cement on Peri-implant Disease Development: A Preclinical Study in Lewis Rats *Bhuvana Lakkasetter Chandrashekar[1], Claudia Biguetti[2], Alexandra Arteaga[1], Andres Miramontes[1], Danieli Rodrigues[1]. [1]The University of Texas at Dallas, United States. [2]University of Texas Rio Grande Valley, United States

Cement mediated peri-implantitis accounts for about 1.9-75% of dental implant failures associated with peri-implant diseases, of which most are associated with residual cements. However, there is a lack of preclinical studies that evaluate dental cements as a primary cause of peri-implant disease development. Understanding these failures will further help initiate better treatment methods and prognosis. Thus, in this study, we investigated the impact of residual dental cement on osseointegrated implants using a rat model. A total of 25 rats (12 weeks old) were distributed into 5 groups: negative controls soft (S) diet and (H) diet; positive controls S and H diet (n=3); Implant+Cement (BC) S and H diet (n=4). Commercially pure titanium screws (0.76x1mm) were placed on either sides of the maxillae and were treated with standard H diet for 14 days. At day 14 post-implantation, both sides of experimental groups were subjected to re-entry surgery for implant head exposure to simulate a clinical cementation procedure. The right side was loaded with 0.61mg of permanent bioceramic cement, while the left side was used as sham. Standard chow moistened with water was introduced in S diet groups. Bone samples containing the implants were harvested for microtomographic (MicroCT), and histological analysis (H&E and Goldner's Trichrome stains) for evaluation of distance between the implant head and the alveolar bone crest, tissue healing/inflammatory infiltrate and Bone to Implant contact (BIC) percentage respectively. Quantitative data was analyzed by one way ANOVA and Tukey tests ($p<0.05$). MicroCT results indicated circumferential bone resorption around BC implants in comparison to NC group. H&E stains revealed remaining cements particles surrounded by foreign body giant cells adjacent to the implant thread area accompanied by biofilm resembling structures in the soft tissue for S groups. Both cemented and sham sides of BC indicated intense bone loss and resorption around the threads accompanied by signs of osteolysis and biofilm infiltration when compared to NC rats (Fig1). Additionally, cemented groups depicted significantly lower BIC than NC. Altogether, these findings point to the negative biological effect of cement extravasation on healed peri-implant tissues depicting that excess of dental cements affect peri-implant health leading to adverse foreign body reaction. Thus, careful consideration must be given to the use of dental cements with implant prostheses.

SAT-149

Selcopintide Assists the Elongation of PDL Fibroblasts by Altering Microtubules with TAU *Eunhoo Park[1], Joo-cheol Park[1]. [1]Dental Research Institute and School of Dentistry, Seoul National University, Republic of Korea

Ligaments are dense fibrous tissue that connects bones and essential in order that the musculoskeletal system functions properly. In a similar context, the periodontal ligament(P-DL) that connects the root of the tooth and the alveolar bone is indispensable for the correct function of teeth. Although a gomphosis constituted by teeth and alveolar bones doesn't show dynamic movement unlike general synovial joints, PDLs should also tolerate various mechanical forces such as tensile, compressive, and shear forces caused by mastication. Just as general ligaments are formed by tenocytes, PDLs are formed by PDL fibroblasts, which have different properties from those of tenocytes. Not only do they secrete collagen, but they also elongate themselves and are directly involved in the formation of PDLs. Thus, the elongation of PDL fibroblasts are important phenomenon.To ensure that Selcopintide assists the elongation of PDL fibroblasts by altering microtubules with TAU, a series of in vitro study was conducted with siTAU-transfected human PDL fibroblasts. Live cell imaging and laser scanning microscopy were used to investigate their morphologic transition and cytoskeletal structure. Subsequently, immunoblotting is done for evaluating post-translational modification of Tubulin and its associated proteins.Selcopintide promoted the elongation of PDL fibroblasts, it couldn't take its effect on siTAU-transfected cells. Active lamellipodia were observed in TAU-transfected cells, however they withdrew soon showing short-periodic reciprocating manner and couldn't grow into long and thin celluar process. Also, Selcopintide disentangled condensed microtubules of lamellipodial region both in normal

and siTAU-transfected cell. However, their direction corresponds with that of microfilament only in normal cell, not in siTAU-transfected cell. Total amount of ?-Tubulin wasn't altered by siTAU nor Selcopintide, however acetylation of ?-Tubulin was decreased by siTAU and recovered by Selcopintide.Therefore, this study indicates that Selcopintide makes microtubules follows actin filaments and promoting ?-Tubulin acetylation. It also implies that TAU is involved in the effect of Selcopintide that cause the elongation of PDL fibroblasts.

SAT-151

Comparative Effects of Metformin and Melatonin on Alveolar Bone Remodeling in Doxorubicin-treated Rats *Bhumrapee Srivichit[1], Chanisa Thonusin[2], Ratchaneevan Aeimlapa[3], Narattaphol Charoenphandhu[3], Nipon Chattipakorn[2], Siriporn Chattipakorn[4]. [1]Department of Oral and Maxillofacial Surgery, Faculty of Dentistry, Chiang Mai University, Thailand. [2]Department of Physiology, Faculty of Medicine, Chiang Mai University, Thailand. [3]Department of Physiology, Faculty of Science, Mahidol University, Thailand. [4]Department of Oral Biology and Diagnostic Sciences, Faculty of Dentistry, Chiang Mai University, Thailand

Doxorubicin (Dox) is a widely used chemotherapeutic agent for several types of cancers. However, previous studies reported that Dox increased the risk of alveolar bone loss, leading to periodontitis, delayed wound healing, and dental implant failure. Melatonin and metformin have been shown to increase alveolar bone mass in certain types of oral surgery and dental implantation, but their potential benefits in alleviating Dox-induced alveolar bone impairment have never been investigated. Herein, 24 male Wistar rats were randomly divided into 4 groups (n = 6/group) to receive either (i) 1 mL of normal saline solution on days 0, 4, 8, 15, 22, and 29 (Control), (ii) 3 mg/kg/day of Dox i.p. on day 0, 4, 8, 15, 22, and 29 (Dox), (iii) 3 mg/kg/day of Dox i.p. on day 0, 4, 8, 15, 22, and 29 plus 10 mg/kg/day of melatonin orally on day 0-29 (Dox + Mel), or (iv) 3 mg/kg/day of Dox intraperitoneally on days 0, 4, 8, 15, 22, and 29 plus 250 mg/kg/day of metformin orally on day 0-29 (Dox + Met). The rats were euthanized on day 30. Blood and left maxillary alveolar bone were collected to evaluate oxidative stress using malondialdehyde (MDA) measurement. The right maxillary alveolar bone was used to assess the microarchitecture and periodontal status by using an ultra-high-resolution E-Class VecTor6CT system in 5 µm voxel size. The results showed that Dox-treated rats exhibited increases in serum and bone MDA levels, decreased trabecular bone volume fraction (BV/TV), decreased trabecular thickness (Tb.Th), decreased mineral density, and increased periodontal ligament (PDL) space, as compared to the control group (Fig. 1A-1F). Melatonin and metformin equally decreased serum MDA levels in Dox-treated rats to become comparable with that of the control (Fig. 1A). Interestingly, melatonin was superior to metformin in terms of reducing bone MDA levels and restoring bone microarchitecture, but both drugs were equally effective in improving periodontal status in Dox-treated rats (Fig. 1B-1F). In conclusion, our findings suggested that melatonin is more effective than metformin in attenuating Dox-induced alveolar bone impairment.

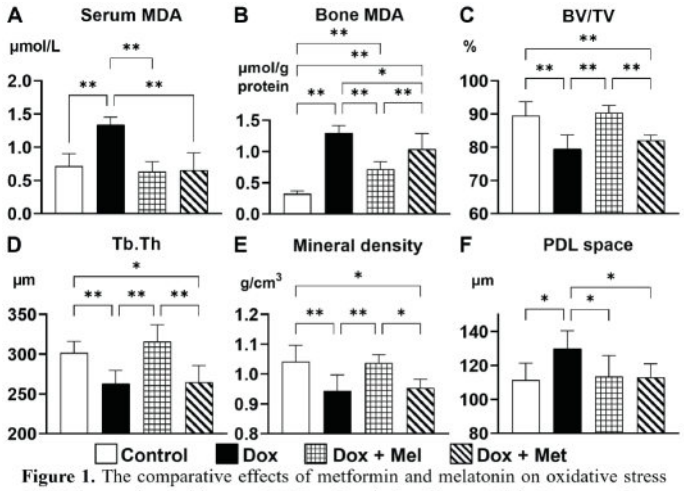

Figure 1. The comparative effects of metformin and melatonin on oxidative stress (A, B), bone microarchitecture (C-E), and periodontal status (F) in Dox-treated rats. Data are expressed as mean ± SD. Statistical analysis was performed using one-way ANOVA with Tukey's post-hoc test. * $p < 0.05$; ** $p < 0.01$ compared between the indicated groups.

Elevated Pedf contributes to increased bone mineralization in diabetes *Maude Gerbaix[1], Badoud Isabelle[1], Delphine Farlay[2], Ryan Tomlinson[3], Marie Helene Lafage-Proust[4], Frederic Dutheil[5], Serge Ferrari[6]. [1]Division of Bone Diseases, Geneva University Hospitals and Faculty of Medicine, Geneva, Switzerland, Switzerland. [2]INSERM, UMR1033; Universite De Lyon, France. [3]Thomas Jefferson University, United States. [4]SAINBIOSE, INSERM U1059, Jean Monnet University, SAINT-ETIENNE, France, France. [5]Université Clermont Auvergne, CHU Clermont-Ferrand,University Hospital of Clermont-Ferrand Preventive and Occupational Medicine, Clermont Ferrand, France, France. [6]Geneva University Hospital and Faculty of Medicine, Switzerland

Diabetic bone is characterized by low bone turnover and a higher degree of mineralization. Pigment Epithelium derived factor (Pedf) is expressed by bone-forming cells and activates bone mineralization by attracting mineralizing factors at osteoid surfaces. We previously observed increased Pedf bone gene expression in mice fed with high fat diet (HFD) and decreased expression in response to caloric restriction (CR) and exercise. Here we investigate circulating Pedf levels in relation to bone turnover in type 2 diabetic subjects (T2D) and the role of Pedf on bone properties in a diabetic mouse model.Pedf serum levels, Hb1Ac and bone turnover markers (BTMs: OCN, P1NP and CTx) were assessed in 29 obese T2D and 50 control (Ctr) subjects from the ReSoLVE trial (Dutheil et al. 2013) before and 6-month after CR plus exercise. Pedf -/- and Pedf +/+ adult male mice were fed with Chow or HFD during 8wks and assessed for metabolic markers, bone microarchitecture (µ-CT), formation and mineralization (histology), gene expression (Nanostring) and material properties (nano-indentation).T2D subjects had higher Pedf levels (+20%; $p<0.05$) and lower BTMs (-40% to -56%; $p<0.001$) vs. Ctr. CR + Exercise significantly decreased Hb1ac and Pedf serum levels, respectively improved BTMs in T2D. Pedf correlated positively with Hb1Ac (r =0.468; $p<0.001$) and negatively with CTX, OCN and P1NP (range r =-0.414 to -0.331; $p<0.001$).As compared to WT, Pedf -/- mice exhibited lower Tb. BV/TV (-50%), higher Tb. osteoid surfaces (+326%), and lower mineralization gene expression levels (Mepe, Alpl, BSP, OPN and osteonectin, range -67 to -34%; $p<0.05$), confirming the role of pedf on bone mineralization.HFD induced higher body weight, insulin levels and insulin resistance (AUCglucose) in both genoptypes (Pedf +/+HF : +30%, +210%, +28% vs Pedf +/+chow; Pedf -/-HF: +37%; +308%,+23% vs Pedf -/- chow; pHF< 0.001; pgenoNS). HFD increased Tb. MS/BS, Tb. BFR and Pedf, Mepe and Alpl bone genes expression in Pedf +/+ mice (+34%, +80%, +29%, +62%, +29%; pHF<0.05), but not Pedf -/- (pgeno<0.05). In turn HFD increased endosteal tissue hardness in Pedf +/+ but not in Pedf -/- mice (Pedf +/+HF : +58%; pHF<0.05; pgeno<0.01).Overall, these data suggest that Pedf is involved in bone mineralization and material properties alterations induced by insulin resistance. The degree of bone mineralization in these diabetic mice is currently being analyzed by micro-radiography. Elevated serum Pedf levels could potentially reveal pathological increases in bone mineralization in T2D.

Effect of endogenous melatonin depletion on metabolic markers in bone, fat and muscle in AA-NAT KO transgenic mice *Afsana Jahan[1], Afsin Malik[1], Yong Myoung[1], Diane Carlisle[2], Robert Friedlander[2], Paula Witt-Enderby[3]. [1]Duquesne University School of Pharmacy Div Pharm Sci, United States. [2]University of Pittsburgh School of Medicine Dept Neurological Surgery, United States. [3]Duquesne University,School of Pharmacy, United States

Background: Therapeutic doses of melatonin (~6mg nightly dose or 50nM in vitro) have been shown in in vitro, pre-clinical and clinical studies to produce strong effects on osteoblastogenesis to increase bone density, bone formation, and normalize bone marker turnover. In MSCs, melatonin induces osteoblastogenesis through MT2s and MEK1/2 and MEK5 pathways. In MSCs and mouse bone, melatonin, via MT2/MEK1/2- and MEK5-mediated pathways, inhibit PPAR?, the metabolic switch driving MSCs down an osteoblastic lineage, and away from an adipogenic lineage. Although much is known about the role of pharmacogical doses/concentrations of melatonin on bone and MSCs, little to no information is known about the role of physiological levels of melatonin on bone and the proteins that govern its physiology. This is important because conditions that suppress nocturnal melatonin levels (i.e., shift work, light at night) in people demonstrate decreases in bone mineral density and increases in fracture risk.Objective: To determine the role of endogenous melatonin on PPAR? and metabolic proteins governing this switch point (i.e., UCP-1, C/EBP, ACRP30, DIO2) in bone and metabolic tissues (white fat, WAT, brown fat, BAT and muscle) in an AA-NAT (melatonin-depleted) knockout model and compared to wild-type (WT; CBA) mice. The AA-NAT KO mice were made on CBA background known to have robust melatonin synthesis and circadian rhythms similar to WT mice.Methods: Tissue lysates were prepared from bone, muscle, WAT and BAT taken from AA-NAT KO mice. Protein levels were measured by western blot analysis and quantified using Odyssey and LiCor Imaging systems. Protein bands were normalized by total protein levels detected

using Revert 700.Results: The results of this study demonstrate that in AA-NAT knockout mice and when compared to WT mice, PPAR?, UCP-1, C/EBP, ACRP30 and DIO2 levels decreased in BAT; no changes in protein levels were observed in the other tissues except for ACRP30, which demonstrated trends (p= 0.0655) towards increases in muscle.Conclusion: These data demonstrate that melatonin produces distinct effects on metabolic proteins in bone and metabolically active tissues dependent upon dose suggesting that to achieve beneficial effects of melatonin on bone, pharmacological doses may be required. Further studies on bone biomechanics and density are required.

[6]Department of Medicine, Division of Nephrology, Icahn School of Medicine at Mount Sinai, United States. [7]Department of Biomedical Sciences, Korea University College of Medicine, Republic of Korea. [8]Mount Sinai Medical Center, United States

The main feature of skeletal abnormality in type 1 diabetes (T1D) is low bone turnover with decreased osteoblastic bone formation [1, 2]. However, the mechanism of osteoblast dysfunction remains unclear. We generated T1D mice using low dose streptozotocin (STZ). T1D mice showed lower bone mass (g/cm2) at the femur (0.07 vs. 0.09*) and trends at lumbar spine (0.05 vs. 0.06, p=0.08) compared with control group at 8 weeks after inducing T1D. Osteoblasts were differentiated using bone marrow mesenchymal stem cells, and RNAseq was performed to analyze the transcriptome of osteoblasts. In gene set enrichment analysis, several pathways including immune, hypoxia, and glycolytic pathway were enriched. The osteogenic genes panel showed decreased Bglap and Col1a1 expression, together with lower expression of Bmp2 and Wnt5a, suggesting decreased bone formation might be related to the suppression of BMP and WNT signaling. Particularly, P4ha2, encoding prolyl 4-hydroxylase subunit alpha-2, which are responsible for posttranslational modification of collagen were downregulated in T1D osteoblasts (log2FC = - 1.7**). Among genes in hypoxia pathway, Egln3 encoding prolyl hydroxylase domain-containing protein 2 and Vhl encoding von Hippel-Lindau tumor suppressor, both of which stabilize HIF-? were downregulated (log2FC = - 2.8** and - 0.31*, respectively) likely for promoting HIF-? dependent gene expression in hypoxia. However, genes of the growth signaling pathway, namely Pgf, Vegfa, and Igf1r, which were normally upregulated in hypoxic condition, were downregulated (log2FC = - 3.1**, - 0.4* and - 0.5**, respectively). Altogether, our findings suggest that maladaptation to hypoxic condition in T1D with compromised growth signaling pathway and impaired collagen synthesis might be related to osteoblasts dysfunction in T1D bone. (* $p < 0.05$ and ** $p < 0.001$)

High-fat Diet Induced Skeletal Muscle Metabolic Memory and Its Implication in Hyperglycemia and Associated Muscle Atrophy *Wei Ting Hsiao[1], Yuk-wai Lee[2], Chien-Wei Lee[3]. [1]Department of Orthopaedics & Traumatology, Faculty of Medicine, The Chinese University of Hong Kong, Hong Kong SAR, China, Hong Kong. [2]Li Ka Shing Institute of Health Sciences, The Chinese University of Hong Kong, Prince of Wales Hospital, Hong Kong SAR, China, Hong Kong. [3]Center for Translational Genomics & Regenerative Medicine Research, China Medical University Hospital, China Medical University, Taichung 40402, Taiwan, Taiwan, Province of China

Metabolic memory is a description of the lasting effects of pre-exposed stimulations, which can be manifested in a variety of aspects, including transcription, translation, post-translational modification, epigenetic modification, etc. In diabetes, long-term clinical trial follow-up studies showed that metabolic memory leads to a higher risk of diabetic complications and mortality. However, the role of metabolic memory in the early stage of hyperglycemia is unclear. Since skeletal muscle insulin resistance is an early response to hyperglycemia development and disease progression, we hypothesized that short-term repeated high-fat diet (HFD) feeding causes metabolic memory in skeletal muscle and influences the development of hyperglycemia.This study aimed to investigate the effects of repeated HFD on muscle structure and function in 12-week-old male C57BL/6J mice. The continuous control diet (CTL) and the repeated HFD feeding regimens shown in Figure 1 were used to investigate metabolic memory phenomenon. Six mice were sacrificed at each designated timepoints, then extensor digitorum longus (EDL) and gastrocnemius (GA) muscles were collected for analysis. Bulk RNA Sequencing was performed to identify DEGs during the treatment. In vitro functional experiments were employed to verify the in vivo findings. Two-way ANOVA statistical analysis was used in this study.According to the definition of metabolic memory which proposed by Poonam in 2020, persistent alteration metabolic memory patterns, including ECM remodeling, muscle stiffening, contraction relaxation deterioration, and force reduction, as well as increased sensitivity metabolic memory patterns, including the extent of hyperglycemia and weight gain, were identified in HFD group when compared with the CTL group (Figure 2.) Furthermore, the RNA Sequencing analysis revealed two clusters of DEGs exhibiting metabolic memory-like patterns, which are enriched with ECM remodeling and AGE-RAGE signaling pathways. In vitro experiments with myoblast cell line showed a causal relationship between substrate stiffness and the preservation of high-glucose-induced insulin resistance.Our findings revealed that muscle structural and functional alteration occurred at least 2 weeks before the fasting glucose was upregulation; thus, altering aberrant ECM remodeling in muscle through more in-depth investigation could provide a new avenue to develop new approaches to ameliorate the disease onset/progression.

Placental tissue derived allograft enhances bone healing and reduces pain behaviors in a surgically induced murine fracture model. *UPASANA GANGULY[1], Sonali J Karnik[2], Amy Creecy[3], Aamir Tucker[2], Murad Nazzal[2], Marko V Dragisic[2], Saveda Majety[2], Sarah L Mostardo[2], Rachel J Blosser[2], Fletcher A White[4], Jill C Fehrenbacher[5], Melissa Kacena[6, 1], , [2]Department of Orthopaedic Surgery, Indiana University School of Medicine, Indianapolis, IN, United States, United States. [3], United States. [4]Department of Anesthesia, Indiana University School of Medicine, IN, USA, United States. [5]Department of Pharmacology and Toxicology, Indiana University School of Medicine Indianapolis, IN USA, United States. [6]Indiana University School of Medicine, United States

Connective Tissue Matrix (CTM) allografts are structural implants intended to supplement or replace damaged or inadequate tissues. Generated from human amnion, chorion, and umbilical elements, these allografts contain structural proteins as well as tissue-specific and -agnostic growth factors. In damaged dermal and mucosal tissues, application of CTM allografts is associated with lower levels of pro-inflammatory cytokines in vivo. In these studies, we examined the efficacy of CTM allografts to improve bone healing and whether CTM alters injury-associated pain behaviors in a pre-clinical animal model. Forty-five, 12-week-old, male C57BL/6J mice were divided into four groups: Saline Control, Membrane, Paste, and Membrane+Paste. All mice underwent a surgically induced femur fracture and treatments were administered intraoperatively. Baseline and weekly post-surgery complete blood counts were conducted, and no significant change in the blood cell numbers were noted. Additionally, upon euthanasia no gross abnormalities with any organs were noted, suggesting no obvious cross-species immune reaction. X-rays were performed twice weekly post-surgery. Surgical and contralateral femurs were collected and processed for µCT and histological analysis. µCT analysis demonstrated that the Membrane+Paste group showed a significant 13% increase in the trabecular number and 98% increase in the mineralized callus area when compared to the saline controls ($p<0.05$ and $p<0.0001$, respectively). Histological analysis indicated the Membrane+Paste group exhibited a 90% increase in the percentage of bone within the callus when compared to the saline controls ($p<0.01$). Open field assessments demonstrated no significant differences in the activity of mice among groups. Weightbearing testing demonstrated that the Membrane+Paste group was able to bear more weight on their fractured limb 4 days post-surgery ($p<0.05$) and a stimulus-evoked nociception assay using Von Frey probes suggested that the same group displayed significantly less “pain-like” behavior ($p<0.01$). In the studies described here, allograft application at the fracture site is associated with increased bone formation in the callus and reduced pain-like behavior. The latter may allow earlier weightbearing and accelerated bone healing. Taken together, these findings suggest that CTM allografts may promote fracture repair and support a randomized control trial in humans for fracture repair in weightbearing bones.

Quantifying Tibial Stress Fractures Using Computed Tomography Finite Element Analysis *Rashad Madi[1], Makayla Clark[1], Rasleen Grewal[1], Julio Ojea Quintana[1], Christiana Cottrel[1], Scott Epsley[2], Gregory Chang[3], Chamith S. Rajapakse[4]. [1]University of Pennsylvania, United States. [2]Independent Researcher, United States. [3]New York University, United States. [4]Univeristy of Pennsylvania, United States

Introduction: Recent advancements in computed tomography (CT) scans have facilitated high-resolution imaging of tibial stress fractures in clinical settings. This has led to the application of finite element analysis (FEA) for studying the biomechanical properties of diseased bone (1). In our study, we employed FEA modeling to test the hypothesis that stiffness in stress fractures (measured in kN/mm) is lower than the stiffness in normal bone for the same individual in the same bone.Methods: We examined 10 tibial CT scans from 9 patients diagnosed with anterior/posteromedial tibial stress fractures (Figure 1A), including one patient with bilateral stress fractures. The study population comprised 6 males and 4 females with a mean age of 34 +/- 18. Each CT scan was individually analyzed using Sectra MSK (Version 24.2.6.5829, Linkoping, Sweden). In-house software was used to segment fracture regions. To simulate "pre-fracture" bone, we modified the 3D models by virtually filling the fracture region with normal cortical bone HU values derived from neighboring regions without fractures. We then employed FEA to model the tibia and simulate compression along the bone's axial direction, as described by Rajapakse et al. (2).Results: Our findings revealed a 2.8% [1.58% - 6.68%] decrease in bone stiffness in stress fracture patients compared to the pre-fracture baseline (Table 1B). HU analysis demonstrated that stress fractures have significantly lower HU values than normal bone, with a mean difference of 300 HU and a P-value of < 0.001 (Figure 1C). As the bone of a stress fracture heals and returns to its normal state, both HU and stiffness increase until they reach values indicative of normal bone.Discussion: By utilizing FEA modeling, we calculated the stiffness of bone in both pre- and post-stress fractures. These measurements can aid in determining when an athlete is ready to return to competition without risking further complications. Moreover, they provide valuable insights into an individual's bone health and progress toward full bone strength recovery.

Automated quantification of lipid storage and cellular dysfunction induced by glucocorticoid signaling in BMSC-derived osteoblasts *Colby Gross[1], HUSAM BENSRETI[2], Meghan McGee-Lawrence[3]. [1]Department of Cellular Biology and Anatomy, Medical College of Georgia at Augusta University, , United States. [2], United States. [3]Medical College of Georgia, Augusta University, United States

Glucocorticoids (GCs) are released in a circadian manner and during stress to regulate tissue metabolic activity. GCs can bind either glucocorticoid receptors (GR) or mineralocorticoid receptors (MR), which then act as transcription factors to mediate downstream effects. We previously showed that GC-induced signaling promoted lipid storage and dysfunction in BMSC-derived osteoblasts, but the relative contributions of the GR and MR were unclear. Here we report the effects of two experimental GR/MR inhibitors on the in vitro behavior of BMSCs using a novel automated method for quantifying intracellular lipid storage. Bone marrow stromal cells (BMSC) from 12-wk old female CD-1 mice were cultured for 14 days in osteogenic media with or without the GC dexamethasone (Dex). Cells were fixed and stained with Oil Red O (ORO) to detect lipids and Hoechst to highlight the nucleus (for easier counting of total cell number). Automated imaging and quantification were performed using a Cytation 5 plate reader and Gen5 software (Agilent BioTek). Manual quantification of ORO+ cells was used for verification. To test this new methodology in a previously established mouse model, BMSC from 6 mo old Osx-Cre: GR conditional knockout (GR- CKO) and WT littermates were cultured in osteogenic media in the presence of Dex and either the GR-specific inhibitor Relacorilant (RELA) or the GR/MR targeting drug Miricorilant (MIRI) for 14 or 21 days. Comparison between manual and automated quantification of ORO-containing osteoblasts showed no difference (p=0.806) between the approaches; both methods demonstrated that Dex significantly increased osteoblastic lipid storage compared to osteogenic media alone (p=0.0003, p=0.0115, respectively). Applying this methodology in our GR-CKO model, the GR-CKO cultures showed 30% more ORO-containing osteoblasts than WT cells, comparable to our previous reports. RELA increased lipid storage in WT cells by nearly 25%, while MIRI treatment rescued lipid storage in the GR-CKO cultures back to WT levels. These effects on lipid storage impacted mineralized matrix production, as the blunted matrix production seen in GR-CKO cultures (-6% vs. WT) was rescued to above WT levels by MIRI. Together, these data support a role for GC-mediated signaling via GR and MR in osteoblast lipid storage and dysfunction and established an unbiased, automated methodology for quantifying this phenomenon.

Evocalcet suppresses cyclin D1 oncogene-derived parathyroid cell proliferation in a murine model for primary hyperparathyroidism *Yasuo Imanishi[1], Tomoe Hirakawa[2], Waka Haruyama[3], Keigo Tsushida[3], Mariko Sakai[3], Tetsuya Kitayama[3], Takehisa Kawata[4], Ikue Kobayashi[1], Andrew Arnold[5], Masanori Emoto[1]. [5]Center for Molecular Oncology and Division of Endocrinology & Metabolism, University of Connecticut School of Medicine, United States

Background: Evocalcet, a calcimimetic compound, suppresses parathyroid (PTH) hormone secretion from parathyroid glands in both primary hyperparathyroidism (PHPT) and secondary hyperparathyroidism (SHPT) similar to cinacalcet's activity. We previously reported the suppressive effect of cinacalcet on parathyroid cell growth in vivo in a PHPT model mouse, in which parathyroid-targeted overexpression of the cyclin D1 oncogene caused chronic biochemical hyperparathyroidism and parathyroid cell hyperplasia. In this study, the effect of evocalcet on parathyroid cell proliferation was analyzed in the PHPT mice.Methods: Evocalcet (0.25 mg/g chow) or cinacalcet (1 mg/g chow) was mixed into the rodent diet and orally administrated to 59-71 week-old PHPT mice for 10 days before sacrifice. 5-bromo-2'-deoxyuridine (BrdU) (240 µg/day) was infused by an osmotic pump for five days before sacrifice, followed by immunostaining of the thyroid-parathyroid complex using an anti-BrdU antibody to estimate parathyroid cell proliferation.Results: Compared to untreated PHPT mice, evocalcet or cinacalcet significantly suppressed both serum calcium and PTH and increased serum phosphate. The proportion of BrdU-positive cells to the total cell number in the parathyroid glands increased considerably in untreated PHPT mice (5.23 +/- 4.64%, mean +/- SD) compared to wild-type mice (1.15 +/- 0.82%), and was significantly suppressed by evocalcet (1.87 +/- 2.34%) or cinacalcet (1.38 +/- 0.95%). These compounds did not affect the expression of calcium-sensing receptor or vitamin D receptor in the parathyroid cells of the PHPT mice.Conclusions: These data suggest that evocalcet suppressed both serum PTH levels and parathyroid cell proliferation as effectively as cinacalcet in vivo in PHPT.

Loss of 24-Hydroxylase in Murine Fetuses Causes Hypercalcemia and Hypophosphatemia *David Bennin[1], Sarah A. Hartery[1], Alexandre S. Maekawa[1], Beth J. Kirby[1], René St-Arnaud[2], Christopher S. Kovacs[1]. [1]Memorial University of Newfoundland, Canada; [2]McGill University and Shriners Hospital for Children-Canada, Canada

Calcitriol circulates at low levels in normal human and rodent fetuses due to increased 24-hydroxylation of calcitriol and 25-hydroxyvitamin D. Prior human and animal studies have shown that absence of vitamin D, calcitriol, or vitamin D receptor do not disturb fetal mineral homeostasis or skeletal development. However, whether high concentrations of calcitriol affect fetal bone and mineral metabolism has not been assessed. Inactivating mutations of CYP24A1 cause high postnatal levels of calcitriol and the human condition of infantile hypercalcemia type 1, but whether the fetus is disturbed by this is unknown.We hypothesized that loss of Cyp24a1 in fetal mice will cause high calcitriol, hypercalcemia, and increased placental calcium transport.Cyp24a1+/- mice were mated to create pregnancies with WT, Cyp24a1+/- (HET) and Cyp24a1-/- (null) fetuses. On embryonic day (ED) 18.5, maternal and fetal blood, placentas, and intact fetuses were collected. On ED 17.5, amniotic fluid was collected; placental calcium and phosphate transport were assayed after intracardiac injections of 45Ca and 32P to the mother. Intact fetuses were either reduced to ash with ash mineral content assayed by atomic absorption spectroscopy, or were rendered transparent and stained with Alcian blue and alizarin red S to visualize the intact skeletons. Placental and kidney gene expression were examined by qPCR.Null fetuses were markedly hypercalcemic (3.37+/-0.81[SD] vs 2.15+/-0.80 mmol/L in WT, p<0.001) and hypophosphatemic (1.44+/-0.46 vs 1.97+/-0.68 mmol/L in HET, p<0.02). They also showed increased calcitriol (358+/-124 vs 190+/-42 pmol/L in WT, p<<0.001) and FGF23 (706+/-50 vs 204+/-47 pg/mL in WT, p<<0.001) while PTH was unchanged. qPCR confirmed absence of Cyp24a1 and 2-fold increases in S100g, Ncx1 and Casr in null placentas but not fetal kidneys; these changes predicted an increase in placental calcium transport. However, placental 45Ca and 32P transport were unchanged in nulls. Fetal ash weight and mineral content, placental weight, crown-rump-length, and skeletal morphology did not differ among the genotypes. Overall, loss of Cyp24a1 in fetal mice caused increased calcitriol, hypercalcemia, hypophosphatemia, increased FGF23, but no disturbance in placental mineral transport or skeletal development and mineralization. These results indicate that the human condition of infantile hypercalcemia type 1 likely begins with hypercalcemia in utero.

Cyp24a1 Ablation in Mice Causes Increased Intestinal Calcium Absorption, Hypercalcemia in Pregnancy, and Reduced Lactational Bone Loss *Alexandre S. Maekawa[1], David Bennin[1], Sarah A. Hartery[1], Beth J. Kirby[1], René St-Arnaud[2], Christopher S. Kovacs[1]. [1]Memorial University of Newfoundland, Canada; [2]McGill University and Shriners Hospital for Children-Canada, Canada

Homozygous inactivating mutations of 24-hydroxylase (CYP24A1) cause mild hypercalcemia in humans, which can become severe and life-threatening during pregnancy (gestational hypercalcemia). The mechanisms are unclear and effects on lactation and post-weaning have not been studied.We studied the effects of Cyp24a1 ablation in mice on maternal calcium and bone metabolism during pregnancy, lactation, and post-weaning. We hypothesized that a normal 2-3 fold rise in calcitriol during pregnancy would be greater due to loss of its catabolism. In turn this would cause a marked increase in intestinal calcium absorption (IntCaAbs) during pregnancy; if sustained during lactation, less bone resorption would result.WT and Cyp24a1 null sisters were mated to Cyp24a1+/- males. Main timepoints included before mating (BL), late pregnancy (LP), mid-lactation (ML), late lactation (LL), and weekly to 28 days post-weaning (R1-4). Bone mineral content (BMC by PIXImus DXA), serum, and urine were collected at all time points. IntCaAbs was assayed after oral gavage of 45Ca. Serum and urine minerals, calcitriol, FGF23, and PTH were measured.At LP, whole body BMC increased equally ~12% in null and WT. Calcitriol was 2.5 fold higher in nulls vs WT (189+/-68 vs 76+/-20 pmol/L, p<0.001), accompanied by higher IntCaAbs (3.6+/-0.5 vs 1.2+/-0.2%, p<0.002), hypercalcemia (3.2+/-0.5 vs 2.7+/-0.4 mmol/L, p<0.05), hypercalciuria (9.4+/-9.6 vs 1.0+/-1.5 mmol/L, p<0.001), and higher FGF23 (1716+/-803 vs 260+/-151 pg/mL, p<0.001). PTH was suppressed in both. 20% of null dams died during delivery but their serum calcium at LP was the same as null survivors.At ML, calcitriol, IntCaAbs, and FGF23 had declined in both genotypes but remained higher in nulls over BL (91+/-49 vs 20+/-5 pmol/L, 2.2+/-0.9 vs 0.5+/-0.3%, and 736+/-752 vs 203+/-75 pg/mL, respectively). By LL, nulls were still hypercalcemic vs WT (2.61+/-0.48 vs 2.07+/-0.38, p<0.05), and had lost less mean whole body BMC (11% vs. 21%) to reach 0.572+/-0.056 vs 0.519+/-0.035 g, p<0.02. Lactational losses in BMC were restored by R4 in both.In summary, ablation of Cyp24a1 caused increased IntCaAbs during pregnancy and lactation, hypercalcemia at both time points, reduced lactational bone loss, and late gestational mortality in some nulls. Treating women with gestational hypercalcemia from CYP24A1 mutations should focus on methods to reduce IntCaAbs or lower calcitriol, since increased bone resorption is not the mechanism for hypercalcemia in this condition.

Gender Affirming Hormone Therapy does not impair skeletal maturation in young mice and regulates Bone via the Gut Microbiome *Subhashis Pal[1], Hamid Dar[1], Andreea Stoica[2], Yijuan Hu[3], Rheinallt M. Jones[3], Neale Weitzmann[4], Roberto Pacifici[4]. [1]Post Doctoral Researcher, Emory University, United States; [2]Research Specialist, Emory University, United States; [3]Associate Professor, Emory University, United States; [4]Professor, Emory University, United States

Gender affirming hormone therapy (GAHT) is used by ~80 % of transgenders to alleviate gender dysphoria and to align physical characteristics with the affirmed gender. GAHT is often started during adolescence, potentially impacting skeletal maturation. In this study, we evaluate the effects of GAHT on postnatal skeletal development and the involvement of gut microbiome in the skeletal effects of GAHT. We modeled GAHT used by transwomen by performing orchidectomy (orx) in 6-weeks-old male mice and treating orx mice with estrogen (E2) for 10 weeks. GAHT used by transmen was modeled by treating intact female mice with testosterone from 6 to 16 weeks of age. Neither E2 treatment of orx male mice, nor testosterone treatment of eugonadic female mice impaired skeletal maturation, bone structure, or turnover, in 6-16 weeks old animals. In fact, GAHT in male mice, resulted in better bone microarchitecture and higher serum osteocalcin, a marker of bone formation. Measurement of gut permeability through serum lipopolysaccharide and sCD14 quantification revealed that GAHT didn't alter gut permeability in male or female mice. Intriguingly, GAHT did result in sex-specific changes in the composition of the gut microbiome, and induced modifications to bacterial metabolic pathways within the microbiome that were associated with changes in bone structure. Confirming the causal role of the microbiome change, fecal material transfer studies revealed that GAHT-shaped gut microbiome was a communicable regulator of gut permeability, bone structure, and turnover in mice. Mediation analysis identified three strains of Bacteroides (Bacteroides acidifaciens JCM 10556, Bacteroides caecimuri, and Bacteroides caecimuris) as responsible, in part, for the skeletal effects of GAHT in male mice. Bacteroides promote the expansion of intestinal regulatory T cells (Tregs), a sex steroid-regulated T cell population known to affect bone formation and resorption. Accordingly, GAHT was found to regulate the frequency of intestinal and bone marrow Tregs, indicating that a higher number of Tregs could account for the improved bone microarchitecture of GAHT-treated male mice. In summary, GAHT treatment mice did not

impair skeletal maturation in young male and female animals, and improved bone structure in male mice. GAHT acted, in part, by regulating microbiome composition and function. Mechanistically, GAHT-induced microbiome changes may regulate bone maturation affecting Treg differentiation.

A Diurnal Trough in Glucocorticoid Signaling is Essential for Bone Health *Annelies Smit[1], Jan Kroon[1], Sander Kooijman[1], Maaike Schilperoort[2], Salwa Afkir[1], Bram van der Eerden[3], Marijke Koedam[3], Patrick Rensen[1], Onno Meijer[1], Elizabeth Winter[4]. [1]Department of Medicine, Division of Endocrinology, Leiden University Medical Center, Leiden, the Netherlands, Netherlands. [2]Department of Medicine, Columbia University Irving Medical Center, New York, USA, United States. [3]Department of Internal Medicine, Erasmus MC, Rotterdam, Netherlands, Netherlands. [4]Department of Medicine & Center for Bone Quality, Division of Endocrinology, Leiden University Medical Center, Leiden, the Netherlands, Netherlands

PurposeWe recently have shown that a flattened glucocorticoid (GC) circadian rhythm in itself induces an osteoporotic phenotype in mice. Here, we investigated whether the diurnal trough in GC signaling is essential to preserve bone mass and structure.MethodsFemale C57Bl/6J mice were implanted with slow-release 7.5 mg corticosterone (CORT) or vehicle pellets for 7 weeks to flatten GC circadian rhythm without increasing total exposure. Additionally, mice received daily subcutaneous injections with vehicle or non-specific GC receptor antagonist RU-486 to reintroduce a diurnal trough in GC signaling. To investigate a timing effect, mice were injected either at the time of the endogenous GC trough, i.e. zeitgeber time (ZT) 1, or GC peak (ZT11). Bone remodeling was assessed by serum turnover markers, osteoblast and osteoclast surface area was determined via osteocalcin and tartrate-resistant acid phosphatase (TRAP) staining respectively, and bone microarchitecture was evaluated by micro-CT (n=12/group).ResultsThe various interventions did not affect serum bone resorption marker TRAP levels. The timing of peak bone formation marker procollagen type I N-terminal propeptide (P1NP) levels was notably synchronized to the timing of RU-486 injection, resulting in a reversed P1NP pattern in mice injected at ZT11, as compared to vehicle. Osteoclast and osteoblast surface area were unchanged across groups. CORT pellets induced a loss of lean mass compared to vehicle (-6.5%, $p<0.01$), which was rescued by RU-486 injection at both ZT1 and ZT11, suggesting prevention of bone wasting. Indeed, CORT pellets significantly reduced cortical thickness (-13.0%, $p<0.001$), cortical bone area (-10.0%, $p<0.01$) and trabecular bone volume (-31.8%, $p<0.05$), as compared to vehicle. RU-486 injection at either timepoint significantly improved cortical thickness (ZT1 +10.5%, $p<0.01$; ZT11 +9.2%, $p<0.01$) and cortical bone area (ZT1 +8.7% $p<0.05$; ZT11 +9.5% $p<0.01$), as compared to CORT mice. Notably, RU-486 injection at ZT1 prevented trabecular bone volume loss, while RU-486 injection at ZT11 did not (-30.6%, $p<0.05$, as compared to vehicle).ConclusionReinstating a diurnal trough in GC signaling under the condition of flattened GC levels is sufficient to rescue bone mass and structure. The fact that these effects were more pronounced when the GC receptor antagonist was injected at the time of the endogenous GC trough suggests that the circadian context of bone tissue is also important.

Paradoxical effects of abaloparatide on 1,25-dihydroxyvitamin D formation and blood calcium level change *Yanmei Yang[1], Wei-Ju Tseng[1], Bin Wang[1]. [1]The Center for Translational Medicine, Departments of Medicine, Sidney Kimmel Medical College, Thomas Jefferson University, Philadelphia, Pennsylvania 19107, United States

Paradoxical effects of abaloparatide on 1,25-dihydroxyvitamin D formation and blood calcium level changeYanmei Yang, Wei-Ju Tseng, and Bin WangThe parathyroid hormone (PTH)-related peptide(1-34) analog, abaloparatide (ABL) is the second anabolic agent for the treatment of osteoporosis. Previous research demonstrated that ABL had a potent anabolic effect but caused hypercalcemia at a significantly lower rate. 1,25-dihydroxyvitamin D [1,25(OH)2D] plays an important role in intestinal calcium absorption and renal calcium reabsorption. However, it is unknown whether ABL affects 1,25(OH)2D synthesis and its downstream signaling. Osteocalcin (Ocn) is synthesized by osteoblasts and is the most abundant non-collagenous protein in bone. The carboxylated Ocn (Gla-Ocn) is released into the circulation and exhibits high affinity to bind ionized calcium (Figure 1), which in turn induces Gla-Ocn conformational change and then increases Gla-Ocn binding to hydroxyapatite to form new bone matrix. During the bone remodeling, Gla-Ocn in bone matrix can be converted into a form with a lower grade of carboxylation and uncarboxylated Ocn (Glu-Ocn), and then be released into the bloodstream when osteoclasts are activated to form acidic pH. Although ABL was reported to increase total Ocn formation in the circulation, the effects of ABL on both Gla-Ocn and Glu-Ocn levels and their ratio in bloodstream and bone are unknown. Our in vivo data showed that ABL significantly increased rat 1,25(OH)2D formation, however, without raising the blood calcium values. ABL also significantly augmented the levels of Gla-Ocn and Glu-Ocn, as well as the ratio of Gla-Ocn to Glu-Ocn in blood and bone. The in vitro data showed that 1,25(OH)2D concentration-dependently induced Gla-Ocn formation in rat osteoblastic cells, confirming that Ocn is the downstream signaling of 1,25(OH)2D. ABL had little direct effects on 1,25(OH)2D synthesis and Ocn formation in non-renal cells (rat osteoblastic cells). However, ABL significantly promoted both 1,25(OH)2D and Gla-Ocn formation when 25-hydroxyvitamin D, the substrate of 1alpha-hydroxylase, was added to the cells. Our data also showed that the increased Gla-Ocn levels are vitamin K-dependent in osteoblasts. Thus, the increased 1,25(OH)2D levels in rats treated by ABL result in high level of Gla-Ocn and transient calcium increase in the circulation. The ionized calcium then binds to Gla-Ocn that increases Gla-Ocn to bind to hydroxyapatite to form new bone matrix. We conclude that Gla-Ocn at least, in part, eliminates the paradoxical effects of abaloparatide on 1,25(OH)2D formation and blood calcium level change, which may help understand the mechanism of ABL for osteoporosis therapy.

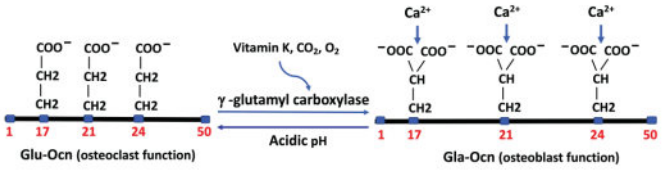

Figure 1. Schematics of osteocalcin (Ocn) post-translational modification. Post-translational carboxylation at three glutamic acid residues at positions 17, 21 and 24 in rat occurs by γ-glutamyl carboxylase that uses vitamin K, CO_2, and O_2 as cofactors, which results in the formation of three Ca^{2+}-binding γ-carboxyglutamates (Gla) in osteoblasts. The carboxylated form of OCa (Gla-Ocn) can be converted into a form with a lower grade of carboxylation (Glu-Ocn) when osteoclasts are activated to form acidic pH. In contrast to Gla-Ocn, Glu-Ocn has no affinity to ionized calcium.

SAT-177

PTH-dependent stabilization of RANKL mRNA is associated with a selective increase in binding of phosphorylated KSRP, an AU-rich element binding-protein, to RANKL transcripts. *Gang-Qing Yao[1], Meiling Zhu[2], Karl Insogna[1]. [1]Yale University School of Medicine, United States. [2]Yale University, United States

PTH1R agonists promote bone formation but also increase osteoclastogenesis in part by increasing RANKL expression. Consistent with previous reports, we observed a significant 10+/-1.2-fold increase in RANKL mRNA expression in UAMS cells treated with PTH for 6 hours. However, despite pretreating these cells with triptolide, a powerful inhibitor of transcription, PTH still increased RANKL transcript levels by 7.4+/-2.4-fold. RANKL mRNA stability is regulated by AU-Rich Element binding proteins (ABPs), which bind to AREs (AU-Rich Elements) in the 3' UTR of RANKL transcripts. PTH did not change transcript expression levels of four ABPs: KSRP, AuF1, HuR, and TTP. ABPs are phosphorylated by protein kinases and dephosphorylated by Pin1. Phosphorylating Pin1 blocks Pin1's enzymatic activity. PTH increases the phosphorylation of KSRP and Pin1 in opossum kidney cells1, suggesting that PTH-dependent phosphorylation of KSRP reflects inhibition of Pin1. Whether these pathways are operative in bone is not currently known.Levels of phosphorylated KSRP in UAMS cells pretreated with triptolide and subsequently treated with PTH, were significantly increased compared to those treated with vehicle (0.225+/-0.012 µg/ per 106 cells vs. 0.083+/-0.009 µg/ per 106 cells, $p<0.001$). Phosphorylation of AuF1, HuR, and TTP proteins either remained unchanged or were slightly reduced in response to PTH treatment. KSRP was subsequently immunoprecipitated from PTH-treated cells and the RANKL mRNA content of the immunoprecipitated quantified by RT-PCR. The immunoprecipitates from PTH-treated cells contained considerably more RANKL mRNA than did vehicle treated cells. In an initial experiment the amount of RANKL mRNA in immunoprecipitates of AuF1, HuR, and TTP did not change significantly with PTH treatment. There were no changes in the cellular content of phospho-Pin1 protein with PTH treatment. We speculate that PTH selectively increases binding of phosphorylated KSRP (which is not active) to RANKL mRNA and either displaces, or competes for binding of non-phosphorylated KSRP to the mRNA, thereby stabilizing the transcript.We conclude that, 1) PTH induces KSRP phosphorylation by a mechanism that does not involve changing the activity of Pin 1. 2) PTH appears to selectively increase binding of phosphorylated KSPR to RANKL transcripts, which may play an important role in PTH-independent RANK mRNA stabilization.

Dual anti-resorptive and anti-inflammatory activity of tanshinone IIA-sulfonate attenuates rheumatoid arthritis in mice *Preety Panwar[1], Pierre M Andrault[2], Dieter Bromme[2]. [1]University of British Columbia, Canada. [2]The University of British Columbia, Canada

Rheumatoid arthritis (RA) is an autoimmune disease characterized by joint inflammation and tissue destruction. An effective treatment for RA needs to combine both anti-inflammatory and anti-resorptive properties. Here, we demonstrate the potent dual activity of tanshinone IIA sulfonate (T06) effectively reducing inflammation as well as cartilage/bone loss in a mouse arthritis model. T06 effectively suppresses the percentage of synovial fibroblast, various immune cells and osteoclasts which was corroborated by the decreased production of inflammatory cytokines (tumor necrosis factor (TNF)-?, interleukin-1? (IL-1?), IL-17, IL-6, IFN?, and RANKL. Interestingly, a significant reduction in T helper (Th17) cells that activate osteoclasts by inducing synovial fibroblasts via IL-17 is caused by T06 resulting in less osteoclasts and bone resorption. The anti-inflammatory activity of T06 is based on the interference of the NF-kB pathway by preventing the phosphorylation of I?B?/NF-?B signaling in immune cells, and thus its nuclear translocation resulting in the reduced expression of inflammatory cytokines. We also demonstrated that the activation, nuclear location, and DNA binding of NF-kB is decreased by T06-treatment. The anti-resorptive activity of T06 is based upon its interference with the formation of collagenolytically active CatK oligomers resulting in a selective inhibition of its bone and cartilage-destroying collagenase activity. In contrast, the selective active-site-directed CatK inhibitor, odanacatib, reduced bone and cartilage resorption but did not alleviate inflammation. Our study illuminates the immune regulatory and antiresorptive effect of T06 in arthritis.

Extracellular Matrix Protection Factor 1, a Novel Therapeutic, Demonstrates Chondroprotective Properties in a Rat Model of Post-Traumatic Osteoarthritis *Marina D'Angelo[1], Amy Bhatt[1], Brian Heist[1], Lyudamila Lukashova[2], Patrisia Mattioli[1], Victoria Datillo[1], Ellen Cho[1], Sarah Chmielewski[1], Tiffany Holmes[1], Abdulhafez Selim[1]. [1]Philadelphia College of Osteopathic Medicine, United States. [2]University of Pittsburgh, United States

Osteoarthritis (OA) is a common degenerative joint disease causing pain and disability in more than 654 million, or 23% of adults worldwide. Post-traumatic osteoarthritis (PTOA) occurs after articular or meniscal injury to the joint and accounts for 12% of symptomatic OA cases. PTOA offers an opportunity to explore novel therapeutic treatments because the starting point is clear. Current pharmacological treatment targets inflammation and pain management through non-steroidal anti-inflammatory drugs and intraarticular corticosteroids. Extracellular Matrix Protection Factor 1 (ECPF-1) is a novel therapeutic that inhibits specific matrix metalloproteinases that are involved in degradation of the cartilage extracellular matrix (ECM) during PTOA. In this study, an experimental rat model of PTOA was replicated by an injection of mono-iodoacetate (MIA) infrapatellar to the ligament of 150g male, Wistar rats. This model is characterized by osteophyte formation at the edges of the joint, fibrillation and erosion of the cartilage within 30 days of the injections. One week following MIA, animals were injected weekly for 4 weeks with various doses of ECPF-1(0.25uM - 5uM), saline (negative control), or BMP-7 (500 ng, positive control) and sacrificed between 28 and 56 days. Total mineralization in the femur and tibial cartilages and 3D reconstructions were scanned through µCT of 15um voxel size, 55KVp, 0.36 degrees rotation step (180 degrees angular range) and a 600ms exposure per view from joints immersed in phosphate buffered saline solution (Scanco µCT software and HP, DEC windows Motif 1.6). Volumes were segmented using a global threshold of 0.4g/c for bone and 0.25g/c for soft tissue. Following µCT scanning, specimens were decalcified, embedded in paraffin, sectioned and stained with Safranin-O to detect proteoglycans or Periodic-acid Schiff for general cartilage architecture. The µCT images showed that at both the 28-day post-loading (4 weekly injections) and 56-day protection phase (4 weeks beyond the final injection), ECPF-1 decreased ECM degradation compared to untreated controls. Improved articular cartilage histological staining of the ECPF-1 treated joints supported the µCT image data for the femur and tibia. We are currently compiling the µCT mineralization data. These preliminary results suggest a chondroprotective property to ECPF-1 and its potential as a therapeutic that may slow the progression of PTOA.

SAT-180

Characterisation of Spatial Variations of Epiphyseal Growth Plate Bridging In Loaded Post-traumatic Murine Model of Osteoarthritis *Hasmik Jasmine Samvelyan[1], Kamel Madi[1], Livia Rocha Dos Santos[1]. [1]Dr, United Kingdom

Our recent studies indicated uncharacteristic growth plate (GP) changes may contribute to osteoarthritis (OA) in mouse models. However, the precise relationship between spatial variation in GP bridging and cartilage mechanics has yet to be determined, and how this may increase OA vulnerability.We investigated GP dynamics in non-invasive mechanically loaded murine model of OA, to understand associations between abnormalities in these dynamics and biomechanical material properties of calcified cartilage, found beneath the hyaline cartilage, underpinning post-traumatic OA development.The right knee joints of 19-week-old wild type C57BL/6 male mice (n=7) were subjected to dynamic axial mechanical loading for 7 min/day, 3 alternate days a week for 2 weeks to induce OA-like changes in vivo. Left knee joints were non-loaded controls in each animal. Subchondral bone (SCB) and trabecular bone (Tb.) parameters were measured using microCT in tibiae of these mice (n=14) and correlated to GP bridging using novel 3D quantification method. All procedures were approved by University Ethics Committee.3D quantification revealed enriched GP bridging (540+35 vs 750+19; p<0.001) and higher bridge densities (16+1 vs 21+0.5; p<0.001) in medial compared to lateral tibiae in loaded knee joints. Anatomical variations were observed in all samples, with focal high-density clusters forming in anterior region of medial loaded tibiae compared with those more central and posterior of non-loaded tibiae. GP dynamics were associated with increased SCB and epiphyseal Tb. volume fraction (BV/TV) in medial compared to lateral tibiae of loaded knee joints.Results confirm AC chondrocyte transiency and characteristic thickening of medial tibiae SCB and Tb. in loaded model of post-traumatic OA. We reveal spatial variation of GP bridging in this model and how these may contribute to anatomical variation in vulnerability of OA development. Ongoing experiments will further determine these associations, establish biomechanical and morphological properties across calcified cartilage underpinning post-traumatic OA development and examine relevance to human OA.

Implant loosening in bone can be detected by bone biomarkers in rodents *Andreas A. Kurth[1], Björn Habermann[2], Konstantinos Kafchitsas[3]. [1]Marienhaus Klinikum Mainz, Germany. [2]Dep. Orthopedic Surgery, University Medicine Mainz, Germany. [3]Spine Center Oberpfalz, Orthopaedic Hospital Lindenlohe, Germany

Aseptic loosening of implants is the leading cause of implant failure. Currently, this can only be diagnosed with a combination of medical history, clinical symptoms and imaging. Detection of aseptic implant loosening at an early stage would improve surgical outcome, and future pharmacologic intervention may prevent further bone destruction. Since aseptic implant loosening is caused by increased periprosthetic bone resorption, parameters of periprosthetic bone metabolism may offer an option for early detection.Material and methods:60 female OVX Wistar rats were randomized into experimental group (n=50) and control group (n=10). All animals in the experimental group were implanted with a tibial hemiarthroplasty, and polyethylene particles were continuously infused into the operated joint via a diffusion pump to induce implant loosening. All animals in the control group underwent sham surgery.

Blood was taken preoperatively every 42 days, once on the day of surgery and postoperatively every 7 days. In the serum, osteocalcin (OC) and PINP were determined as parameters of bone formation, and C-terminal type I collagen telopeptide (CTX) and tartrate-resistant acid phosphatase 5b (TRAP 5b) as parameters of bone resorption.Results:_ OC showed an identical course in both groups. PINP showed significantly increased concentrations postoperatively in the experimental group ($p<0.05$). CTX showed significantly higher postoperative concentrations in the experimental group only on day 14 and 21 ($p<0.05$). TRAP 5b showed significantly higher activity postoperatively in the experimental group ($p<0.05$). Conclusion:Implant loosening was expected from day 28 in the model used. CTX showed increased concentrations prior to the expected changes, but is not very sensitive enough to bone resorption, and has a pronounced circadian rhythm. TRAP 5b activity was significantly increased temporally before and during the first histological changes and could therefore be considered as a predictor of aseptic implant loosening. PINP was elevated due to ineffective bone formation in the context of aseptic prosthesis loosening and may contribute to the early diagnosis of aseptic prosthesis loosening in combination with TRAP 5b serum activity. Due to the low influence of metabolism, food intake and circadian rhythmicity, TRAP 5b has many merits for clinical application and should be investigated further for its clinical use in identifying the initial stage of aseptic implant loosening.

Static Strain, but Not Dynamic, Inhibits the Hippo Pathway to Activate YAP in MSC *Zhihui Xie[1], Buer Sen[1], Sean Howard[2], Cody McGrath[1], Maya Styner[1], Gunes Uzer[2], Janet Rubin[1]. [1]UNC@Chapel Hill, United States; [2]Boise State, United States

Skeletal progenitors require mechanical input to direct appropriate formation of the skeleton. In-vitro application of dynamic mechanical force to mesenchymal stem cells (MSC) promotes stemness and constrains adipogenesis (1). Nuclear transport of YAP (Yes-associated protein) is involved in force signaling: YAP nuclear entry due plating of MSC stiff substrate has been ascribed primarily to stretching of nuclear pores via F-actin/LINC connections (2). We previously showed in primary murine marrow MSC that application of static stretch promoted YAP translocation, but that dynamic strain did not (3). As both strain applications generate indistinguishable accretion of phalloidin stained F-actin cables in the cytoplasm and crossing the nucleus, we asked what distinguishes static strain, which allows YAP entry, from dynamic strain, which does not. We examined the Hippo pathway, which when activated, induces phosphorylation of YAP and prevents its transport to the nucleus (pMST? pLATS? pYAP? nuclear exclusion of YAP). Hippo protein phosphorylation and immunofluorescence microscopy were performed 3 hours after application of 2% strain using murine MSC: a) static = x 1/hold and b) dynamic = x 200 cycles @ 0.2 Hz with release. We found dynamic strain increased phosphorylation of MST (180%) and YAP (113%), and that nuclear YAP did not increase (micrography assessment of nuclear YAP). In contrast, static strain induced de-phosphorylation of MST, LATS and YAP on western blots (50%, 57% and 38% respectively). To investigate the mechanism whereby static strain caused dephosphorylation of Hippo pathway members, we pulled down MST and found that association of the STRIPAK phosphatase catalytic subunit PP2AC was increased. Inhibiting PP2A with okadaic acid prevented static strain YAP nuclear entry. To ascertain a potential contribution of F-actin/LINC forces on the nucleus to YAP transfer, we utilized MSC transfected with a lentiviral DOX-inducible dominant-negative KASH expression: preventing F-actin association with LINC member KASH disrupts mechanical force on the nucleus. Treatment with DOX induced expression of DN KASH labelled with cherry red. In DOX treated cells, DN-KASH expression did not impair static strain induced nuclear YAP entry. Our results indicate that the predominant effect of static strain, rather than altering nuclear membrane mechanics, is to promote PP2AC association with MST, thus preventing activation of the Hippo pathway to phosphorylate YAP. Dynamic strain, in contrast, activates the Hippo pathway, preventing the nuclear transport of YAP through promoting its phosphorylation.1. Sen JBMR 2020 2. Elosegui-Artola Cell 2017 3. Adaptive Response to Loading is Impaired in a Mouse Model of Osteogenesis Imperfecta *David Bertrand[1], JOSEPHINE T. TAUER[2], Joan Marini[3], Frank Rauch[4], Bettina Willie[1]. [1]McGill University, Canada; [2]Shriners Hospital, Canada; [3]National Institute of Child Health and Human Development, United States; [4]Shriners Hospital for Children, Montreal, Canada

IntroductionOsteogenesis imperfecta (OI) is a connective tissue disorder characterized by increased bone fragility with frequent fractures. The cross-sectional area of long bones, as measured by periosteal circumference, is consistently low in individuals with OI This appears to be due to reduced periosteal bone apposition and may be related to a reduced adaptive loading response. Thus, we aimed 1) to determine strains engendered in tibias during locomotion and assess strain-load relationship, and 2) to examine the bone remodeling response in OI mice following a 2-week in vivo tibial loading.MethodsStrain gauges were attached to the antero-medial surface of the tibias of ten-week-old female Brtl+/- mice and wild type (WT) littermates (n=7/genotype). Strains engendered during walking and cyclic tibial compressive loading (3N to 12N) were then measured. Based on these results, the bone adaptive response to two weeks of in vivo tibial loading (5 days/week) at 10N was assessed in both Brtl+/- and WT mice (n=10/genotype; left tibia loaded, right tibia nonloaded control). The change in bone mass and microstructure was assessed via in vivo ?CT (? =day 15-day 0). ?CT-based timelapse morphometry was performed to assess endocortical (Ec) and periosteal (Ps) mineralized and eroded volumes and surface areas over the 15-day interval. Activity analysis, dynamic fluorochrome-based histomorphometry, assessment of bone formation markers (P1NP, TRAP5b), and characterization of the osteocyte lacunocanalicular network (LCN) are ongoing.ResultsAt day 0, as expected, Brtl+/- mice showed significantly reduced cortical area (CtAr), total area (TtAr), marrow area (MaAr), second moment of area (Imax, Imin) and cortical thickness (CtTh) compared to WT. Following two weeks of loading, ?CtAr, ?CtTh, Ec. MV/BV, Ec. MS/BS were significantly increased in loaded compared to non-loaded limbs for both genotypes. Strikingly, ?TtAr, Ps.MV/BV and Ps. MS/BS were significantly increased in the loaded vs non-loaded limb of WT mice, but not in Brtl+/- mice. In terms of resorption, both Ec and Ps EV/BV and ES/BS were reduced in the loaded compared to control limb of both genotypes.ConclusionOur results suggest that Brtl+/- mice have a diminished loading-bone formation response on the periosteal surface, which is believed to be a contributing factor to their low bone mass phenotype. Ongoing research aims to investigate the mechanisms responsible for this reduced mechano-adaptive response.

Detrimental Effects of Microgravity on Osteoblast and Osteoclast Activity *Isaiah Taylor[2], Sardar Uddin[2], David Komatsu[3]. [2]Stony Brook University, ; [2]Stony Brook University, United States; [3]Stony Brook University, Dept. of Orthopaedics and Rehabilitation, United States

Mars 2030 is rapidly approaching, and despite recent breakthroughs in space biology, sending the first humans to Mars remains a significant challenge. During space flight, astronauts lose 1-1.5% of their bone mass per month. Because of our inadequate understanding of the mechanisms causing microgravity-induced bone loss, as well as the difficulties in developing effective remedies, NASA has designated microgravity-induced bone loss as a high-priority knowledge gap.Osteoblast-osteoclast coupling is a dynamic process regulating bone remodeling. This study uses osteoblast-osteoclast co-cultures to identify the direct and indirect cell communication pathways disrupted by microgravity (MG). Simulated MG is hypothesized to disrupt osteoblasts-osteoclasts communication, resulting in increased resorption and decreased bone formation.Primary human osteoblasts and osteoclasts (25,000 cells/chip) were seeded on tricortical human decellularized blocks and subjected to either microgravity or gravity using a rotary cell culture system (Synthecon®) for 28 days. The mechanical integrity of tricortical blocks was assessed using unconstrained uniaxial compression. Briefly, a monotonic load to failure was applied at 5mm/min, and data were analyzed for stiffness, energy to failure, yield force, ultimate force, and failure force.The biomechanical strength was significantly reduced in MG-exposed samples compared to samples experiencing normal gravity. Specifically, stiffness was 140% lower, energy to failure was 419% lower, yield force was 274% lower, ultimate force was 269% lower, and failure force was 269% lower in microgravity conditions compared to gravity. The biomechanical results for osteoclasts are in progress.Future experimental work includes RNAseq, ELISA, histomorphometry, and biomechanical analysis. The functional analyses will show the effects of osteoblast-osteoclast decoupling on bone structure and mechanical integrity. The utilization of primary human cells in the physiological environment significantly enhances the data's translational value in providing potential therapeutic targets for reducing microgravity-induced bone loss and further recognizing potential clinical targets for treating osteoporosis and osteopenia. In addition, the data from these studies will enhance our understanding of the effects of microgravity on the osteoblast-osteoclast coupling and identify biomolecular targets to regulate bone remodeling and regeneration.

Effects of zoledronic acid on skeletal phenotype in female C57BL/6 mice undergoing chemical or surgical estrogen deficiency *Claudia Biguetti[1], Nataira Momesso[2], Ana Carolina Bacelar[2], Juliana Meira[2], Antonio Hernandes[2], Edilson Ervolino[2], Mariza Matsumoto[2]. [1]Research Laboratory of Regenerative Medicine, School of Podiatric Medicine, University of Texas Rio Grande Valley, United States; [2]School of Dentistry, São Paulo State University (UNESP), Brazil

Animal models are crucial for studying osteoporosis, but diverse induction methods may impact investigations on antiresorptive drugs and bone health. The purpose of this study was to evaluate the differences in chemical or surgical models of induced ovarian failure with or without treatment with zoledronate (ZL) in analyzing the skeletal microar-

chitecture of female C57Bl/6 mice. Twenty-two female C57Bl/6 mice, weighing around 28 grams and 4-6 months old, were divided into five groups: CT (negative control), OVX (ovariectomized), VCD (treated with 160 mg/Kg/day of diepoxyd 4-vinylcyclohexene), CT+ZL (treated with 500µg/Kg of ZL, once a week), OVX+ZL (ovariectomyzed treated with ZL), and VCD+ZL (treated with VCD and ZL). ZL treatment was administered throughout 7 consecutive weeks, initiating 10 days before confirming permanent diestrus of the animals that underwent induced ovarian failure and matched time with the animals of CT+ZL group. After the experiment, femurs and L5 vertebrae were microCT scanned to quantify cancellous bone (BV mm³, BV/TV%, Tb.N, 1/mm, Tb.Th, mm, Tb.Sp, mm, and SMI for L5 vertebra). Data was analyzed using Shapiro-Wilk and Two-way ANOVA followed by Tukey test ($p<0.05$). While femurs did not present significant differences induced by ovarian failure models (OVX and VCD), vertebrae of OVX and VCD mice presented significantly reduced values of BV/TV, BV, and Tb/Th in comparison with CT. However, femurs of the CT+ZL group presented significantly increased values of BV/TV and BV in comparison with CT and significantly reduced values of Tb.Sp in relation to CT. ZL treatment was also effective in vertebrae of OVX and VCD groups, with significantly increased values of BV/TV, BV, Tb.Th, and Tb.N when compared with the non-treated mice. SMI values were also significantly higher in OVX and VCD groups in comparison with their matched ZL-treated groups. Both models of induced ovarian failure, OVX and VCD, induced osteoporosis in the present animal model. ZL treatment improved trabecular quality in the mice vertebrae; however, it was not observed in the distal metaphysis of the femur. In conclusion, the study showed that both chemical and surgical methods of inducing ovarian failure in female C57BL/6 mice resulted in osteoporosis. Furthermore, treatment with ZL improved the trabecular quality of vertebrae in both mice models with induced ovarian failure but did not have the same effect on the distal metaphysis of the femur.

Artificial gravity (AG) by centrifugation is a potential countermeasure to mitigate deleterious musculoskeletal changes associated with microgravity (µG). Yet, the responses of the musculoskeletal system to varied magnitudes of AG are not known.Adult (12 weeks) male C57Bl/6 mice were exposed to either 0G, 0.33G, 0.67G, or 1G (n=5-6/group) via centrifugation using the JAXA Multiple Artificial-gravity Research System (MARS), during a 30-day mission on the International Space Station. Ground controls were housed in an identical environment (HGC, n=12). Groups were assigned based on pre-flight body mass, no significant differences between mean body mass was detected between groups. Mice underwent pre- and postflight testing of grip strength, body composition and BMD via DXA (lnAlyzer, Medikors). Following euthanasia, the hindlimb muscles were harvested and weighed. Bone microarchitecture of the femur was assessed via microcomputed tomography (Scanco Medical). Group differences were evaluated using a one-way ANOVA with Tukey's Post Hoc Test in R.Pre-flight body mass was similar among the groups. HGC animals gained significantly more mass than 0.66G mice (+4.0% vs -1.9%, $p<0.05$). Gastrocnemius wet mass was lowest in 0G (-18.2% less than HGC), and inversely related to level of AG (Fig. 1A). Soleus wet mass showed a similar pattern. Front paw grip strength declined ~ 50% in 0G and 0.33G, but was unchanged in the 0.67, 1G and HGC groups. Rear paw grip strength did not differ among groups. At the distal femur, trabecular (Tb) BV/TV (-31.0%, $p<0.0001$), Tb thickness (-10.6%, $p<0.01$), Tb.BMD (-20.6%, $p<0.0001$, Fig. 1C), cortical (Ct) thickness (-9.6%, $p<0.0001$, Fig. 1B), and Ct area (-12.8%, $p<0.05$) were lower in the 0G compared to HGC and 1G. AG had varied effects on bone microstructure, but AG groups tended to show similar intermediate values as compared to those observed in 0G and 1G.Mice exposed to different levels of artificial gravity via centrifugation during one month of spaceflight dose-dependently mitigated atrophy of the gastrocnemius and soleus, and front paw grip strength. Declines in bone density and microarchitecture due to microgravity were partially mitigated by artificial gravity. Ongoing work will further explore the mechanisms underlying the musculoskeletal response to AG.

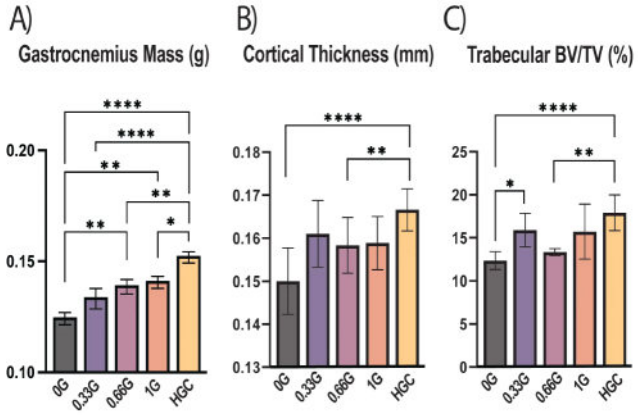

Figure 1: Muscle mass and bone microarchitectural changes associated with micro- and artifical gravity. **A)** Gastrocnemius wet mass, **B)** Cortical Thickness, and C) Trabecular Bone Volume Fraction (BV/TV). Data are presented as mean and standard deviation. Statistical significance of Tukey's post hoc test: * - $p<0.05$, ** - $p<0.01$, *** - $p<0.001$, **** - $p<0.0001$.

Background: Primary hyperparathyroidism (PHPT) is characterized by hypercalcemia with elevated parathyroid hormone (PTH). In India, the known genetic causes of familial forms of PHPT such as multiple endocrine neoplasia 1 (MEN1), MEN2A, MEN4, hyperparathyroidism-jaw tumour syndrome and familial isolated hyperparathyroidism has been published in the form of few case reports, however, there is no comprehensive study of genetic analysis of sporadic and familial PHPT cases till now.Aim: To establish an Indian database of both germline and somatic variants in 18 genes panel of parathyroid tumour and its validation through PCR array.Methods: 20 PHPT patients and 5 normal were recruited. Post operatively, histopathological characteristics were checked for parathyroid tumours by H & E staining of the respective patients followed by their demographic, clinical and biochemical profile. Further, the blood and tissue samples were analysed for germline and somatic variants respectively through targeted next generation sequencing. Also, real-time PCR array of the respective genes was performed keeping 18S as housekeeping gene.Results: The mean age of the patients recruited was 43.50 +/- 12.6 years with sporadic: familial ratio of 15:5. Clinical manifestations were bone pain, renal stone disease, fractures and osteoporosis. Biochemically, the corrected serum calcium (11.3 +/- 1.4 mg/dL), vitamin D (27.7 +/- 16.3 ng/ml), serum PTH (1058 +/- 1029 pg/ml), and phosphorus (3.8 +/- 4.4 mg/dL) levels were fluctuated in comparison to control. For genetic analysis, libraries for both germline and somatic samples were prepared in two different pools generating ~20 GB and ~60 GB respectively. Using in-silico approaches, two germline frameshift and non-synonymous pathogenic mutations were observed in MEN1 gene. A total of 7 somatic mutations have been observed out of which 2 were non-synonymous likely pathogenic and 1 stop gain mutations in EZH2 gene; 2 non-synonymous likely pathogenic mutations in GNA11 gene; 1 stop gain pathogenic mutation both in MEN1 and CASR genes respectively. Finally, the gene expression of MEN1, EZH2 and GNA11 genes was upregulated and CASR was downregulated in parathyroid tumours.Conclusion: It is the first comprehensive study of identification of somatic and germline variants in parathyroid tumours in Indian patients which might lead to design a DNA based targeted gene panel to be used as clinical diagnostic method for sporadic or familial PHPT.

Sea Snails Conotoxins As Bone Remodeling Therapeutic Agents *Brenda Iduarte-Frias[1], Pavel Galindo-Torres[1], Claudia Ventura-Lopez[1], Johanna Bernaldez-Sarabia[1], Alexei Licea-Navarro[1], Pierrick Fournier[2], Patricia Juarez[3]. [1]Centro de Investigación Científica y de Educación Superior de Ensenada (CICESE), Mexico. [2]Centro de Investigacion Cientifica y de Educacion Superior de Ensenada (CICESE), Mexico. [3]Center for Scientific Research and Higher Education, Mexico

Disruption of the normal cycle of bone renewal causes an excess of bone producing high bone mass and bone fragility diseases, including osteosarcoma and bone metastases. New molecules that modulate bone remodeling are needed. Conotoxins, small peptides from the venom sea snails, exhibit high affinity and selectivity for ion channels, and transporters are also present in bone cells. Thus, we characterize the effects of two synthetic conotoxins on bone cells and their microenvironment.Transcriptomic analysis of osteoblast treated with conotoxin revealed a significant down-regulation of multiple genes associated with Gene Ontology categories such as “ossification”, “bone development”, “bone mineralization”, and “osteoblast differentiation”. In vitro, conotoxins decreased the mineralization of mice osteoblasts and increased the differentiation of mouse bone marrow cells into osteoclasts by RANKL and M-CSF. In contrast, osteoclast resorption activity was significantly increased (p=0.0003). Cultures without RANKL demonstrated that this pro-osteoclastic effect was RANKL-dependent.RT-qPCR revealed that conotoxins modulated the expression of nAChR on bone cells and downregulated the expression of osteoblastic genes like Runx2, Alpl, and Col1a1. In contrast, osteoclastic genes such as Nfatc1 and Rank were upregulated. Conotoxins treatment in osteocyte-enriched bone significantly increased gene expression of Dmp1, Mepe, Rankl, Sost, and nAChR.Lastly, We tested the effect of conotoxins on an ex vivo calvaria culture model. Histological analysis of calvaria treated with conotoxins indicated a significant decrease in the bone area (p=0.0053) and an increase in the number of osteoclasts associated with a reduction in the expression of Runx2, and increased Rankl/Opg ratio, Ctsk, and Sost expression levels.Our results indicate that the evaluated conotoxins can disrupt bone remodeling, affecting bone cell differentiation and activity in vitro and ex vivo. These results support the potential use of conotoxins as a therapeutic strategy for bone-related diseases, particularly those characterized by excessive bone formation.

Introduction Primary hyperparathyroidism, a common endocrine disorder characterized by hypercalcemia and elevated parathyroid hormone. Recently, an epigenetic modification was found to play a pivotal role in gene silencing in PHPT patients. Among these factors, the polycomb group (PcG) proteins encompassing enhancer of zeste 2 (EZH2), embryonic ectoderm development (EED), and suppressor of zeste 12 homolog (SUZ12) was found to regulate gene activity at the chromatin level through histone modifications having a crucial role in tumor development. The lacunae exist in the expression and mechanisms by which PRC2 repress target genes in PHPT. Therefore, this study has been designed to investigate the clinical and prognostic significances of EZH2, EED and SUZ12 in PHPT patients. ObjectiveTo analyse the gene and protein expression of PRC2 complex key components (EZH2, EED, SUZ12) and its clinico-pathological correlation in patients with sporadic parathyroid tumorsMethodologyA total of 40 parathyroid tumors (25 non-aggressive and 15 aggressive and 5 normal parathyroid tissues samples) were collected in this study. mRNA and protein expression analysis of PRC2 components (EZH2, EED, SUZ12) was evaluated by quantitative real-time PCR and immunohistochemistry respectively.ResultsWe found that overall mRNA expression of EZH2 with mean fold change [Mean+/-S.E; (9.1+/-1.6 vs 1.2 +/-0.3, p=0.005), EED; (6.1+/-1.0 vs 1.5+/-0.5,p=0.01) and SUZ12; (4.9+/-0.9 vs 0.95+/-0.2,p=0.02)] was significantly increased in aggressive PHPT and non -significantly in non-aggressive [EZH2; (4.2+/-2.7 vs 1.2 +/-0.3, p=0.4), EED (2.1+/-1.9 vs 1.5+/-0.5,p=0.9), SUZ12 (2.6+/-1.6 vs 1.2 +/-0.3,p=0.5)] in comparison to normal parathyroid tissues. This increase in EZH2 expression is statistically correlated with serum calcium (p=0.0002), PTH levels (p=0.006) and tumor weight (p=0.005). Moreover, EED (p=0.03) and SUZ12 mRNA expression (p=0.05) was also directly associated with elevated PTH levels in aggressive parathyroid tumors. Furthermore, the protein expression is also consistent with the gene expression having 90% nuclear positive of EZH2 , 80% nuclear positive of EED and SUZ12 (50% cytoplasmic and membranous positivity) in aggressive parathyroid tumors in comparison to normal parathyroid gland (negative staining).ConclusionsThis was the first expression study that elucidated the high expression of EZH2, EED and SUZ12 components that might contribute to the parathyroid tumorigenesis.

Introduction
Primary hyperparathyroidism, a common endocrine disorder characterized by hypercalcemia and elevated parathyroid hormone. Recently, an epigenetic modification was found to play a pivotal role in gene silencing in PHPT patients. Among these factors, the polycomb group (PcG) proteins encompassing enhancer of zeste 2 (EZH2), embryonic ectoderm development (EED), and suppressor of zeste 12 homolog (SUZ12) was found to regulate gene activity at the chromatin level through histone modifications having a crucial role in tumor development. The lacunae exist in the expression and mechanisms by which PRC2 repress target genes in PHPT. Therefore, this study has been designed to investigate the clinical and prognostic significances of EZH2, EED and SUZ12 in PHPT patients.

Objective
To analyse the gene and protein expression of PRC2 complex key components (EZH2, EED, SUZ12) and its clinico-pathological correlation in patients with sporadic parathyroid tumors

Methodology
A total of 40 parathyroid tumors (25 non-aggressive and 15 aggressive and 5 normal parathyroid tissues samples) were collected in this study. mRNA and protein expression analysis of PRC2 components (EZH2, EED, SUZ12) was evaluated by quantitative real-time PCR and immunohistochemistry respectively.

Results
We found that overall mRNA expression of EZH2 with mean fold change [Mean±S.E; (9.1±1.6 vs 1.2 ±0.3, p=0.005), EED; (6.1±1.0 vs 1.5±0.5,p=0.01) and SUZ12; (4.9±0.9 vs 0.95±0.2,p=0.02)] was significantly increased in aggressive PHPT and non -significantly in non-aggressive [EZH2; (4.2±2.7 vs 1.2 ±0.3, p=0.4), EED (2.1±1.9 vs 1.5±0.5,p=0.9), SUZ12 (2.6±1.6 vs 1.2 ±0.3,p=0.5)] in comparison to normal parathyroid tissues. This increase in EZH2 expression is statistically correlated with serum calcium (p=0.0002), PTH levels (p=0.006) and tumor weight (p=0.005). Moreover, EED (p=0.03) and SUZ12 mRNA expression (p=0.05) was also directly associated with elevated PTH levels in aggressive parathyroid tumors. Furthermore, the protein expression is also consistent with the gene expression having 90% nuclear positive of EZH2 , 80% nuclear positive of EED and SUZ12 (50% cytoplasmic and membranous positivity) in aggressive parathyroid tumors in comparison to normal parathyroid gland (negative staining).

Conclusions
This was the first expression study that elucidated the high expression of EZH2, EED and SUZ12 components that might contribute to the parathyroid tumorigenesis.

Effect of the Bone-Targeted Prostaglandin E2 Receptor 4 Agonist Mes-1022 on a Rat Model of Duchenne Muscular Dystrophy *Juliana Marulanda[1], Ashok Narasimhan[2], Lin Yi[2], Katie Day[2], Keitaro Yamanouchi[3], Fabio MV Rossi[2], Frank Rauch[1]. [1]Shriners Hospital for Children, McGill Univeristy, Canada. [2]School of Biomedical Engineering, University of British Columbia, Canada. [3]Department of Veterinary Physiology, Graduate School of Agricultural and Life Sciences, The University of Tokyo, Japan

Background: Duchenne muscular dystrophy (DMD) is a devastating muscle disorder that also leads to bone loss and fractures. In this study, we characterized bone mass in a rat model of DMD and performed treatment studies with a novel bone anabolic drug, Mes-1022, a bone-targeting prostaglandin E2 receptor EP4 agonist.Methods: The bone phenotype of CRISPR/CAS9-generated male DMD rats (Nakamura et al. Sci Rep. 2014;4:5635) was analyzed by microCT at various ages. Vehicle or Mes-1022 (3mg per kg body mass) was administered subcutaneously once a week for 8 weeks, starting at 30 weeks of age.Results: We found that, compared to wild type littermates, DMD rats had consistently lower trabecular bone mass at the distal femur at 1, 3, 6 and 9 months of age, becoming significant at 6-9 months. No differences were detected in the midshaft femur periosteal and endosteal diameter at any timepoint, but cortical thickness was slightly higher in 9-month-old DMD rats than in controls. Treatment with Mes-1022 was associated with significantly increased amounts of trabecular bone, both at the distal and the midshaft femur. At the distal femur, trabecular bone volume was markedly increased in the treated group, due to a higher trabecular number, whereas trabecular thickness was similar between groups. At the midshaft femur, cortical geometry (periosteal diameter, endosteal parameter and cortical thickness) was similar in Mes-1022 and vehicle-treated rats, but cortical porosity and trabecular bone volume were higher in rats that had received Mes-1022.Conclusion: The DMD rat appears to be a suitable model for bone-targeting treatment studies. Treatment with Mes-1022 was associated with a markedly higher trabecular bone mass at the femur. Mes-1022 warrants further study for the treatment of DMD-associated bone disease.

Differences Between the Effects of Anti-Catabolic and Anabolic Treatments on Bone in Adult Ovariectomized Rats *Jukka Morko[1], Jukka Vaaraniemi[1], Katja M. Fagerlund[1], Mari I. Suominen[1], Jukka P. Rissanen[1]. [1]Pharmatest Services Ltd, Finland

Human osteoporosis is a systemic skeletal disease characterized by low bone mass, deterioration of bone microarchitecture, and increased risk for fractures. Effective osteoporosis therapies are available including various anti-catabolic and anabolic agents. These treatments have been associated with adverse effects on the skeleton, including atypical fractures and osteosarcoma. Therefore, new therapies are needed with improved efficacy/safety ratio. In nonclinical efficacy studies, ovariectomized (OVX) rats suffering from osteopenia are used as the major small animal model of human postmenopausal osteoporosis. In this study, we compared the effects of anti-catabolic and anabolic treatments on bone in more detail in adult OVX rats. Nitrogen-containing bisphosphonate zoledronate (ZOL) was used as the anti-catabolic agent and recombinant human parathyroid hormone (PTH) analog (1-34) as the anabolic agent. Female Sprague-Dawley rats were ovariectomized or Sham-operated at 6 months of age. OVX rats were treated subcutaneously with ZOL at 20 ?g/kg, PTH(1-34) at 40 ?g/kg/d or vehicle, and Sham-operated rats with vehicle for 2 months. Treatment effects were evaluated by peripheral quantitative computed tomography, bone histomorphometry, bone ash weight determination, biomechanical testing, and the measurements of bone turnover biomarkers. Surgical OVX operation decreased the amount of metaphyseal trabecular bone, and enhanced osteoclastogenesis, bone resorption, and bone formation on the trabecular surface and bone formation on the periosteal surface. Both ZOL and PTH(1-34) prevented the OVX-induced reduction in the amount of metaphyseal trabecular bone and the OVX-induced enhancement of osteoclastogenesis on the trabecular surface as well as increased ash weight in the femur and tibia. ZOL prevented and PTH(1-34) enhanced the OVX-induced increase in bone formation on the trabecular surface. PTH(1-34) enhanced the OVX-induced increase in bone formation on the periosteal surface, increased the amount of diaphyseal cortical bone and bone formation on the endocortical surface, and improved bone strength in the femoral neck and tibial shaft. This study demonstrated significant differences between the effects of anti-catabolic ZOL and anabolic PTH(1-34) treatments on bone in adult OVX rats. The anabolic PTH(1-34) treatment was more potent, also increasing the amount of diaphyseal cortical bone and improving bone strength in the femoral neck and long bone diaphysis.

Sclerostin-neutralizing antibody reverses alveolar bone loss and promotes periodontium repair in type 2 diabetes *Xue Yuan[1], Hakan Turkkahraman[2], Shannan Flanagan[1], Tianli Zhu[2], Nisreen Akel[3], Silvia Marino[4], Dayane Ortega-Gonzalez[1], Teresita Bellido[5]. [1]Indiana University School of Medicine, United States. [2]Indiana University School of Dentistry, United States. [3]University of Arkansas for Medical Sciences, United States. [4]University of Arkansas, United States. [5]University of Arkansas for Medical Sciences , United States

Type 2 diabetes (T2D) is on the rise worldwide and is associated with several complications of the oral cavity. Developing an appropriate model of adult-onset T2D is essential to identifying novel approaches for treating diabetes-induced oral diseases. We recently established a T2D mouse model in the setting of high-fat diet (HFD) feeding and streptozotocin (STZ) injection, allowing for both environmental as well as temporal control of T2D onset. Utilizing this adult-onset diabetes model, we characterized the periodontal alterations in mice eight weeks after T2D was established. T2D mice had inflamed gingiva with increased immune cells, disintegrated periodontal ligaments (PDL) with reduced cell numbers and osteogenic potential, and overwhelming alveolar bone loss with unbalanced bone formation and resorption. Further, the Wnt signaling inhibitor sclerostin was elevated in the T2D mice. Thus, we investigated whether a sclerostin-neutralizing antibody (Scl-Ab) could rescue the periodontium in T2D mice. Four weeks after T2D was established, Scl-Ab was administered subcutaneously once a week for four weeks. Scl-Ab significantly increased bone mass by inhibiting osteoclasts and promoting osteoblasts in both control and T2D mice, completely rescuing the bone loss under the T2D condition. Scl-Ab treatment also stimulated PDL cell proliferation, partially rescued the PDL fibers, and suppressed the inflammation in the periodontium. Additionally, the Scl-Ab treatment slightly enlarged the edentulous bone and mandible but displayed a minimal effect on the premaxillary suture. In conclusion, our results describe a novel T2D-induced periodontitis model in mice characterized by inflammation and tissue degeneration. Systemic administration of Scl-Ab effectively reverses the detrimental effects of T2D on the periodontium while displaying minor effects on other craniofacial hard tissues.

Deficiency of Trps1 in Osteoblasts and Cementoblasts-compromises Formation of Alveolar Bone and Cementum *Kaoru Fujikawa[1] Mairobys Socorro[1] Priyanka Hoskere[1] Catherine Roberts[1] Lyudmila Lukashova[1] Konstantinos Verdelis[1] Dobrawa Napierala[1] [1]University of Pittsburgh, United States

Objectives: Trichorhinophalangeal syndrome (TRPS) is caused by heterozygous mutations in the TRPS1 gene, which encodes a GATA-type transcription factor. TRPS is characterized by abnormal skeletal, craniofacial, and dental development, including delayed development of endochondral bones and small mandible. TRPS1 has been also associated with bone mineral density and periodontal disease risk by genome-wide association studies. Periodontium comprises two mineralized tissues - alveolar bone and cementum, ligament that connects them, and the gingiva. Proper function of the periodontium depends on its structural integrity. However, the role of Trps1 in the development and homeostasis of the periodontium is unknown. Since Trps1 is expressed is osteoblasts and cementoblasts, we hypothesized that Trps1 supports formation of bone and cementum by regulating expression of genes critical for the formation of these tissues.Methods: We compared alveolar bone and tooth roots of 1st mandibular molars of 4wk old WT and Trps1col1a1 cKO mice (N=5/genotype/sex) by micro-Computed Tomography (µCT), histology, and immunohistochemistry.Results: µCT analyses revealed significantly lower alveolar bone volume, and shorter and thinner tooth roots in Trps1Col1a1 cKO compared with WT mice. Semi-quantitative histological analyses detected reduced the cellular cementum area and unevenly distributed cementoblasts (?III Tubulin-positive cells) in Trps1Col1a1 cKO mice compared to WT mice. There were fewer Osterix-positive cells on the surface of the alveolar bone and cementum in Trps1Col1a1 cKO mice. Moreover, we detected decreased levels of tissue-nonspecific alkaline phosphatase (TNAP) in alveolar bone, cementum, and periodontal ligament in Trps1Col1a1cKO mice. Bone sialoprotein (Bsp) was unevenly distributed and accumulated in the margin of the alveolar bone matrix in Trps1Col1a1 cKO mice, while there was no difference in the Bsp distribution in the cementum. Picrosirius staining revealed impaired organization of collagen fibers in periodontal ligaments in Trps1Col1a1 cKO mice.Conclusions: Trps1 transcription factor supports expression of key proteins required for proper formation of the alveolar bone, cementum, and the structure of the periodontium, hence highlight the importance of Trps1 for the function of osteoblasts and cementoblasts. Our data suggest that the compromised periodontal structure in Trps1 deficiency is the contributing factor to predisposition to periodontal disease.

Spatial transcriptomics identified in vivo FGF23 and CKD-mediated transcriptional reprogramming within distinct kidney nephron segments *Lainey Hibbard[1] Sheng Liu[1] RAFIOU AGORO[1] Yamil Marambio[1] Kayleigh Jennings[1] Steven Welc[1] Jun Wan[1] Kenneth White[1] [1]Indiana University School of Medicine, United States

Background: Osteocyte-secreted FGF23 acts in the kidney via Klotho (KL) to control phosphate metabolism. However, in CKD, KL is lost and FGF23 is pathologically increased, disrupting mineral homeostasis. KL is expressed in multiple nephron segments, thus localization of FGF23 actions on intra-nephron regions remain unclear. Herein, we tested for novel FGF23 bioactivity localized with KL, as well as hypothesized that CKD alters FGF23/KL signaling and causes spatially unique transcriptional reprogramming.Methods: Visium spatial transcriptomics (ST) was performed on kidney sections from normal mice injected with FGF23 (250 ng/kg) for 1 or 4 h, and male mice with adenine diet induced CKD (0.2% for 4 weeks).Results: The FGF23-injected and CKD kidney sections had >6900 genes/sequencing spot and formed 12 and 10 UMAP cell clusters, respectively. Mapping nephron segment-specific markers showed clear demarcation of cortical and medullary gene expression. Proximal tubule S1/S2 marker Slc5a2 was highly expressed in the cortex, and S3 marker Eci3 localized to the outer stripe of the medulla (OSOM). FGF23 increased MAPK-dependent transcription factor Egr1 more at 1 h (2.3 log2-fold) compared to 4 h (1.2 log2-fold). The vitamin D metabolic enzymes Cyp24a1 and Cyp27b1 mRNAs were increased (2.3 log2-fold) or decreased (22%), respectively, at 4 h and overlapped with KL. The ST data were validated by qPCR as well as in independent kidney scRNAseq data from FGF23-injected mice. We also identified novel changes in response to FGF23, including increased Cyp4b1 in the cortex at 4 h, which decreases in CKD. Mice with CKD had a 55% reduction in KL mRNA and increased Cyp27b1. Consistent with CKD fibrosis, Col1a1, -1a2, -3a1, and -4a1 were ubiquitously increased, although Col3a1 was more focused to the inner stripe of the medulla (ISOM). Further, pro-fibrotic Tgfb1 broadly increased, whereas its target Mmp7 was elevated in the ISOM. In contrast, the damage and injury markers C3 and Havcr1 were restricted to the cortex and OSOM, respectively. Finally, evidence of wider immune infiltration was present in CKD with increased neutrophil marker Lcn2, and macrophage markers Cd68 and Ptprc.Conclusion: Using ST, we identified unbiased, spatially identifiable effects of FGF23 bioactivity in kidney, including potentially new FGF23 targets. This approach also localized pathologic KL-dependent and -independent CKD gene alterations that differentially occur within distinct cell populations.

The Effects of Nfi-C Epithelium-Specific Deletion on Ameloblast Differentiation *Joo-Cheol Park[1] Hyun-Sook Bae[2] Si Hyoung Ki[1] [1]Department of Oral Histology-Developmental Biology, School of Dentistry and Dental Research Institute, Seoul National University, Republic of Korea [2]Department of Oral Hygiene, Namseoul University, Cheonan, Republic of Korea, Republic of Korea

Rodent incisors continuously grow throughout their whole life. This growth is made by the complicated interactions between epithelium and ectomesenchyme during tooth formation. The Nuclear factor I (NFI) family consists of four genes (NFI-A, NFI-B, NFI-C, and NFI-X). In our previous research, we found that conventional Nfic Knock-Out (KO) mice exhibited defective phenotypes in molar roots and incisor. Furthermore, Nfic is necessary for maintaining the stem cell population in several mineralized tissues by controlling Sox2 expression. continuously The purpose of this study is to compare phenotypes of Nficfl/fl, K14-Cre;Nficfl/-(Hemi), and K14-Cre;Nficfl/fl (Homo) to clarify the mechanism of Nfic-mediated tooth formation.To investigate the phenotypic changes in epithelium-specific Nfic KO mice, K14-Cre;Nficfl/-, and K14-Cre;Nficfl/fl mice were generated using the Cre-loxP system. Histological analysis was performed using microscope.1-month-old K14-Cre;Nficfl/-, and K14-Cre;Nficfl/fl mice did not exhibit any morphogenetic changes in their teeth, including dentin. However, In the 6-months-old K14-Cre;Nficfl/- and K14-Cre;Nficfl/fl mice, incisor pulp space was narrowed compared to Nficfl/fl mice, respectively. Compared to Nficfl/fl mice mature ameloblasts of K14-Cre;Nficfl/- mice exhibited lost their polarity, and mature ameloblasts of K14-Cre;Nficfl/fl showed flatten shape.Our findings suggest that Nfic deficiency in dental epithelium could alter late-stage ameloblast differentiation.

SAT-203

The Vitamin D Receptor (VDR) in Osteoblastic Cells but Not Parathyroid Hormone (PTH) Secretion Is Critical for Soft Tissue Calcification Induced by the Proresorptive Activity of 1,25(OH)2D3 *Yuko Nakamichi[1] Ziyang Liu[2] Tomoki Mori[2] Zhifeng He[3] Hisataka Yasuda[4] Naoyuki Takahashi[3] Nobuyuki Udagawa[5] [1]Matsumoto Dental University, Japan [2]Graduate School of Oral Medicine, Matsumoto Dental University, Japan [3]Institute for Oral Science, Matsumoto Dental University, Japan [4]Oriental Yeast Co., Ltd., Japan [5]Department of Biochemistry, Matsumoto Dental University, Japan

VDR is expressed most abundantly in osteoblasts and osteocytes (osteoblastic cells) in bone, and regulates bone resorption and calcium (Ca) and phosphate (P) homeostasis in concert with PTH. We reported that near-physiological doses of vitamin D analogs suppressed bone resorption through VDR in osteoblastic cells (JBMR 2017). We also reported that supra-physiological doses of 1?,25-dihydroxyvitamin D3 [1,25(OH)2D3] increased bone resorption, serum Ca and FGF23 levels, and decreased the body weight via VDR in osteoblastic cells. Serum P levels tended to increase but did not significantly elevate (Endocrinology 2020). The present study demonstrated that the latter, a proresorptive dose of 1,25(OH)2D3, induced soft tissue calcification through VDR in osteoblastic cells. Excess amounts of vitamin D affect various organs and induce ectopic calcification, with increases in bone resorp-

tion, serum Ca and FGF23 levels, and decreases in body weight. Such a wide range of symptoms is called as hypervitaminosis D, which is caused by not only too much intake of vitamin D but also malfunctions of vitamin D metabolism and diseases that produce 1,25(OH)2D3 ectopically. To clarify a biological process hierarchy in hypervitaminosis D, a proresorptive dose of 1,25(OH)2D3 was administered to wild-type mice whose bone resorption was suppressed with neutralizing anti-RANKL antibody. Proresorptive doses of 1,25(OH)2D3 increased the serum Ca x P product, induced calcification of the aortas, lungs, and kidneys, and decreased serum PTH levels in the control-IgG pretreated wild-type mice. Pretreatment of wild-type mice with anti-RANKL antibody did not affect the down-regulation of PTH levels by 1,25(OH)2D3, but inhibited the increase in the serum Ca x P product and soft tissue calcification induced by 1,25(OH)2D3. Consistent with the effects of anti-RANKL antibody, VDR ablation in osteoblastic cells also did not affect the down-regulation of PTH levels by 1,25(OH)2D3, but inhibited 1,25(OH)2D3-induced increase of the serum Ca x P product and calcification of soft tissues. These data suggest that bone resorption induced by VDR signaling in osteoblastic cells is crucial for the pathogenesis of hypervitaminosis D, but PTH is not relevant to it. These findings indicate that the use of bone resorption inhibitors is a treatment option not only for patients with hypervitaminosis D but also for patients with other diseases having complications of hypercalcemia and ectopic calcification.

Multi-Trait Analysis of Mineral Metabolism Markers Identifies Novel Genetic Associations for PTH *Nicholas Vartanian[1], Cassianne Robinson-Cohen[1], Elvis Akwo[1]. [1]Vanderbilt University Medical Center, United States

Introduction: Genome-wide association studies (GWAS) have identified numerous genetic loci associated with mineral metabolism markers but have exclusively focused on single-trait analysis. In this study, we performed a multi-trait analysis of GWAS data of mineral metabolism markers, exploring overlapping genetic architecture between the traits, to identify novel genetic associations for parathyroid hormone.Methods: We applied multi-trait analysis of GWAS (MTAG) to genetic variants common to GWAS of 5 genetically correlated mineral metabolism markers (phosphorus, fibroblast growth factor-23, calcium, 25-hydroxyvitamin D and PTH) in European-ancestry subjects. We integrated information from the UKBioBank GWAS for phosphate and calcium (n=366,484), and two GWAS from the CHARGE consortium for PTH (n=29,155) and FGF23 (n=16,624).Results: MTAG increased the effective sample size for all mineral metabolism markers, to over 50,000 for PTH. After clumping, MTAG identified independent genome-wide significant SNPs for all traits, including 47 loci for PTH. Many of these loci have not been previously reported in single-trait analyses, including loci involved in inflammation, lipid metabolism, glucose metabolism, and bone health.Conclusions: MTAG boosted the number of genome-wide significant loci PTH. Our findings highlight the importance of performing multi-trait analysis in GWAS studies of mineral metabolism markers to identify novel genetic associations. These genetic loci may provide insight into the biological mechanisms underlying mineral metabolism and may have implications for the development of therapies for mineral-related disorders.

Local activation of endogenous glucocorticoids by 11?-hydroxysteroid dehydrogenase type 1 in bone contributes to musculoskeletal decline during aging *HUSAM BENSRETI[2], DIMA ALHAMAD[2], KANGLUN YU[2], Wendy B. Bollag[3], Mark W. Hamrick[4], Carlos Isales[5], Meghan McGee-Lawrence[6, 2], United States[, 2], , [3]Department of Physiology Medical College of Georgia at Augusta University , United States[, 4]Department of Cellular Biology and Anatomy, Medical College of Georgia at Augusta University, , United States[, 5]Augusta University, United States[, 6]Medical College of Georgia, Augusta University, United States

Glucocorticoids (GCs) have been implicated in the fate of BMSCs differentiating into osteogenic vs. adipogenic lineages. Unlike most signaling mechanisms, GC signaling has an additional layer of regulation in the form of enzymes 11?-hydroxysteroid dehydrogenase type 1 and 2 (Hsd11b1/2) that control local GC activation and downstream signaling. The current study explored the role of Hsd11b1 in the aging skeleton. Hsd11b1 expression was measured by qPCR in cortical bone from wildtype (WT) mice at 12 and 23 mo of age. BMSC and sorted MSCs (Sca1+ / CD29+ / CD44+) from 22 mo old mice were treated with an Hsd11b1 inhibitor (385581) for 21 days in osteogenic media and mineralization was evaluated with Alizarin red. Hsd11b1 floxed mice were crossed with Osx-Cre to generate Hsd11b1-WT and osteoprogenitor-targeted Hsd11b1 conditional knockout (Hsd11b1-CKO) mice. Mice were raised on doxycycline until 3 mo of age to negate the developmental impact of Osx Cre. Musculoskeletal phenotype data were collected at 21 mo of age. Muscle endurance was measured via hang time and muscle strength and fatigue via grip strength meter (Bioseb). Body composition and BMD were measured via DXA. Groups were compared by t-tests or two-way ANOVA as appropriate. Hsd11b1 was significantly up-regulated in bone from aged mice, with a 20-fold increase over adult animals (p=0.04), and osteoblasts from aged mice exhibited enhanced mineralization with pharmacological Hsd11b1 inhibition. Osx-Cre-mediated recombination of Hsd11b1 was seen in bone but not off-target tissues such as skeletal muscle, liver, kidney, spleen, or white or brown fat depots. Whole-body BMD was 12% higher in aged CKO as compared to WT littermate mice, suggesting a beneficial impact from the loss of Hsd11b1 activity on the skeleton. While DXA revealed no effect of Osx-Cre-mediated Hsd11b1 knockdown on whole body composition, brown fat pads tended to be smaller in the CKO mice, and aged CKO mice had higher muscle endurance and lower muscle fatigue score as measured by forelimb muscle grip testing (p=0.002). While we previously saw no difference in fasting blood glucose levels between WT and CKO mice at 6 mo old, aged Hsd11b1 CKO mice exhibited elevated fasting blood glucose levels (p=0.02). These results suggest a crucial role of local GC activation by Hsd11b1 in bone homeostasis during aging and support the importance of local endogenous glucocorticoid signaling in mechanisms of skeletal crosstalk with other organ systems.

Alterations in Soft Tissue Quality and Quantity in People Living with HIV *Zehra Akkaya[1], Katie Kenny[2], Jannis Bodden[3], Bo Fan[1], Isra Saeed[1], Phyllis Tien[4], Gabby Joseph[1], Thomas Link[1], Roland Krug[1], Galateia Kazakia[1]. [1]University of California, San Francisco, Department of Radiology and Biomedical Imaging, San Francisco, CA, United States[. 2]University of California Berkeley, Department of Biomedical Engineering, Berkeley, CA, United States[. 3]Technical University of Munich Diagnostic and Interventional Neuroradiology Clinic, Munich, Germany, Germany[. 4]University of California, San Francisco, Department of Medicine and Department of Veterans Affairs Medical Center, San Francisco, CA, United States

People living with HIV (PLWH) experience systemic and metabolic alterations particularly involving adipose tissues. Chronic HIV infection and earlier anti-retroviral therapy (ART) regimens were known to cause subcutaneous adipose tissue (SAT) loss. With contemporary ART, lipoatrophy is of less concern, while visceral adipose tissue (VAT) has become a growing concern. In addition to differences in quantity, density of adipose tissue, measured by quantitative computed tomography (QCT), was shown to be positively associated with inflammatory biomarkers in PLWH. Sarcopenia is characterized by deteriorated skeletal muscle quantity and function and is also associated with chronic inflammation. There are contradictory reports on HIV-associated sarcopenia.The aim of this study was to investigate the impact of HIV on 1) adipose tissue quality and quantity in the thigh and trunk, and 2) skeletal muscle quality and quantity in the thigh.This cross-sectional study included 109 participants (mean age=58.8+/- 4.93 years) comprised of 54 PLWH (40 M / 14 F; on stable long-term antiretroviral therapy) and 55 age-matched seronegative control subjects (SNC; 22 M / 33 F). QCT measurements of cross-sectional areas and densities of abdominal VAT and SAT and non-dominant thigh SAT and thigh muscles (total, quadriceps, and hamstrings) were obtained using in-house developed software built on the MIPAV platform. The impact of HIV serostatus on QCT measurements were investigated by linear regression models, adjusted for a) age, sex and race and b) age, sex, race, and BMI.VAT area and thigh SAT density were statistically significantly higher in PLWH in demographically adjusted models as well as models also adjusted for BMI (Table 1). Intramuscular quadriceps fat density was higher in PLWH but reached significance only in models additionally adjusted for BMI (p=0.038). Quadriceps total and lean areas were lower in both models in PLWH. Total thigh area and thigh muscle bundle area were lower in PLWH but reached significance only in models after BMI adjustment (p=0.012 and p=0.020, respectively).In conclusion, PLWH have higher adipose tissue density at the thigh, both subcutaneously and in the intramuscular quadriceps fat depots when compared to those without HIV. These may reflect increased inflammatory burden as a consequence of chronic HIV infection and ART. Being HIV seropositive is associated with lower total and lean muscle areas in the quadriceps which supports that chronic HIV infection may be associated with sarcopenia.

Table 1. The beta coefficient (β) represents the difference in the outcome measure of interest (i.e., total thigh area) between PLWH and SNC (reference group). Models are adjusted for age, sex, and race (a), and age, sex, race, and BMI (b). Bold indicates statistically significant results ($p < 0.05$).

The impact of neutrophil efferocytosis by MSCs on MSC mitochondrial function and inflammatory signaling *Sandra Castillo Aguirre[1], Matthew McArthur[1], Emily Quarato[4], Laura Calvi[3], Roman Eliseev[4]. [1]University of Rochester , United States, [4]University of Rochester, , [3]University of Rochester School of Medicine, United States, [4]University of Rochester, United States

Bone marrow stromal, a.k.a. mesenchymal stem, cells (MSCs) senescence plays a critical role in age-related musculoskeletal diseases and bone loss. Despite their role in bone homeostasis and repair, the mechanism of age-dependent MSC dysfunction remains incompletely understood. Studies have shown that MSCs can perform efferocytosis, i.e., phagocytosis and clearing of apoptotic cells. Efferocytosis of end-stage neutrophils by MSCs increases with age, as aged marrow macrophages exhibit impaired efferocytotic capacity. This upregulation is accompanied by oxidative stress and mitochondrial fission and dysfunction, which in non-professional phagocytes such as MSCs may lead to inflammation, senescence, and decreased osteoblastic differentiation. The significance of efferocytosis in MSC function and osteoimmunology is unknown.Therefore, our objective is to understand the mechanism of efferocytic neutrophil attraction, MSC mitochondrial dysfunction, and inflammation. We have observed that after neutrophil efferocytosis, mitochondria in MSCs become less functional, more ROS-producing, and fragmented. To investigate the effect of high efferocytic loads on inflammatory signaling in a mice bone marrow MSC cell line (ST2), we seeded cells on a chamber slide. We treated them with end-stage neutrophils using ratios of 0, 1:1, 3:1, and 10:1 (neutrophils: MSC). After 24 hours, p65 nuclear translocation was visualized using a confocal microscope. We observed an increase in the percent of positive cells for nuclear translocation from 7.4% for the 0 ratios to 39.75% for the 10:1 ratio, indicating a trend for higher inflammation with increased efferocytic load. To study the paracrine crosstalk between MSCs, and neutrophils, we will use a microdevice as an in vitro platform to mimic the interactions in the bone marrow. Preliminary observations confirm the transendothelial migration of neutrophils to the MSC monolayer. Ongoing studies are focused on manipulating oxidative stress using primary bone marrow MSCs isolated from the following mouse models: a) expression of mitochondrial catalase (mCatTG) to combat oxidative stress, mitochondrial fission (Drp1ff and Mfn1ff), and inflammation (Relaff). Cells will be infected with GFP or Cre adenovirus to induce recombination in vitro and treated with different efferocytic loads, then analyze with flow cytometry after 3- and 24-hours post-neutrophil addition and updated data will be presented on these findings.

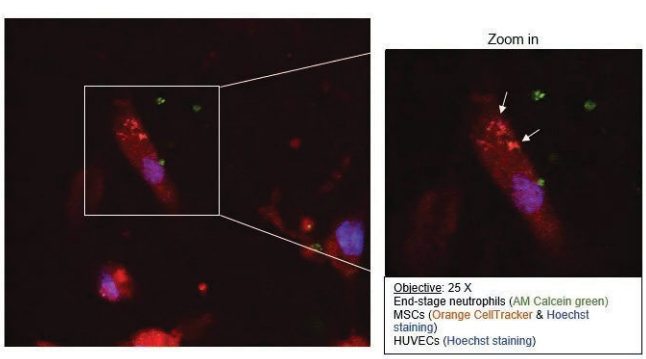

Figure 1. Efferocytosis of end-stage neutrophils by hMSCs. A) Two-photon microscopy image depicts efferocytosis of neutrophils by MSCs (white arrows) in a microdevice with a dual scale ultrathin (<100 nm) silicon-based membrane (μSiM device), containing nanopores and micropores. It shows the transendothelial migration of neutrophils (green) across the membrane containing a human umbilical vein endothelial cells (HUVECs) barrier to the MSC monolayer.

Early Clearance of p21+ Senescent Cells Suppresses the Radiation -Induced Pro-Inflammatory Secretome from Cd11b+ Myeloid Cells and Mitigates Chronic Bone Loss *Abhishek Chandra[4], MADISON DOOLITTLE[2], Sundeep Khosla[3], Robert Pignolo[4]. [4]Mayo Clinic, , [2]University of Rochester, United States, [3]Mayo Clinic College of Medicine, United States, [4]Mayo Clinic, United States

We recently demonstrated that injury to bone by focal radiation treatment (RTx) is a p21-dependent process. Using p21-ATTAC mice, we showed that bi-weekly clearance of p21-positive senescent cells over a 42-day period resulted in significant mitigation of bone damage generated by 24Gy of RTx. To identify the RTx-induced p21-expressing cell types and their senescent-associated secretory phenotype (SASP), we performed single-cell mass Cytometry by Time of Flight (CyTOF) and identified several cell clusters based on their cell surface or intracellular protein expression profile. Interestingly, we identified unique clusters for p21+ and p16+ expressing cells. On day 4 post-RTx, Cd11b+ myeloid cells had the highest p21 expression, accompanied by elevated SASP factors, such as pNf?b, Cxcl1, Il6, Pai-1, and Il1?. To confirm the source of these factors, magnetic-sorted Cd11b+ cells were isolated from non-radiated (NR) and radiated (R)-bones before and after clearance of p21+SEN cells. As expected, Cd11b+SEN cells showed elevated levels of Ccl2 (~150-fold), Ccl3 (~20-fold), Ccl5 (~3-fold), Ccl7 (~200-fold), Cxcl1 (~50 fold), Cxcl12 (~2.5-fold), Il6 (~15-fold) and Mmp12 (~12 fold) in R-bones, suggesting that Cd11b+ myeloid cells were the major contributors to the SASP in RTx-induced bone loss. Upon clearance of p21+SEN cells in the p21-ATTAC mice, the SASP of magnetically sorted Cd11b+ myeloid cells were significantly reduced in the R-bones [AP20187(AP)-group], as compared to the R-bones (vehicle) group, and approaching the levels found in NR bones. To further understand the dynamics of the early events post-RTx, we performed a targeted clearance of p21+SEN cells limited to first week post-RTx, with no subsequent treatment before ?CT analysis at 6-weeks. Bone parameters assessed by ?CT on day 42 post-RTx showed improved BV/TV (11.2% in AP vs -46.5% in veh, p=0.01), improved Tb.N. (-10.8% in AP vs -25.6% in veh, p=0.011), reduced Tb.Sp. (12.9% in AP vs 39.2% in veh, p= 0.015), and increased Tb.Th. (20.9% in AP vs -4.3% in veh, p=0.013). In summary, early clearance of p21+SEN cells abrogated bone loss caused by RTx. Thus, our data strongly indicate that acute generation of Cd11b+SEN cells following RTx are predominately responsible for the deleterious SASP and identifies an early therapeutic window within which targeting these senescent cells or their SASP may be effective to prevent RTx-induced bone deterioration.

Bisphosphonates Protect Against Oxidative Stress Induced Apoptosis via an FPPS-independent pathway *Helen Knowles[3], Jinsen Lu[3], Srinivasa Rao Rao[3], Haoqun Zhan[3], Anne Horne[2], Ian Reid[2], R Graham Russell[3], James Edwards[3]. [3]University of Oxford, United Kingdom, [2]University of Auckland, New Zealand, [3]University of Oxford,

Bisphosphonates (BP) are the leading medicines targeting disorders of excessive bone loss (eg. osteoporosis, cancer-induced bone disease). BPs inhibit farnesyl pyrophosphate synthase (FPPS) within the mevalonate pathway, impairing protein prenylation. Two placebo-controlled trials have shown Zoledronate reduces mortality whilst several observational studies indicate BPs confer beneficial effects in diverse age-related disorders (cardiovascular disease, cancers, respiratory infections). Increased accumulation of reactive oxygen species in tissues of older individuals is a key ‘hallmark of aging’ and contributing factor

to age-related disease. To test whether BPs alter the cellular response to increased oxidative stress seen in aging organs, we challenged monocytes (THP1), T cells (Jurkat), fibroblast (MRC-5), kidney (HEK) and cardiomyocyte (HL-1) cell lines in an oxidative stress environment (H2O2) +/- pre-treatment with a panel of BPs, and assessed cellular responses by live cell imaging and involvement of new and established mechanisms of action. Levels of antioxidant proteins following BP treatment in osteopenic patients was also assessed. High dose BP treatment (>10uM, up to 7d) led to consistent cell death ($p<0.0001$), which was blocked by a key downstream metabolite in the mevalonate pathway, geranylgeraniol (GGOH, 10mM, 3d, $p<0.01$), confirming the role of FPPS-inhibition. Low dose BP treatment (0.1nM-100nM) protected against basal cell death and prolonged lifespan/proliferation in monocytes, fibroblasts, T cells (up to 67% in 0.1nM ZOL-treated fibroblasts, $p<0.05$). A correlation between basal level of cell death and BP protection was observed ($R2=0.7679$) where cells with lower levels of basal apoptosis have this reduced even further by 0.1nM BP. Treatment with GGOH did not alter this effect suggesting a FPPS-independent effect. Oxidative stress-induced apoptosis (50-300uM H2O2, 24h) was reduced by pre-treatment with BPs (48h) in monocytes, cardiomyoblasts (0.1nM-1uM, $p<0.001$), with up to 99% protection by 100nM ALN in monocytes ($p<0.001$). Addition of GGOH showed no effect. Osteopenic women treated with ZOL showed significantly increased levels of the plasma antioxidant catalase known to accelerate the decomposition of H2O2 ($log2FC=0.67$, $p<0.001$), and reduced levels of pro-oxidants ROCK2, STAT3 and MAPK14. These data suggest treatment with BPs protect against oxidative stress through mechanisms independent of mevalonate pathway inhibition.

Anti-inflammatory effects of Selcopintide by recovering mitochondrial function in periodontitis *Howon Jang[1], Dong-Seol Lee[2], Ji-Huyn Lee[2], Joo-Cheol Park[1]. [1]Seoul National University, Republic of Korea. [2]HysensBio, Republic of Korea

Periodontitis is a chronic inflammatory disease caused by bacterial plaque accumulation around the tooth-supporting tissues. Long-term uncontrolled inflammation of the gums can lead to loss of periodontal tissue, and treatment or preventive solutions for periodontitis are lacking. Mitochondria are cell organelles that produce energy and regulate cellular metabolism, apoptosis, and calcium signaling. Mitochondrial dysfunction has been linked to various human diseases, and recent studies have suggested a potential association between mitochondrial dysfunction and periodontitis. Studies have reported that mitochondria in patients with periodontitis show decreased function, increased oxidative stress, and inflammatory responses. These functional changes in mitochondria may be related to the progression of periodontitis. Previously, our results reported that Selcopintide (SCPT), a CPNE7-derived peptide, repairs the periodontal ligament by TAU-mediated cytoskeleton reorganization and regulation of cementum attachment protein to enhance the attachment activity of periodontal ligament cells (PDLCs). However, the anti-inflammatory effects of SCPT in periodontal diseases are unknown. In this study, we examined the potential anti-inflammatory effect of SCPT in the periodontal ligament and its possible association with mitochondrial function. To investigate the effects of SCPT, we induced an inflammatory response in PDLCs and ligature-induced periodontitis animal models. Inflammatory responses of PDLCs were stimulated by LPS. Mice were used and divided into three groups (no ligature, ligature only, ligature and SCPT treatment), and periodontal tissue damage and alveolar bone loss were confirmed by histological analysis. The gene expression levels of pro-inflammatory cytokines were significantly reduced after treatments with SCPT with or without LPS-stimulated PDLCs. Furthermore, the expression of fusion and fission protein were upregulated after SCPT treatments. These findings suggest that the SCPT-mediated regulation of mitochondria function may contribute to the alleviation of oxidative stress in PDLCs with inflammation. In vivo micro-CT analysis showed that bone loss occurred in the ligature group. However, the SCPT treated group was protected from periodontal damage and attenuated periodontitis compared to the control (ligature-only) group. These results indicated that Selcopintide might be a potential preventive and therapeutic agent for periodontal diseases.

Long-term Voluntary Wheel Running Generates Skeletal Muscle-derived Anti-inflammatory Oxylipins correlating with Osteocyte-derived Anti-inflammatory Cytokines in Aging Female Mice *Yukiko Kitase[1], Zhiying Wang[2], Chenglin Mo[3], Julian A. Vallejo[4], Michael Wacker[5], MARCO BROTTO[6], Lynda Bonewald[7]. [1]Indiana University, School of Medicine, United States. [2]Bristol Myers Squibb Princeton, United States. [3]The University of Texas at Arlington, United States. [4]University of Missouri-Kansas City, United States. [5]University of Missouri-Kansas City School of Medicine, United States. [6]University of Texas-Arlington (UTA), United States. [7]Indiana University School of Medicine, United States

Low-grade, systemic, chronic inflammation is a key contributor to tissue dysfunction leading to aging-related disease. Exercise reduces chronic inflammation and prevents the loss of skeletal muscle and bone. We have previously shown that long-term exercise initiated in middle age has positive effects against aging-induced skeletal muscle and bone deterioration in female mice. To identify potential mechanisms, muscle was analyzed for oxylipins, bioactive lipid mediators known to regulate inflammation, and RNA-seq was performed on bones from female mice that were allowed access to wheels from 12 mo to 18 mo of age. The animals were divided into high body weight (HBW) and low body weight (LBW) based on median body weight for analysis. There were no differences in run distance between these two groups. Oxylipins in skeletal muscle were quantitated by LC-MS/MS, and Spearman correlation analyses were performed to determine if VWR plays a role in muscle-bone crosstalk through muscle oxylipins and bone inflammatory cytokines.The anti-inflammatory oxylipin 13-KODE, known to reduce LPS-induced inflammation, was elevated in muscle from the VWR mice ($p<0.05$). However, the anti-inflammatory oxylipin, 15-HETE, known to inhibit the formation of leukotriene, a pro-inflammatory oxylipin, was only elevated in muscle from HBW ($p<0.05$) but not LBW mice. 13-KODE showed positive correlations with soleus muscle functions, such as maximal force with calcium depletion, fatigue, and recovery. GO analysis of bone RNA-seq identified the immune system as the topmost significantly impacted biological process with elevated anti-inflammatory genes and decreased pro-inflammatory genes. 13-KODE negatively correlated with inflammatory genes in bone, including Tnfsf11 mRNA (?=-0.94, p=0.017), coding for RANKL, but positively correlated with Il-27 mRNA (?=0.89, p=0.033), an interleukin known to antagonize RANKL-induced osteoclastogenesis. Il-27 showed a positive correlation with soleus muscle mass and maximal force with calcium depletion and with EDL relaxation rate. In contrast, Tnfsf11, shown to have a negative effect on muscle function and myogenesis, was negatively correlated with muscle function. In summary, VWR elevated anti-inflammatory oxylipins in skeletal muscle from HBW mice and reduced pro-inflammatory cytokines in bone. Correlation analyses suggest that the beneficial effects of VWR on the aging musculoskeletal system are due to reciprocal crosstalk between muscle and bone.

Inhibition of Schnurri-3 protects from systemic and articular bone loss in murine serum transfer arthritis *Priyanka Kushwaha[1], Ellen M. Gravallese[1], Jae-Hyuck Shim[2], Catherine A. Manning[1], Tadatoshi Sato[2], Yeon-Suk Yang[2]. [1]Brigham and Women's Hospital, United States. [2]University of Massachusetts Chan Medical School, United States

Rheumatoid arthritis (RA) is a chronic inflammatory disease that activates osteoclasts (OCs) to resorb bone while simultaneously suppressing the ability of osteoblasts (OBs) to build bone. Current therapeutic agents are inadequate to fully prevent inflammation-induced systemic and articular bone loss. Our previous studies identified Schnurri-3 (SHN3) as a potent suppressor of bone formation and inhibition of SHN3 protects from systemic trabecular bone loss and articular joint bone erosion in RA models. These data suggest that inhibition of SHN3 could be a promising approach to limit bone loss and promote bone repair in RA1. To test SHN3's role in bone erosion healing at articular sites, we used the K/BxN serum transfer arthritis model. We administered arthritogenic serum generated in K/BxN mice to induce inflammation in wildtype mice, then allowed inflammation to completely resolve within 28-30 days. To test whether Shn3 knockdown could promote healing of articular erosions once established, we administered a bone-targeting recombinant adeno-associated virus (rAAV) vector carrying an artificial miRNA that silences expression of Shn3 (amiR-Shn3) or control (amiR-Ctrl) at day 7, three days prior to peak inflammation. Expression of SHN3 was reduced in bone (by ~17%) in amiR-Shn3 mice. Furthermore, microcomputed tomography analysis suggests that knockdown of SHN3 promotes bone formation at the articular erosion site as inflammation resolved. Clinical inflammation scores and joint inflammation scores are comparable in both amiR-Ctrl and amiR-Shn3 groups, demonstrating that knockdown of SHN3 does not affect inflammation. Importantly, AAV treated mice didn't lose body weight and have normal activity, supporting safety of this approach. These results suggest that bone-targeting AAV-mediated silencing of SHN3 may be a promising and safe therapeutic strategy to treat bone loss in rheumatoid arthritis and may promote erosion healing. Hindlimb Unloading Induces Microarchitectural and Transcriptomic Changes in the Femur and Tibia in an Age- and Sex-Dependent Manner *STEVEN MEAS[1], Gabriella Daire[1], Michael Friedman[1], Henry Donahue[1]. [1]Virginia Commonwealth University, United States

Age and disuse-related bone loss both result in decreases in BMD, cortical thickness, and trabecular thickness and connectivity. An emerging concept is that disuse induces physiological changes in bone similar to those seen with aging. Animal studies used 4, 6, and 22-month-old C57BL/6J male and female mice that were hind-limb unloaded (HLU) for 3 weeks. Ingenuity Pathway Analyses (IPA) included a publicly available dataset (GLDS647) from 3-month female C57BL/6 mice unloaded for 7 days.In females, three weeks of HLU induced an intermediary bone phenotype in femurs between 6-month-old and 22-month-old mice. Specifically, CTAr/TAr significantly decreased in young HLU mice (n=7) and further in aged control mice (n=13) compared to young ground control mice (n = 7; young control: 55%, young HLU: 48.86%, aged control: 43.25%; $p < 0.0001$). In males, CTAr/TAr remained similar between young control mice (n=8, 42.63%) and young HLU mice (n=8, 42.25%) but there was a decrease in CTAr/TAr with aged control (n=11, 38.91%) and aged HLU mice (n=3, 34.00%). Metaphyseal trabecular bone indices were unchanged. Epiphyseal trabecular bone volume (BV/TV) in female mice was lower in young HLU mice (22.0%) compared to young control (29.7%, $p < 0.05$) and aged control (28.7%, $p < 0.05$) mice. Male mice demonstrated similar trends, with a decrease in BV/TV due to HLU ($p < 0.05$).RNA extracted from whole-bone marrow-flushed tibias was sequenced and analyzed. Gene ontology analysis demonstrated that mitochondrial function was downregulated after HLU whereas cell-cycle transition was downregulated with aging. These ontologies suggest that HLU leads to dysfunctional mitochondria that can perhaps lead to cellular errors in transcription and translation, whereas in aging there is primarily a downregulation of cell cycle processes. IPA was used to identify the leading canonical pathways and upstream regulators in each HLU age group. IPA identified "Senescence Pathway" as the fourth leading canonical pathway enriched in mice exposed to HLU. HLU induced activation of the senescence pathway in 3 month ($p < 0.05$, $z = 3.464$) and 4 month ($p < 0.001$, $z = 0.6$) old mice, inhibited it in 6 month ($p < 0.01$, $z = -3.153$) old mice and did not change it in 22 month ($p = 0.1$, $z = -1$) old mice.In conclusion, we demonstrate that hind-limb unloading initiates changes in bone microarchitecture and gene expression similar to aging, but with distinct differences.

SAT-218

High levels of efferocytosis by mesenchymal stromal cells increases their senescence and decreases bone *Emily Quarato[2], Noah Salama[2], Yuko Kawano[2], Allison Li[3], Roman Eliseev[2], Laura Calvi[4]. [2]University of Rochester, . [2]University of Rochester, United States. [3]Yale University, United States. [4]University of Rochester School of Medicine, United States

Age-dependent bone loss is a manifestation of skeletal aging. Hallmarks of skeletal aging include mesenchymal stromal/stem cell (MSC) dysfunction and cellular senescence. However, the mechanisms inducing MSC senescence remain unclear. We found that MSCs contribute to the clearance of apoptotic cells in the bone marrow (efferocytosis). While rates of efferocytosis are low at homeostasis, in aging, MSCs increase their efferocytic activity. Thus we hypothesized that excess efferocytosis may contribute to MSC dysfunction and senescence, and represent a previously unknown mechanism of bone loss. In vitro, excess efferocytosis induced MSC dysfunction through increased mitochondrial fission and metabolic disruption. Additionally, MSCs with high efferocytic burden had transcriptional evidence of increased senescence, which we confirmed functionally. In a mouse model of enhanced efferocytosis by MSCs (Bai1xPrxCre), we confirmed increased efferocytosis by MSCs (70% to 85%), and found that efferocytic MSCs had increased rates of senescence compared to controls (40% vs 20%). Consistent with a negative effect of excessive efferocytosis on bone homeostasis, Bai1xPrxCre mice at 3 months had decreased cortical thickness, which significantly declined with age (12m) compared to controls. In this model, MSC dysfunction was also decreased by CFU-F/OB. We next profiled the efferocytic machinery in MSCs, and identified Axl as the primary efferocytic receptor on MSCs. In mice with global loss of Axl, MSCs had decreased efferocytic efficiency, and increased bone mineral density/content and cortical thickness, in both young (3m) and aged (24m) mice. To determine the translation potential of this finding, we tested small molecule inhibitors of the TAM receptors (Tyro3, Axl, MerTK) on MSC in vitro and found that combined Axl and Tyro3 inhibition blocks MSC efferocytosis. Collectively, our data support the idea that excess efferocytosis is a novel mechanism of bone loss. MSC efferocytosis is activated by defects in professional phagocytic cells, such as macrophages. Therefore, senescence induced by excessive MSC efferocytosis may be an underappreciated mechanism of bone loss in settings of defective macrophages, as in aging, obesity, and diabetes-induced bone loss. Given the unique reliance of MSC efferocytosis on Axl, this novel mechanism may be pharmacologically targetable for the treatment of bone loss in aging and in other diseases caused, in part, by MSC efferocytic excess.

Dementia Is More Associated With Osteosarcopenia Than With Other Musculoskeletal Phenotypes. Results From the Sarcos Study *Lorena Sallovitz[1], Angela Paes[1], ALBERTO FRISOLI JUNIOR[2]. [1]FICSAE, Brazil. [2]UNIVERSIDADE FEDERAL SAO PAULO,

Dementia has been associated with low physical activity and inflammatory process. These conditions are associated with sarcopenia and osteoporosis. However the association between dementia and the musculoskeletal phenotypes remain unclear.Aim: To evaluate the association between dementia and osteosarcopenia, sarcopenia and osteoporosis phenotypes using two different diagnosing methods of sarcopenia, in older adults.Methods: SARCOS is a prospective cohort study on the association between sarcopenia and osteoporosis and difficult outcomes in older adults with cardiovascular disease. Population: subjects aged > 60 years from the cardiovascular disease outpatient clinic. All patients underwent DXA analysis for appendicular muscle mass, bone mineral density, in addition, handgrip strength and walking speed were measured. Sarcopenia was diagnosed following the EWGSOP II (EW)

and SDOC recommendations. Osteoporosis was diagnosed according to the WHO guidelines. Osteosarcopenia was categorized into four phenotypes (osteosarcopenia-OPSAR, sarcopenia-only-SAR, osteoporosis-only-OP, and robust-ROB) for each sarcopenia diagnosis. Dementia was defined by recommended score on the Mini Mental State Examination (MMSE). Regression analyses were adjusted for significant variables for osteosarcopenia SDOC and EWGSOP II (Age>80, depression, chronic obstructive pulmonary disease and years of schooling).Results: In this study, 408 patients were evaluated. The mean age was 77.87(7.6) years, female gender 57.5%(235). Dementia occurred in 68,4%(279); osteosarcopenia phenotypes: OPSAR-SDOC: 17.9% (73), SAR-SDOC: 26.7% (109), OP-SDOC: 11.5% (47); p<0.013; and OPSAR-EW: 9.6% (39); SAR-EW: 7.8%(32); OP-EW: 19.9% (81); p=0.197. In patients with dementia, 21.5% had OPSAR-SDOC, 11.5% OPSAR-EW; 27.6% SAR-SDOC, 6.8% SAR-EW; 9.7% OP-SDOC and 19.7% OP-EW. In regression analyses, dementia showed odds ratio for OPSAR-SDOC: 2.36 (1.16-4.81; 0.018), SAR-SDOC: 1.25 (0.73-2.14; 0.405); OP-SDOC 0.72 (0.37-1.41; 0.344), while for phenotypes with EW, the OR for OPSAR-EW: 1.87 (0.77-4.55; 0.165); SAR-EW: 0.64 (0.3-1.38; 0.258); OP-EW: 0.994 (0.58-1.72; 0.983).Conclusions: In our study dementia showed greater association only with the osteosarcopenia phenotype by SDOC recommendation. Implications: These results highlight the importance of differentiating osteosarcopenia phenotypes in clinical practice.

[5]5Departments of Computer Science and Psychiatry, University of North Carolina, United States

Introduction: Longitudinal effect of diet-induced obesity on bone is uncertain. Prior work showed both no effect versus a decrement in bone density or quality when obesity begins prior to skeletal maturity. We aimed to quantify long-term effects of obesity on bone and bone marrow adipose tissue (BMAT) in adulthood. Methods: Skeletally mature, female C57BL/6 mice (n=70) aged 12-weeks were randomly allocated to low-fat (LFD; 10%kcal fat; n=30) or high-fat (HFD; 60%kcal fat; n=30) diet, with analyses at 12,15,18 and 24-weeks (n=10/group). Tibial microarchitecture was analyzed by µCT, and volumetric BMAT was quantified via 9.4T MRI/advanced-image-analysis. Histomorphometry of adipocytes and osteoclasts, qPCR, and bone metabolomic subset analyses were performed. Results: Body weight and visceral white adipose tissue accumulated in response to HFD started in adulthood. Trabecular bone parameters declined with advancing experimental age. BV/TV declined 22% in LFD (p=0.0001) and 17% in HFD (p=0.0022) by 24-weeks. HFD failed to appreciably alter BV/TV and had negligible impact on other microarchitecture parameters. Both dietary intervention and age accounted for variance in BMAT, with regional differences: distal femoral BMAT was more responsive to diet, while proximal femoral BMAT was more attenuated by age. BMAT increased 60% in the distal metaphysis in HFD at 18 and 24 weeks (p=0.0011). BMAT in the proximal femoral diaphysis, unchanged by diet, decreased 45% due to age (p=0.0002). Marrow adipocyte size via histomorphometry supported MRI quantification. Osteoclast number did not differ between groups. Tibial qPCR showed attenuation of some adipose, metabolism, and bone genes. A regulator of fatty-acid ?-oxidation, Cytochrome C (CYCS), was 500% more abundant in HFD-bone (p<0.0001; diet effect). CYCS also increased due to age, but to a lesser extent. HFD mildly increased OCN, TRAP, and SOST. Metabolomic subset analysis (24-week HFD vs LFD; n=3/group) showed enrichment in some fatty acid and amino acid pathways in bone. Conclusions: Long-term high fat feeding after skeletal maturity, despite upregulation of visceral adiposity, body weight, BMAT, and attenuation of local energy metabolism, failed to worsen bone microarchitecture. In adulthood, we found aging to be a more potent regulator of microarchitecture than diet-induced obesity.

Follistatin-compound hFST?HBS-FC improves bone, muscle mass and body weight during immobilization and ageing and adds to bone effect of bisphosphonates *Bram van der Eerden[1], Andreas Lodberg[2], Mikkel Bo Brent[2], Marijke Koedam[3], Renate Brandt[4], Jeroen Essers[4], Jesper Skovkus Thomsen[2], Ingrid van der Pluijm[5], Annemarie Brüel[6], Johannes Van Leeuwen[7]. [1]Erasmus MC, Netherlands. [2]Department of Biomedicine, Health, Aarhus University, Denmark. [3]Dept. Internal Medicine, Erasmus MC, Netherlands. [4]Department of Molecular Genetics, Erasmus MC, Netherlands. [5]Department of Vascular Surgery, Erasmus MC, Netherlands. [6]Department of Biomedicine, Health, Aarhus University, , Denmark. [7]Erasmus University Medical Center, Netherlands

Background: Sarcopenia, loss of muscle mass and strength, and osteoporosis, loss of bone mass and strength, are natural consequences of aging and often related. Sarcopenia is associated with increased fracture risk, while immobilization leads to loss of muscle and bone mass. We developed a follistatin (FST)-based compound (hFST?HBS-FC) that can bind activin A and myostatin and prevents OVX-induced bone loss (Lodberg et al, FASEB J. 33:6001; 2019)Aim: In this study we examined the impact of hFST?HBS-FC on bone and muscle mass in a premature aging mouse model (Ercc1 ?/-) and a botox-induced immobilization mouse model. We also examined the combined treatment of hFST?HBS-FC and zoledronate (ZOL).Methods: For both models, female mice (Botox model 16 weeks old; Ercc1 ?/- model, 8 weeks old) were treated with either vehicle, 10 mg/kg hFST?HBS-FC twice a week intraperitoneally, a single subcutaneous injection of 100 ?g/kg zoledronate once, or a combination of both treatments. After 3 weeks, animals were sacrificed, and tissues were harvested.Results: Botox-treatment led to a decrease in both bone mass (BV/TV(%): 11.1>6.7%) and muscle mass (quadriceps: -17%). hFST?HBS-FC and ZOL both increased BV/TV (6,7>8,6% and 6.7>16.9, respectively), which was further elevated by the combination treatment of hFST?HBS-FC with ZOL (6.7>20.3%). Similar effects were observed for other bone parameters like Tb.N and Tb.Sp. hFST?HBS-FC prevented weight loss and the loss of muscle mass caused by systemic stress of immobilization. ZOL did not affect muscle mass. Bone and muscle mass were both reduced in the premature aging model compared to wild type mice (Vermeij et al. Nature 537:427; 2016). ZOL prevented the decrease in bone mass which was strongly further enhanced by co-treatment with hFST?HBS-FC (see Table). hFST?HBS-FC also increased muscle mass (+20%) as well as total body weight (+7%) in prematurely aging mice, which was not observed for ZOL.Conclusion: hFST?HBS-FC not only improves bone mass and bone structure but also increases muscle mass and prevents weight loss in conditions reflecting immobilization and aging. hFST?HBS-FC adds to the positive treatment effect of bone loss by zoledronate. These results hold promise for a hFST?HBS-FC combination therapy with bisphosphonates against bone loss with the additional benefit of a muscle anabolic effect.

Captopril Alleviates Chondrocyte Senescence and Cartilage Loss In Spontaneous Hypertensive Rats *Yuqi Zhang[1], Chunyi WEN[2]. [1]Department of Biomedical Engineering, The Hong Kong Polytechnic University, Hung Hom, Kowloon, Hong Kong, China, Hong Kong. [2]Hong Kong Polytechnic University, Hong Kong

Background: Mounting epidemiological evidence suggests a close association between hypertension and osteoarthritis (OA). Their causal relationship remains not established yet. Hereby, we aimed to examine knee joint structural integrity in spontaneously hypertensive rats (SHR) compared to normotensive Wistar Kyoto (WKY) rat with or without surgical induction, and investigate the efficacy of FDA-approved anti-hypertensive medication, captopril, on joint structure in SHR.Method: First, we used 6 male SHR and 6 male WKY at the age of 4 months for comparison. They were randomly allocated to sham or anterior cruciate ligament transection (ACLT) groups with n=3 for each group. Then we further tested the efficacy of captopril on SHR. SHR were divided into the placebo and captopril treatment groups (n=3 for each group). In addition to blood pressure, carotid arterial stiffness and knee joint vascularity were measured non-invasively via ultrasonic and photoacoustic imaging at baseline, 1 and 2 months after surgery. Bone mass and microstructure of knee joint was evaluated via in-vivo micro-CT. The animals were sacrificed at postoperative 2 months and knee joints and aorta were harvested for routine histology and immunostaining for detection of p16INK4a+ senescent cells and MMP13 expression.Results: Hypertension induced p16IN-

K4a+ senescent cells accumulation not only in the aorta but also knee joint, increased expression of MMP13 in knee joint, and ultimately contributed to cartilage degradation in SHR compared to WKY. Captopril not only lowers blood pressure but also removes p16INK4a+ senescent cells from aorta and knee joint, reduced the level of MMP13 in joint cartilage, and preserved the thickness of articular cartilage in SHR. SHR showed bone loss, but captopril did not rescue bone loss. After ACLT induction, WKY and SHR have almost the same degree of cartilage senescence and damage in joints.Conclusion: Hypertension contributes to senescent cells accumulation and cartilage degeneration. Anti-hypertensive medicine such as captopril emerges as a promising senolytic approach for rescue of degenerative joint disorder. However, for joints already suffering from OA, hypertension did not further aggravate OA, or the aggravation effect was very weak.

SAT-225

Laminopathy-like pathology due to Runx2-dependent downregulation of LINC protein expression underlies the pathogenesis of Cleido cranial dysplasia *Akiko Saito[1], Shoko Onodera[1], Natsuko Aida[1], Hiroyuki Okada[2], Hironori Hojo[2], Shigeaki Kato[3], Toshifumi Azuma[4]. [1]Tokyo Dental College, Japan. [2]Tokyo University, Japan. [3]Iryososei Unicersity, Japan. [4]Tokyo Dental Collge, Japan

Severe laminopathies (such as Hutchinson-Gliford progeria syndrome) caused by mutations in the LINC protein genes, including the lamin A/C genes, exhibit bone lesions such as clavicle and cranial suture. RUNX2 heterozygous deficiency, cleido cranial dysplasia (CCD), are known to exhibit bone lesions in areas similar to laminopathy. Hoewever, it is not known whether RUNX2 and LaminA/C share any common roles in the development of bone lesions. In this study, we used human RUNX2-deficient iPS cells to elucidate the mechanisms of chromosome dynamics regulation and epigenetic control mechanisms mediated by nuclear lamina and nuclear conformation by the RUNX2-LaminA/C-nesprin 1 axis. LINC protien(Nesprin 1) and LaminA/C were substantially downregulated in RUNX2-deficient iPS cell-induced osteoblast, and abnormal laminopathy-like nuclear morphology, such as abnormal deep nuclear groovesm was observed in RUNX2 hetero-and homo- deficient cells. Observation of cellular and nuclear propeties by atomic force microscopy and cytoskeletal distribution by fluorescence microscopy revealed prominent nuclear deformation and greatly reduced physical rigidity in RUXN2 -/- cells with loss of perinuclear action cap structure and actin stress fibers and significantly reduced intracellular tension. In RUNX2 -/- cellls with forced expression of Nesprin1, nuclear deformations, nuclear membrane stiffness, nuclear actin cap structure, actin stress fibers and intracellular tensions were recovered to normal. LaminA/C CUT & RUN assay showed that LaminA/C was enriched in the TSS region both RUNX2+/+ cells and RUNX2-/- with forced expression of Nesprin1 cells, while LaminA/C was sparse in the TSS region in RUNX2-/- cells. Single cell RNAseq analysis showed that RUNX2 mRNA was detected even in the Runx2-/- cells, but the RUNX2-positive cells were detected at about half the the frequency of RUNX2+/+ cells, whereas RUNX2-/- with Nesprin 1 cells had the same frequency as RUNX2 +/+ cells. These results indicate that marked downregulation of LaminA/C and Nesprin1 similar to laminopathy by RUNX2 deletion underlies CCD pathogenesis due to nuclear membrane abnormalty, loss of perinuclear actin cap, reduced intracellular tensions, althered chromosome dynamics and dysregulation of LINC protein epigenetic control mechanisms. Therefore we propose that RUNX2-LINC protein axis is a newly discovered osteogenic checkpoint

Mice Lacking COX2 Cyclooxygenase Activity Display Sexual Dimorphism and Respond to Osteogenic Mechanical Loading *Alexandra Ciuciu[1], Ryan Tomlinson[2]. [1]Thomas Jefferson University , . [2]Thomas Jefferson University, United States

Non-steroidal anti-inflammatory drugs (NSAIDs) relieve pain and inflammation by inhibiting prostaglandin synthesis by the cyclooxygenase (COX) enzymes COX1 and COX2. Regular NSAID use is associated with increased stress fracture incidence, but it is unknown if the inhibition of COX2 signaling causes this effect. To investigate COX2-dependent and COX2-independent effects of NSAIDs, we used Ptgs2-Y385F mice, which harbor a point mutation that inhibits the cyclooxygenase activity of COX2 but maintains its peroxidase activity (similar to a COX2-selective NSAID). In adult mice (15-18 weeks old), microCT revealed that female Ptgs2-Y385F mice had significantly increased trabecular BMD (+35%, p=0.05). Surprisingly, male Ptgs2-Y385F mice have significantly reduced relative endosteal BFR/BS (-48%, p=0.042). There were no other significant differences in histomorphometric parameters. Potential compensation by COX2 in the Ptgs2-Y385F mice is being investigated at the mRNA and protein levels. Nonetheless, these data indicate that Ptgs2-Y385F mice are a valuable tool for examining COX2-independent effects of NSAIDs in bone and underscore the need to consider sex as a biological variable when analyzing the effects of NSAIDs in bone.

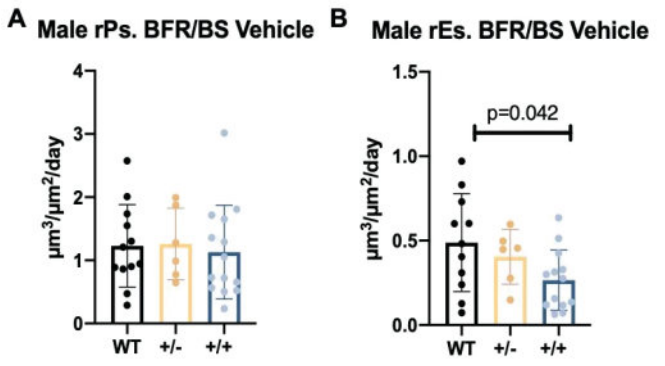

Figure 1: A) Relative periosteal bone formation rate per bone surface of vehicle treated male wild-type (WT), heterozygous (+/-), and Ptgs2-Y385F mice (+/+). B) Relative endosteal bone formation rate per bone surface of vehicle treated male WT, heterozygous, and Ptgs2-Y385F mice. (n=6-13 per genotype)

SAT-227

Chronic treatment with the ?2-adrenoceptor agonist clonidine affects the morphophysiology of epiphysel groth plates but does not modify the longitudinal bone growth of mice. *Vitor Torres[1], Cecilia Gouveia[2]. [1]University of Sao Paulo, Brazil. [2]University of Sao Paulo, Institute of Biomedical Sciences, Brazil

We have demonstrated that ?2-adrenoceptors (?2-AR) are expressed in the epiphyseal growth plates (EGP) of mice, and that mice with isolated gene inactivation of ?2A-AR and ?2C-AR have lower body length and EGP dysgenesis. We showed that tibias isolated from these knockout animals and kept in organ cultures present lower rate of longitudinal bone growth (LBG). We also showed that treatment of wild-type tibias (in organ cultures) with UK, an ?2-AR agonist, decreases the number of hypertrophic chondrocytes (HC) in the EGP, suggesting that ?2-ARs mediate local and negative actions of the sympathetic nervous system (SNS) in the EGP. Considering that ?2-AR agonists are used in clinical practice for various purposes, the present study aimed to investigate whether the chronic use of clonidine (CLO), an ?2-AR agonist, affects the EGP morphology and LBG. C57BL/6J mice (21 day-old) were treated daily with subcutaneous injections of 35 ?g/kg CLO or saline (CLO and control groups, respectively; n=10/group) for 30 days. We showed that CLO treatment did not affect body weight, body growth, and the longitudinal growth of the femur and tibia. However, CLO reduced the thickness and area of the EGP and hypertrophic zone (HZ), while increased the number of proliferative chondrocytes (PC) and decreased the ration between the hypertrophic and proliferative zones (HZ/PZ) of the EGP, which suggests a negative effect of CLO on the differentiation of HC and a positive effect on chondrocyte proliferation. Treatment with CLO did not alter EGP gene expression of IGF-1, Runx-2 and Wnt4, but increased the expression of type II collagen. These findings demonstrate that chronic treatment with CLO does not affect the LBG, but promotes changes in the EGP. Considering that CLO stimulates pituitary secretion of growth hormone (GH), it is possible that CLO acts indirectly and positively in the EGP, via GH actions (chondrocyte proliferation), which probably compensates its direct and negative effects (inhibition of terminal differentiation of chondrocytes), resulting in normal LBG.

SAT-228

Hypertrophic Chondrocyte-Autonomous Roles of YAP/TAZ Signaling in Embryonic Bone Development *Christopher Panebianco[1], Joel Boerckel[1]. [1]University of Pennsylvania, United States

The appendicular skeleton forms through endochondral ossification, in which chondrocytes proliferate, undergo hypertrophy, and then are remodeled at the chondro-osseous junction to form bone. Previously, we found that deleting the transcriptional regulators YAP and TAZ from Osterix (Osx) -expressing cells caused bone fragility, perinatal lethality, hypertrophic zone (HZ) elongation, and a cone shaped chondro-osseous junction.1 Since Osx is expressed in hypertrophic chondrocytes (HCs) and osteoblast-lineage cells, it remains unknown whether the HZ phenotype is caused by HC-autonomous defects or by disrupted chondro-osseous junction remodeling.To answer this question, we generated mice featuring allele dosage-dependent deletion of YAP/TAZ in ColX-expressing cells (i.e., HCs). Wild-type (WT) and ColX-conditional knockout (cKO) mice were evaluated by whole mount imaging and μCT at birth (P0), and by histology at E17.5. In contrast to Osx-cKO mice, ColX-cKO mice were viable, fertile, and had no perinatal bone fractures (Fig 1A). Nonetheless, ColX-cKO mice were smaller, had reduced body mass, and had reduced bone volume

compared to WT littermates (Fig 1B). To explore the cellular basis of this phenotype, we analyzed the growth plate of the E17.5 proximal tibia. ColX-cKO mice had an elongated HZ compared to WT littermates, though both groups exhibited a normal, flat profile at the chondro-osseous junction (Fig. 1C).Our results indicate an HC-autonomous contribution of YAP/TAZ signaling to endochondral ossification. Our previous work with Osx-cKO mice found that deleting YAP/TAZ in HCs and osteoblast-lineage cells impaired growth plate remodeling through HC-autonomous and non-autonomous mechanisms.1 The elongated HZ phenotype present in ColX-cKO mice demonstrates the importance of YAP/TAZ signaling in HC-autonomous matrix remodeling. However, since chondro-osseous junction shape was normal, we verify that non-autonomous mechanisms of matrix remodeling are independent of HC YAP/TAZ signaling. These results are similar to Col2-cKO mice, which displayed HZ elongation and a flat chondro-osseous junction.2 Future studies will study potential mechanisms by which HC-autonomous YAP/TAZ signaling affects endochondral ossification (e.g., HC differentiation, HC matrix degradation), but our data shows that HC-autonomous YAP/TAZ signaling is necessary for proper endochondral ossification.Refs: [1] Collins+ BioRxiv 2023; [2] Vanyai+ Development 2020

SAT-229

Elucidating the Consequences of Wnt16 Cysteine Deletion on Bone *Emily G. Ramirez[1], Maria F. Rojas[1], Jyoti Rai[1], Claire J. Watson[1], Ronald Young Kwon[1]. [1]Department of Orthopaedics and Sports Medicine, University of Washington School of Medicine , United States

Osteoporosis, a polygenic disease characterized by low bone mineral density (BMD) and increased fracture risk, afflicts over 200 million people worldwide [1]. WNT16 is a member of the WNT protein family that has been specifically linked to genetic influence on BMD and fracture risk. The majority of WNT proteins contain 24 conserved cysteines (c1-c24), and mutations for almost half of these cysteines are associated with human diseases or disrupted development in animal models [2]. However, the impact of cysteine 10 (c10) alteration remains unknown. Previous analyses suggest that c10 may form a disulfide linkage with cysteine 11 that contributes to the structure of the thumb-like domain recognized by Frizzled receptors [2]. Previously, our lab showed that wnt16-/- mutant zebrafish exhibit impaired spine development and morphology [3]. We hypothesized that c10 is necessary for WNT16 structure and function, and that loss of c10 in zebrafish will phenocopy wnt16-/- mutants. To test this, we used CRISPR-based gene editing to generate zebrafish harboring mutations at the wnt16 locus at the c10 position, and isolated wnt16w1012 mutants. Sanger sequencing revealed a three amino acid deletion at Cys214, corresponding to c10 (p.Cys214_Gly216del). Calcein staining of wnt16w1012 mutant fish at 14 days post fertilization (dpf) revealed altered mineralization in vertebrae compared to age-matched controls (n=10/group). Analysis of microcomputed tomography scans at 90 dpf revealed significantly reduced centrum length ($p<0.0001$), along with a significant increase in neural arch angle ($p=0.0002$) in wnt16w1012 mutants (n=10/group). Moreover, wnt16w1012 mutants exhibited significantly reduced centrum volume ($p=0.0088$) and significantly increased centrum ($p=0.0404$), haemal arch ($p=0.0264$), and neural arch ($p=0.0166$) tissue mineral density compared to controls. No significant differences were observed between wnt16w1012 and wnt16-/- mutants, indicating that wnt16w1012 mutants phenocopy wnt16-/- mutants. Computational modeling of the encoded protein for wnt16w1012 revealed conformational changes predicted to affect recognition by Frizzled receptors. These studies indicate that c10 is essential for WNT16 function. Our findings suggest that mutations affecting c10 in WNT16 could influence BMD and fracture risk.1. Sözen et al., 2017, Eur. J. Effects of Tetrahydrocannabinol on Prenatal Skeletal Development *Faisal Sadar[1], Nihamul Ehan[1], Samantha Penman[2], Gabriela Miletsky[2], Rania Ahmed[2], Michael Hadjiargyrou[3], Panayotis Thanos[2], David Komatsu[4]. [1]Department of Orthopaedics and Rehabilitation, Stony Brook University, United States, [2]Behavioral Neuropharmacology and Neuroimaging Laboratory on Addictions, Clinical Research Institute on Addictions, Department of Pharmacology and Toxicology, Jacobs School of Medicine and Biosciences, State University of New York at Buffalo, United States, [3]Department of Biological and Chemical Sciences, New York Institute of Technology, United States, [4]Stony Brook University, Dept. of Orthopaedics and Rehabilitation, United States

The rapid expansion of legalized marijuana has been accompanied by an increase in the number of people using this drug. Clinical studies have reported that users of marijuana have an increased incidence of skeletal fractures and decreased bone mineral density. Other studies have shown that 2-5% of woman use marijuana regularly during their pregnancies. Tetrahydrocannabinol (THC) is the primary psychoactive component in marijuana and can cross the placental barrier and potentially affect fetal development. Currently, nothing is known about the effects of prenatal THC exposure on skeletal development. Therefore, we conducted a study in which rats were prenatally exposed to THC. Rat dams were exposed to THC (0.8mg/kg) via inhalation or normal air daily from 3 days prior to pairing for breeding until they gave birth. This dose results in peak THC blood plasma levels of 71.6 +/- 10.9 ng/mL which is similar to the clinical levels detectable after smoking marijuana. The pups were then euthanized on postnatal day 60, corresponding to the end of adolescence in humans. Digital caliper measurements were taken to ascertain tibial and femoral length and mid-diaphyseal diameter on the anterior-posterior (AP) and medial lateral axes (ML). Biomechanical analyses were performed by subjecting femora to 3-point bending tests to determine energy to failure, stiffness, ultimate force, failure force, and yield force. Results were compared between THC and normal air (control) within the male and female cohorts. Sample sizes were 8 for each group. For the caliper measurements, significant differences were found between the control group and the group exposed to THC for tibial ML diameter in both males and females. Specifically, tibial ML diameter was 57% wider in male controls compared to THC exposed and 29% wider in the female controls compared to THC. We also found that femoral length in females was 4% longer in controls compared to THC. Biomechanically, only male femoral yield force differed significantly, with THC exposure resulting in a 28% increase compared to control. Ongoing analyses include safranin O/fast green staining to assess tibial growth plates and tibial microCT to measure bone density and microstructure. The current data suggest that the effects of prenatal exposure to THC on skeletal development are relatively minor. The completion of these studies will provide us with a better understanding of the effects of prenatal THC exposure on skeletal development.

Key Characteristics of Clinicians with Competence in Bone Health Management *Lesley Jackson[1], Sindhu Johnson[2], KEN SAAG[3], Maria Danila[4]. [1]The University of Alabama at Birmingham, United States, [2]University of Toronto, Canada, [3]THE UNIVERSITY OF ALABAMA AT BIRMINGHAM, , [4]University of Alabama at Birmingham, United States

Background: Osteoporosis is managed by clinicians across many specialties. No specific certification in bone health/osteoporosis management exists and the key competencies of clinicians delivering these services have not been systematically established. We aimed to develop a decision rule to define the threshold of adequate bone health competence for a

clinician serving as a referral source for osteoporosis/post-fracture care.Methods: In part 1 using a modified Delphi method, we invited clinicians with expertise in treating osteoporosis and patient advocacy group representatives to create a list of desirable characteristics of a clinician with bone health competence. Characteristics were coded into "attributes" with "levels" within each attribute. Participants prioritized levels by perceived importance. We included levels receiving the highest median scores in the final list of criteria. In part 2, to identify the cutoff for defining adequate competence, participants ranked 20 hypothetical clinicians defined by various levels of attributes from highest to lowest likelihood of having bone health competence. In part 3, we conducted a discrete choice experiment (DCE) to generate a weighted score for each attribute/level such that the sum of weights across the highest level for each attribute would equal 100%. The threshold for competence was a priori determined as the total weighted score at which >=70% of participants agreed a clinician had bone health competence.Results: 13 participants completed Part 1, and 30 participants completed both Parts 2 and 3. The Delphi exercise generated a list of N=108 characteristics, which were coded and grouped into common attributes. Through an iterative process, the attribute categories were reduced to 8 categories. The maximum possible score in the final criteria was 25. Category weights are shown in the Table. A summed threshold score of >12 points classified a clinician as having adequate competence in bone health. For lack of continuing medical education, 1.2 points (~5% of maximum total score) were subtracted from the clinician's score.Conclusions: We developed a numeric additive decision rule to classify clinicians across multiple specialties as having adequate competence in managing bone health/osteoporosis. Our data provides the critical definition of a clinician with competence in bone health and can be used to quantitate the skills of clinicians participating in bone health research and clinical care.

Table. Relative weights of criteria and levels defining a clinician with competence in bone health.

Criteria	Subcriteria	Weighted Score*
Provides bone health care	Performs osteoporosis workup and treatment monitoring, but does not have a dedicated Bone Health Clinic	3.9
	Performs osteoporosis workup and prescription monitoring, has ≥1/2 day per week Bone Health Clinic time	5.7
Prescribing practices	Prescribes only bisphosphonates and denosumab	2.1
	Prescribes all osteoporosis drugs (i.e., anabolic drugs)	4.8
Attends bone health continuing medication education (CME)	None	-1.2**
	Every 2-5 years	1.9
	Once or more per year	3.3
Dual-energy x-ray absorptiometry (DXA) competence	Interprets < 100 DXA scans/year	1.9
	Interprets ≥100 DXA scans/year	2.8
Fracture liaison service (FLS) participation	Leads or participates	2.7
Vertebral Fracture Assessment (VFA) competence	Orders and interprets	2.0
Subspecialty board (Endocrinology, Rheumatology) certification	Currently certified and practicing	1.9
International Society for Clinical Densitometry (ISCD) certified	Certified	1.8

*Summed across all categories, a minimum score of >12 points classifies a clinician as having competence in bone health management.
**If the clinician does not attend CME, subtract 1.2 points from total score.

SAT-233

The POWER Program: Personalized Osteoporosis Care with Early Recognition, Incorporating Virtual Tools Into an Outpatient Fracture Liaison Service *Leah Kennedy[1], Stephanie Yee[1], Melissa Kallas-Koeman[1], Emma Billington[1], Prism Schneider[1]. [1]University of Calgary, Canada

Background: Individuals experiencing a fragility fracture (FF) are 2- to 4-times more likely to have another FF in the future. The COVID-19 pandemic increased existing osteoporosis (OP) care gaps, likely due to reduced assessments, screening, and testing. Provincial treatment initiation declined for oral (43%) and intravenous (26%) bisphosphonates and denosumab (35%) from March to June 2020. Without early identification, investigation, and intervention (3i model), FF incidence will continue to increase globally. Our study evaluated the feasibility, effectiveness, and patient satisfaction regarding a multidisciplinary outpatient fracture liaison service (OFLS), utilizing virtual case conferences and follow-ups and a smartphone application (app).Methods: In August 2020, a 3i OFLS was implemented at our Level 1 trauma centre. Active case finding identified patients >50 years with a new wrist, shoulder, or pelvis FF. The nurse completed a bone health history for each patient, followed by case discussion with the lead physician. We provided education, ordered tests, and initiated pharmacotherapy as needed. Virtual multidisciplinary case conferences were held monthly to review complex patients. Individualized care plans were initiated within three months of enrollment. Participants were followed for 1-year prior to transfer of care to the primary care physician with a bone health care plan. Patient satisfaction surveys were completed serially. Descriptive statistics are presented.Results: Within 12 months, 128 patients were enrolled (mean age=65 [SD +/- 9.9]; 87.5% female), with mainly distal radius (62%) and proximal humerus (21%) fractures. Fifty-four patients were reviewed in multidisciplinary case conferences, with only six requiring referrals for in-person specialist assessment. The virtual conferences required <10 hours of specialist time and avoided over 48 in-person consultations for a minimum estimated direct cost-savings of $12,720 annually. An estimated 270 FFs could be prevented annually at a provincial level. Thirty-nine (30.5%) patients were started on new OP medication. All patient respondents (100%) felt that the OFLS was "good" or "excellent."Conclusions: Our study utilized virtual tools to improve OP education, evaluation, and treatment, and demonstrated promising patient satisfaction, cost-savings, and feasibility. Future directions include provincial implementation of a virtual OFLS to quantify economic impact and fracture prevention.

Emerging Roles of Prostaglandin E2 In Skeletal Muscle Repair and Regeneration *Kamal Awad[1], Jian Huang[2], Leticia Brotto[3], Lynda Bonewald[4], MARCO BROTTO[5]. [1]The University of Texas at Arlington , United States. [2]Rush University Medical Center, United States. [3]Bone-Muscle Research Center, The University of Texas at Arlington, United States. [4]Indiana University School of Medicine, United States. [5]University of Texas-Arlington (UTA), United States

Introduction: Prostaglandin E2 (PGE2) is a signaling molecule protecting skeletal muscle and enhancing regeneration1. was demonstrated that in vivo PGE2 treatment inhibits apoptosis of Hematopoietic stem and progenitor cells2, however this mechanism has not been validated in muscle. Previous studies indicated that Barium Chloride (BaCl2) can induce cell-death in various cell types including muscle cells3. We hypothesized that establishing an in-vitro muscle injury model using BaCl2 to study underlying molecular mechanisms and screen potential therapeutics for muscle regeneration. We tested the role of PGE2 on muscle repair and regeneration after damage by BaCl2.Methods: In-vitro muscle damage using BaCl2 model was developed. Studies using C2C12 and primary muscle cells were performed. Live/dead assay was used to monitor cell's death. Fusion index (FI) calculation was used to quantify the differentiation and muscle damage. Live dynamic imaging used to quantify cell's migration and muscle regeneration. Pathway finder q-PCR array was used to uncover the activated pathways. Ex-vivo FDB myofibers were damaged with BaCl2 and treated with PGE2 while monitored the Ca transient. All experiments were tested with n=4 and in triplicates. T-Test and ANOVA were performed.Results: BaCl2 induces myoblast cell death as indicated by significant increase in number of dead cells after 6 hrs. BaCl2 induced muscle damage via breakdown of myotubes as indicated by significant decrease in FI (p=0.001); while PGE2 attenuated this effect. PCR results indicated that BaCl2 treatment upregulates the BCl-2 gene, involved in programmed cell death "apoptosis". Treatment with PGE2 significantly upregulated the anti-apoptotic gene, Birc-3 (~7.5-fold) vs control. Ex-vivo data from FDB muscle confirmed the same rescuing mechanism with 50 nM PGE2 treatment.Conclusion: BaCl2 induced muscle damage and dysregulated the regeneration through the upregulation of BCl-2 gene, while PGE2 normalizes muscle regeneration after BaCl2 through the upregulation of Birc-3. This study establishes a new in vitro model of BaCl2 damage in muscle cells. The data suggests that BaCl2 induces damage via cell apoptosis, while PGE2 exerts anti-apoptotic effects and rescuing mechanism during muscle damage.1- Mo, C., et. al., (2012). Recent patents on biotechnology, 6(3), 223-229.2- Porter L., et al., (2011). Blood, Volume 118, Issue 21.3- Morton, A. B., et. al. (2019). Skeletal muscle, 9(1), 27.

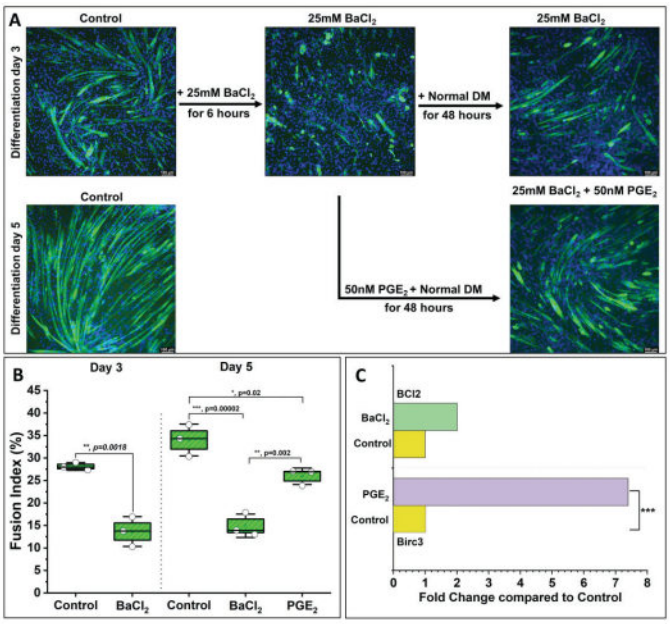

Figure1: $BaCl_2$ significantly damage skeletal muscle while PGE_2 attenuates the damage and significantly enhances the regeneration (A&B) via the upregulation of anti-apoptotic Birc3 gene (C).

Osteoimmunity-regulating nanosilicate-reinforced hydrogel for enhancing osseointegration *Juny Chen[1], Yuanyuan Li[1], Qianbing Wan[1]. [1]West China Hospital of Stomotology, Sichuan University, China

As osteoimmunomodulation was identified as a new and important strategy to enhance material osseointegration, designing an appropriate immune response after biomaterial implantation become a major challenge for efficient bone repair. In this study, a nanosilicate-reinforced sodium alginate (SA) hydrogel is fabricated by introducing montmorillonite (MMT) nanoparticles, meanwhile immunoregulator,harmine (HM) is loaded and released to induce macrophages to differentiate into M2 type. The release of HM and MMT can directly induce bone formation, meanwhile, the release of HM can stimulate the macrophages towards M2 phenotype and secrete osteoblast-related cytokines to indirectly promote bone formation, designed to maximize the material's osteoblastic induction potential (Scheme 1). The fabricated SA/MMT/HM(SMH) hydrogel exhibited improved mechanical stiffness and stability. The hydrogel loaded with HM efficiently promoted macrophage anti-inflammatory M2 phenotype polarization, enhanced the secretion of pro-tissue healing cytokines to induce a favorable immunomodulatory microenvironment for osteogenic differentiation of BMSCs. Further rat air-pouch model and the critical-size bone defect model results showed that SMH hydrogel induced macrophage infiltration into the surrounding tissues and increased the proportion of M2 macrophage, markedly reduces local inflammation while enhancing desirable new bone formation. Transcriptomic analysis revealed that SMH induced acceleration of the M1-to-M2 transition of macrophages by inhibited relevant inflammatory signaling pathways and activation of PI3K-AKT1 signaling pathway. The results above demonstrate that this immunomodulation high-intensity hydrogel might be a promising biomaterial for bone regeneration, which also provides a valuable base and positive enlightenment for massive bone defect repair.

The Collagen Receptor, Discoidin Domain Receptor 2 (DDR2), is Required for BMP-induced Osteogenesis *RENNY FRANCESCHI[1], Fashuai Wu[2], Chunxi Ge[3]. [1]University of Michigan, United States. [2]University of Michigan School of Dentistry, United States. [3]Univ of Michigan School of Dentistry, United States

Objectives: DDR2 is required for normal bone development where it functions in GLI1+ skeletal progenitor cells (SPCs). However, it is not known if it can regulate BMP-dependent bone formation.Methods: Mouse lines used: Ddr2slie/slie (global Ddr2-deficient), Ddr2Mer-icre-Mer;R26RtdTomato; Gli1CreERT;R26RtdTomato and Gli1CreERT;Ddr2loxp/loxp and Ddr2loxp/loxp. Bone formation was measured by subcutaneously implanting BMP2-containing GelfoamTM sponges in mice followed by analysis using microCT, histology, and immunofluorescence (IF). Osteoblast differentiation was measured in BMSCs isolated from Ddr2loxp/loxp mice. BMP signaling was measured by Western blot. RNA-seq was conducted by the University of Michigan Sequencing Core.Results: Comparison of BMP2-induced bone formation in wildtype and Ddr2-deficient (Ddr2slie/slie) mice revealed a strong requirement for DDR2. Similarly, implanted BMSCs from Ddr2-deficient mice are unable to form bone. Lineage tracing in tamoxifen-treated Ddr2Mer-icre-Mer;R26RtdTomato and Gli1CreERT;R26RtdTomato mice showed Ddr2 and Gli1 are expressed in connective tissue cells that rapidly migrate into Gelfoam implants with or without BMP2. In addition, IF analysis showed extensive cellular colocalization (approx. 85%) for DDR2 and GLI1. In the presence of BMP2, DDR2/GLI1-positive cells form bone via an endochondral process. Conditional knockout of Ddr2 in GLI1+ cells using tamoxifen-treated Gli1CreERT;Ddr2loxp/loxp mice strongly inhibited BMP-induced bone formation.The basis for DDR2 actions was explored using BMSCs isolated from Ddr2loxp/loxp mice treated with control or Cre adenovirus. Ddr2 inactivation strongly inhibited osteoblast differentiation. However, it had only a minor effect on rapid BMP2 responses (SMAD1/5/8 phosphorylation/nuclear translocation, AKT and ERK1/2 phosphorylation). In contrast, Ddr2 deficiency was associated with reduction in BMP-induced gene expression as measured by RNAseq and reduction of nuclear/cytoplasmic YAP/TAZ distribution, changes that may explain the loss of osteoblast differentiation.Conclusions: DDR2 is necessary for BMP2-induced bone formation where it functions in GLI1+ SPCs that migrate into implants from adjacent connective tissue. DDR2 is also necessary for BMP2-induced osteoblast differentiation, a response that may be mediated by Hippo signaling.

SAT-239

Central Nervous System Injury Dysregulates Muscle MiRNAs Signaling to Promote Heterotopic Ossifications *Dorothée Girard[1], Jules Gueguen[2], Bastien Rival[1], Juliette Fernandez[1], Marie-Emmanuelle Goriot[1], Sébastien Banzet[1]. [1]IRBA / INSERM UMRS-MD 1197, France. [2]Institut de Recherche Biomédicale des Armées, France

Neurogenic heterotopic ossifications (NHOs) are intra-muscular ectopic bone formations that develop following central nervous system (CNS) damage. NHOs occur in the vicinity of major joints and induce ankylosis, pain, nervous and vascular compressions, ultimately impairing patient recovery. The role of the CNS lesion in the onset of NHO is still poorly understood while therapeutic solutions, apart from surgical resection, remain unsatisfying. At the cellular level, pro-inflammatory macrophages are known to be involved in the pathogenesis by promoting aberrant osteogenic commitment of muscle fibro-adipogenic progenitors (FAPs). In this study, we investigated miRNAs signaling dysregulation in the muscle tissue from a clinically relevant NHO mouse model and in FAPs from NHO patients. NHO was induced in C57Bl/6J mice by combining spinal cord injury (SCI) and cardiotoxin injection (CDTX) in the gastrocnemius muscle. Muscles were harvested at day 2, 4 and 7 for miRNA profiling and FAPs were isolated to study osteo-chondrogenic mRNA and miRNAs expression. Human FAPs were isolated from muscle surrounding NHO and cultured in osteogenic conditions with pro-inflammatory conditioned medium from LPS stimulated macrophages (CM+). Osteo-chondrogenic mRNAs and miRNAs expression were assessed after 1, 3, 7 and 10 days. Human FAPs were also transfected with either miRNAs inhibitors or mimics for functional analysis.We observed the overexpression of osteo-chondrogenic Runx2 and Sox9 mRNAs along with the overexpression of osteo-suppressive miRNAs in CDTX muscle. When combining CDTX with SCI injury, intramuscular mineralization nodules developed and osteo-suppressive miR-199a-3p and miR-214-3p response was hindered. In FAPs isolated from CDTX muscle, SCI induced a global downregulation of osteo-suppressive miRNAs while osteo-chondrogenic Alpl, Runx2 and Sox9 mRNAs were overexpressed. In osteogenic condition, pro-inflammatory CM+ exarcerbated human FAPs in vitro mineralization activity and stimulated ALPL, RUNX2 mRNAs and osteo-suppressive miRNAs expression. Functional analysis of miRNAs candidates confirmed that miR-20a-5p, miR-199a-5p, miR-146a-5p and miR-214-3p were able to inhibit human FAPs mineralization capacities by downregulating osteo-chondrogenic mRNAs expression.This study provides insight into an osteo-suppressive mechanism regulated by miRNAs in response to muscle injury that is ablated by CNS damage in the early stages of NHO pathophysiology.

mRNA profiling of human fracture callus and nonunion tissues *Rishika Thayavally[1], Peter Kloen[2], Leonidas Salichos[1], Michael Hadjiargyrou[1]. [1]New York Institute of Technology, United States. [2]Academic University Medical Centre, Netherlands

Fracture repair is a complex regenerative biological process that ultimately restores the bone's biomechanical, biochemical, physiological and functional properties. In the United States alone, 16 million people each year fracture a bone and most heal within 6-12 weeks with full recovery of function. Unfortunately, for some patients, the fracture does not heal, and it becomes a non-union, needing (revision) surgery. At the molecular level, not much is known about the mechanisms that lead to a nonunion and thus it is imperative that we explore this. In an effort to identify the expression of known mRNAs during human fracture repair, we analyzed RNAseq data from normal fracture callus (FC, Control) and nonunion tissue (Hypertrophic and Oligotrophic; HNU and ONU; experimental) from patient samples. RNA from each condition, FC (n=6), NHU (n=8) and ONU (n=9) was analyzed in order to identify differentially expressed genes between these tissues. Following analysis of RNAseq data and comparison/normalization to the FC sample, 67 and 81 mRNAs were differentially expressed in the HNU and ONU, respectively. From these differentially expressed genes, 20 were common between the two non-union samples. Moreover, out of the 20 common genes, 8 were upregulated and 12 were downregulated. To explore the biological significance of these differentially expressed genes, we analyzed gene ontology and pathway enrichment analyses using the Database for Annotation, Visualization and Integrated Discovery (DAVID) Bioinformatics Resources and identified several relevant and common biological processes (i.e. positive/negative regulation of transcription; positive/negative regulation of inflammatory response; actin filament organization; circadian regulation of gene expression; etc). Taken together, these data provide a comprehensive examination of mRNA expression in fracture callus and nonunion tissues and hopefully they will enable us to decipher some of the molecular mechanisms responsible for normal physiological repair and nonunions.

Biocompatibility and Osteogenic Properties of a new type of Absorbable Magnesium-Based Amorphous Alloy *Talante Juma[1], Yongping Cao[1]. [1]Peking university first hospital, China

Purpose: The treatment of bone defects has always been a difficult problem in orthopedic clinical practice, emerging development of amorphous alloys has been a new hope due to their unique characteristics. In this study, the biological safety and osteogenic property of a new, absorbable magnesium-based amorphous alloy (Mg66Zn30Ca3Sr1) were investigated through animal experiments.Method: 30 SD rats were randomly divided into a blank group, a control group, and an experimental group. Bone defects with the size of 4.5*4.5*5mm were made in the lateral condyle of the left hind leg of all rats. The blank group closed the wound after establishing the bone defect model. The control group was implanted with zinc-magnesium powder and chondroitin sulfate gel in the bone defect, while Mg66Zn30Ca3Sr1 amorphous alloy particles and chondroitin sulfate gels were implanted in the experimental group. Blood samples were collected for detection of serum osteogenic protein levels (BMP-2, OPG, OPN, and RUNX2), serum magnesium ion concentration (Mg2+), zinc ion concentration (Zn2+), blood panel test (white blood cell, hemoglobin, platelet), blood biochemical test (alanine aminotransferase, aspartate transferase, creatinine, urea nitrogen) at 4 weeks, 8 weeks and 12 weeks after the operation. After all the rats were sacrificed 12 weeks postoperatively, X-ray and micro-CT of left knee joints were conducted, as well as the HE and Masson's staining of the knee joint sections.Result: The postoperative conditions of all rats were normal, as well as the blood panel test and blood biochemical test results of all rats at every checkpoint. The ELISA results showed that Mg66Zn30Ca3Sr1 amorphous alloy could promote all of the tested osteogenic protein levels compared to a blank group while the zinc-magnesium powder only promoted the levels of OPG and BMP-2 ($P<0.05$). Compared with the zinc-magnesium powder group, all the tested osteogenic protein levels of the Mg66Zn30Ca3Sr1 amorphous alloy group were significantly increased at every checkpoint ($P<0.05$). Micro CT analysis showed that the volume fraction of new bone and the number of trabeculae both in the Mg66Zn30Ca3Sr1 amorphous alloy group and zinc-magnesium powder group were significantly higher than the blank group at 12 weeks after the operation ($P<0.05$). The volume fraction of new bone and the number of trabeculae in the Mg66Zn-30Ca3Sr1 amorphous alloy group were significantly higher than in the zinc-magnesium powder group ($P<0.05$). HE staining and Masson's staining showed there were more new bone formation and less metal degradation in Mg66Zn30Ca3Sr1 amorphous alloy group than in the zinc-magnesium powder group.Conclusion: Mg66Zn30Ca3Sr1 amorphous alloy is a new kind of degradable material with good biocompatibility and osteogenic ability, which could provide a new sight in the treatment of bone defects.KEYWORDS: Amorphous alloy, Magnesium based, Biocompatibility, Osteogenic ability.

Lipoxin A4 accelerates osseous wound healing in two independent models of bone repair *AMY KOH[1], Ann Decker[2], Conor Locke[2], Kenneth Kozloff[2], Laurie McCauley[3], Hernan Roca[2]. [1]U OF MICHIGAN, United States. [2]University of Michigan, United States. [3]University of Michigan School of Dentistry, United States

Injured bone navigates the healing process via phases including cell apoptosis, inflammation, resolution and remodeling. Lipoxin A4 (LXA4), an eicosanoid lipid mediator derivative of arachidonic acid, is one of the most abundant lipoxin specialized pro-resolving mediators. LXA4 promotes inflammation resolution and has positive osseous effects in conditions that induce bone loss such as periodontitis and ovariectomy, in part due to its inhibitory actions on osteoclasts. In this study, the effects of LXA4 on bone healing were investigated in two models: tooth extraction socket and ulnar stress fracture (sFx). In the socket model, C57Bl/6 male mice (12wk) were anesthetized, and the first maxillary molar extracted. LXA4 (10ng/g; IP) or vehicle (Veh) was administered daily for 14d starting immediately after extraction. µCT analyses revealed a significant increase in bone volume/total volume ($p<0.05$) within the socket with LXA4 treatment. There was a significant decrease in trabecular (Tb) number and a significant increase in Tb thickness and BMD ($p<0.05$). There was no systemic impact of LXA4 as seen via µCT of the tibia, serum TRAcP5b (indicator of OC number), or serum P1NP (indicator of bone formation). Nor were there any differences on TRAP+OC or F4/80+ (macrophage) cell numbers within the socket. In the second wound healing model, C57Bl/6 female mice (16wk) underwent cyclical uniaxial compressive loading to create a sFx in the right ulna. LXA4 (50ng/g; IP) or Veh was administered daily for 5, 7 or 12 days starting immediately after sFx. µCT analyses of sFx sites at d7 showed LXA4 treatment significantly decreased callus bone volume ($p<0.05$), as well as callus ($p<0.01$) and fracture longitudinal length ($p<0.05$), while BMD was unchanged. Serum markers of resorption (TRAcP5b) and formation (P1NP) were also unchanged. At d5, collagen2a1 staining was decreased in the callus ($p<0.05$) in the LXA4 group correlating with the subsequent decrease seen in bone volume at d7. At d12, callus bone volume was no longer different between groups, however mechanical 4-pt bending analyses revealed that LXA4 increased stiffness in the loaded ulna compared to Veh ($p<0.05$). Altogether, these data reveal that the pro-resolving mediator, LXA4 accelerates osseous wound healing in two independent wound regeneration models. Our analysis showed no effect on osteoclasts in these models, highlighting that further studies into the mechanism of LXA4 mediating bone healing are needed.

SAT-243

The role of wnt16 in satellite cell activation *Sumaya Addish[1], W. Joyce Tang[2], Ronald Kwon[2]. [1]University of Washington, United States. [2]University of Washington School of Medicine, United States

The recapitulation of WNT signaling pathways that dually influence bone and muscle during embryonic morphogenesis is a promising approach for developing novel regenerative therapeutics that target both tissues. WNT16 plays a critical role in mediating genetic influence on bone mineral density and fracture risk and is actively being pursued as a target for osteoporosis therapies. Recent work from our lab has demonstrated wnt16 to have dual roles in zebrafish spine and muscle morphogenesis [1]. In embryos, wnt16 was coexpressed with pax7 in the dermomyotome, which contributes myogenic precursors to developing muscle. Prior studies have shown that pax7 promotes muscle differentiation and is a marker of satellite cells that support skeletal muscle regeneration. These findings indicate that wnt16 is necessary for muscle morphogenesis, however, its specific function remains unclear. We hypothesized that wnt16 contributes to skeletal muscle regeneration by regulating pax7 in satellite cells. To test this, we performed a skeletal muscle injury in 3 days post fertilization (dpf) zebrafish. To visualize pax7 and wnt16 expression, we performed HCR RNA FISH at 1 day post injury (dpi) and imaged animals using a confocal microscope. Consistent with previous studies [2], we found that pax7 was upregulated at the injury site and in adjacent tissue. No noticeable changes in wnt16 expression in injured muscle was observed. We previously showed that wnt16 mutants did not exhibit clear differents in pax7 expression during embryonic development [1]. Our studies indicate that wnt16 expression is dispensable for pax7 activation during development and following injury, suggesting that the influence of wnt16 on muscle morphogenesis occurs independently of pax7 regulation. Further investigation into underlying mechanisms is needed to better understand the potential to target WNT16 to treat musculoskeletal disorders and injuries. References:1. Association between musculoskeletal disorders and physical activity in COPD mice *Takayuki Nabeshima[1], Manabu Tsukamoto[1], Yosuke Mano[1], Daisuke Arakawa[1], Takafumi Tajima[1], Yoshiaki Yamanaka[1], Eiichiro Nakamura[1], Ke-Yong Wang[2], Kagaku Azuma[3], Akinori Sakai[1]. [1]Department of Orthopaedic Surgery, School of Medicine, University of Occupational and Environmental Health, Japan. [2]Shared-Use Research Center, School of Medicine, University of Occupational and Environmental Health, Japan. [3]Department of Anatomy, School of Medicine, University of Occupational and Environmental Health, Japan

Introduction: The pathogenesis of musculoskeletal disorders associated with Chronic Obstructive Pulmonary Disease (COPD) is unclear. Since COPD patients have multi factors that contribute to the development of those disorders, basic research using animal models will be needed. We demonstrated that intratracheally administered elastase (PPE) induces emphysema in a mice model (COPD mice), which exhibits trabecular bone loss, fiber type shift from type I to type II muscle fibers and muscle atrophy, however we did not investigate considering physical activity. Our study aimed to investigate whether the musculoskeletal disorders in COPD mice were due to reduced physical activity. Methods: Twelve-week-old male C57BL/6J mice were intratracheally administered saline (Saline group) or PPE (PPE group), and every 4 weeks, food intake, water intake, urine volume, fecal volume and spontaneous activity were measured using a metabolic gauge and the EthoVision XT (Noldus, Wageningen, Netherlands), respectively. At 24 weeks after intratracheal administration, the animals were sacrificed and weighed for leg muscles. Lungs, femurs, and tibiae were harvested, and lungs were measured for mean inter-alveolar distance (Lm) in tissue specimens. The bone microstructure and histomorphometry were analyzed using micro-CT images and tissue specimens. In addition, bone marrow cells were harvested and CAGE-seq was performed. Results: No significant differences in food intake, water intake, urine volume, feces volume, and spontaneous activity were found between the two groups at each time point. At 24 weeks after intratracheal administration, the PPE group had significantly larger Lm values than the Saline group and showed pulmonary emphysema. The value of soleus muscle weight was significantly smaller in the PPE group. In bone histomorphometry of the leg bones, the values of BV/TV, vBMD, Tb.Th, Tb.N, Ob.S/BS and Ob.N/BS were significantly lower in the PPE group. CAGE-seq showed that the expression of musculoskeletal-related genes was decreased in the PPE group. Discussion: In COPD mice, disease-nonspecific factors (age, weight, nutritional status, smoking, and steroids) for muscle and bone were eliminated as much as possible, and physical activity was no exception. Further investigation is needed to take disease-specific pathophysiology into account. Conclusions: COPD mice did not show decreased spontaneous activity, and musculoskeletal disorders occurred regardless of physical activity.

Recovering Bone Tissue Strength Through Fecal Microbiota Transplantation in Adult Mice *CHONGSHAN LIU[2], Erika Cyphert[2], Angie Morales[2], Jacob Nixon[2], Christopher Hernandez[3]. [2]Cornell University, . [2]Cornell University, United States. [3]University of California, San Francisco, United States

Alterations to the gut microbiome can cause reductions in bone strength that are not explained by bone density or geometry. However, it is unclear if microbiome-induced changes in bone tissue mechanical properties can be reversed. Here we ask if repairing the gut microbiota using fecal microbiota transplant (FMT) could improve bone tissue strength. Male and female mice were randomly divided into 5 groups: untreated, initial dosing reconstituted, initial dosing unrecovered, delayed dosing and continuous (134 animals, n=12-17/group/sex). The gut microbiome was altered with antibiotics in drinking water (1g/L ampicillin and 0.5g/L neomycin). Initial dosing groups were treated from 1 to 4 months of age then either received FMT (reconstituted) or no further treatment (unrecovered). The other groups were dosed from 4 to 6 months (delayed) or 1 to 6 months (continuous). At 6 months of age animals were euthanized and the femurs collected. In males, whole bone strength was significantly reduced in the unrecovered ($p = 0.040$), delayed ($p = 0.005$), and continuous ($p = 0.001$) groups as compared to the untreated, indicating impaired bone tissue strength. The whole bone strength in the reconstituted group was comparable to the untreated group (Fig. 1a). Similar trends among groups were seen in females, although differences were not statistically significant ($p = 0.13$, Fig. 1b). The composition of the fecal microbiota mirrored the differences in bone tissue strength, with the continuous, unrecovered, and delayed groups showing a composition similar to one another and distinct from the other groups (which clustered together, Fig. 1c and 1d). Only a small amount of bone tissue is resorbed/formed in the cortex between 4-6 months of age, that changes in the gut microbiome over this period alter bone tissue strength suggests that changes in bone tissue strength do not require matrix turnover, indicating the existence of a yet-to be described mechanism that changes the mechanical properties of existing bone matrix. While future studies are required to characterize this mechanism, our findings provide the first evidence that microbiome-induced alterations to bone tissue strength are recoverable in adults.

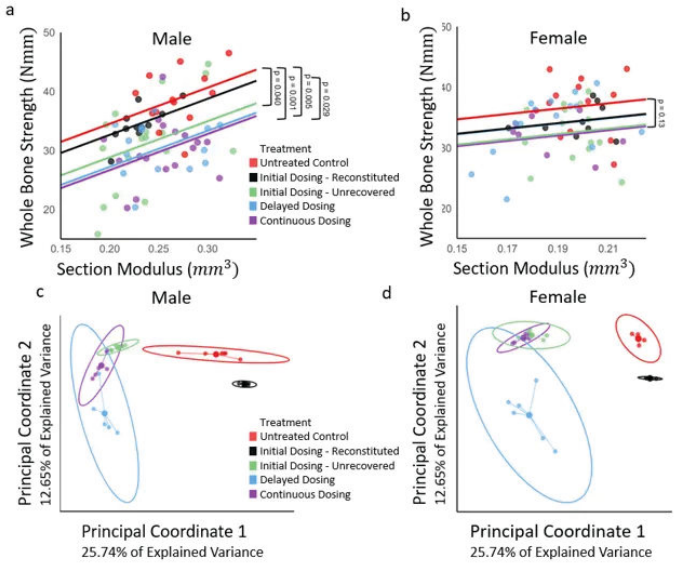

Fig 1. (a, b) Differences in the relationship between section modulus and whole bone strength indicate alterations in bone tissue strength. (c, d) The composition of the fecal microbiota is shown (beta diversity). Clusters closer to one another are more similar to each other.

Yolk-sac Erythromyeloid Progenitors in Fracture Healing and Regeneration *Choiselle Marius[1], Koji Ishikawa[1], Puvi Nadesan[1], Vijitha Puviindran[1], Tomasa Barrientos De Renshaw[1], Tuyet Nguyen[1], Savanna Ma[1], Benjamin Alman[1]. [1]Duke University, United States

Bone fractures are common injuries. However, delayed, and incorrect fracture healing can be a major health issue, particularly in the context of aging. Therefore, strategies to improve the pace of repair and prevent non-union (the body's inability to heal a fracture) will substantially improve patient outcomes as well as lower health care costs. As fracture healing is a dynamic process, many cell types from various lineages are required to restore a broken bone. Macrophages are known to play a critical role in bone healing, and these cells have several embryonic origins enabling unique functions. Yolk-sac derived macrophages are one research candidate, as previous work from our lab identified a reservoir of yolk-sac derived macrophages that reside in the spleen and are capable of not only migrating to a

fracture site, but also differentiating into osteoclasts to contribute to repair. Osteoclasts are essential players in bone repair, serving to resorb unnecessary bone to initiate osteogenesis. Additionally, previous work has shown that when osteoclasts are compromised or macrophages are depleted, fracture healing slows immensely, and the quality of repair suffers. However, while we know that these yolk-sac derived macrophages/osteoclasts can hone to fracture sites, their specific functions are not understood. Yolk-sac derived macrophages also precede the development of hematopoietic stem cells, populate organs, and maintain their populations through self-renewal in peripheral organs, serving as a novel extramedullary source of progenitors. This proposal will further characterize the functions of these yolk-sac derived cells and could potentially also identify targets for future osteogenic therapeutics.

Transcriptional changes in periosteum of an early callus *Sanja Novak[1], Vijender Singh[2], Kurt Hankenson[3], IVO KALAJZIC[4]. [1]UConn Health, , [2]UConn, Institute for Systems Genomics, Computational Biology Core, United States, [3]University of Michigan, United States, [4]University of Connecticut Health Center, United States

Bone has great regenerative capacity that depends on a pool of skeletal stem/progenitor cells (SSPC) and intercellular signaling between mesenchymal and hematopoietic populations. Following fracture there is a dramatic expansion of SSPC within a very short time followed by their commitment to chondrogenic and osteogenic lineages. It is critical to understand the early events regulating fracture healing. Our data showed improved healing ability when Notch1 signaling was overexpressed in ?SMA osteoprogenitors. The aim of this study was to determine molecular changes in SSPC and in hematopoietic lineages and to determine mechanisms involved in improved healing process with Notch1 activation.We have completed single cell RNA-seq from intact and fractured periosteal cells (3 days after the fracture) in ?SMACre+/NICD1 and Cre-/NICD1 mice. Live, mesenchymal (CD45-) and hematopoietic (CD45+) cells were sorted and single cell RNA-seq performed (10x Genomics). Rstudio and Seurat package were used for data analysis. Principal component (PC) analysis was performed, and clusters were identified using 40 PCs at the resolution of 0.25 for CD45- cells and 0.4 for CD45+ cells.We identified endothelial, satellite and muscle cell clusters and trajectories from SSPCs into chondrocytes, osteoblasts. We identified a quiescent cluster termed MSC1 with characteristics of stem cells (inhibition of cell cycle genes and mitosis) that initiates proliferation after fracture and transition into highly proliferating MSCs (cluster 2, 3 and 4).NICD1 (Cre+) injured periosteum had significantly increased expression of Alpl and Ibsp compared to injured Cre-. Unexpectedly, overexpression of NICD1 lead to increases in interferon signaling genes (Ifit1, Ifit3, Iigp1, Ifi203, Ifi27l2a) in mesenchymal and endothelial clusters. We show increased Isg15 and Ifit1 mRNA in isolated periosteal cells upon Jag1 treatment, confirming the scRNA-seq data. In hematopoietic population NICD1 overexpression in the ?SMA expressing cells resulted in decreased pro-inflammatory signals (Tnf and Il6) after bone injury.Induced Notch1 activation in SSPCs led to increased expression of osteogenic genes within CD45- and decreased pro-inflammatory genes within CD45+ populations. We confirmed the importance of Notch signaling in osteoprogenitors leading to distinct transcriptional changes affecting not only osteoprogenitors and their lineage, but also hematopoietic cells during the healing process.

A Refined Murine Growth Plate Injury Model Using Tri-lineage Collagen Reporter Technology *Sierra Root[1], Natasha Patel[2], Sarah Feltz[2], Olivia Ferrigno[2], IVO KALAJZIC[3], Christy Lottinger[4], Liisa Kuhn[2]. [1]UConn Health, School of Dental Medicine, , [2]Department of Biomedical Engineering, UConn Health, United States, [3]University of Connecticut Health Center, United States, [4]Department of Oral Maxillofacial Surgery, UConn Health, United States

The cartilage growth plate (GP) is the most fragile area of growing bones in children making it highly susceptible to injuries. Approximately 30% of GP related injuries will develop an undesirable partial bony closure of the GP from the epiphysis to the metaphysis at the site of injury. Bony bridge formation can hinder normal growth resulting in orthopedic problems such as limb length discrepancy and bone angulation deformity. Small rodent models to study GP injuries are lacking due to the small and difficult to see GP in young mice that developmentally mimic young children. The few models published often involve damage to other areas of the bone including articular cartilage. We aimed to develop a reproducible GP injury model in mice to test future regenerative approaches. Triple transgenic mice fluorescing cyan for Collagen 2a1 expressing chondrocytes, mCherry for Collagen 10a1 expressing hypertrophic chondrocytes and Topaz for Col1a1(3.6 kb) expressing preosteoblasts and osteoblasts were generated. Using tri-lineage fluorescent reporters for collagen types I, II and X, the GP and adjacent bone were visualized under a fluorescent dissecting microscope and enabled the creation of precise injuries with a dental bur. GP injury with a 0.5 mm and 1.4 mm bur were analyzed for limb length discrepancies, bony bridge formation by micro-CT and histology using fluorescent tri-lineage collagen reporters to assess cell types within injured GP. A unicortical defect created with a 1.4 mm bur over the anteromedial aspect of the tibia GP reproducibly caused GP fusion with bony bridge formation starting as early as 1-week post-injury. Light sheet fluorescent microscopy (LSFM) was used to evaluate positive Collagen I Topaz reporter expression in the GP. LSFM allowed us to gain valuable 3D information with respect to cell infiltration that could not be observed in micro-CT or by histology. In conclusion, the use of tri-lineage collagen reporter mice allowed for a consistent GP injury model that mimics limb discrepancies and stunting found in severe GP injuries. Tri-lineage collagen reporter technology also provides a simple histological readout of the location and differentiation status after healing and can be used to test therapeutic strategies to prevent GP fusion.

Mitochondrial function regulates ROS-mediated patterning following injury *Mimi Sammarco[1], Anyonya Guntur[2], Robert Tower[3]. [1]Tulane University, United States, [2]Maine medical center research institute, United States, [3]University of Texas Southwestern Medical Center,

Regeneration of bone and soft tissue after injury has two key requirements: energetic demand and spatial patterning to create a regenerative map. Evidence has emerged that the mitochondria serve a dual function as a hub for reactive oxygen species (ROS) signaling and ATP generation, linking growth signaling and cell metabolism to a single organelle. While ROS signaling is critical, excessive ROS is detrimental. As a result, ROS and the mitochondria that generate them, are tightly regulated through elimination of dysfunctional mitochondria (mitophagy). We unexpectedly found that two mitophagy proteins previously known to function only in mitochondrial or cell homeostasis play key roles in regeneration - BNIP3 (BCL2 interacting protein 3) and NIX (BCL2 interacting protein 3-like) - both separately impeding regeneration. BNIP3 functions to eliminate dysfunctional mitochondria (mitophagy) and modulates cell metabolism to meet the carbon and ATP needs of the cell(1). NIX also regulates mitophagy(2), however, unlike BNIP3, NIX functions to also remodel mitochondrial networks resulting in more efficient mitochondria for cell functions such as differentiation(3, 4). Very little is known about their impact during injury and regeneration. Our preliminary data has led us to hypothesize that BNIP3 and NIX function in a spatially distinct relationship where NIX supports differentiation in the blastema in response to adjacent signaling gradients generated by BNIP3 in the wound epithelium.

The Regulatory Role of Osteoblast-derived Matrix Vesicles *ANNE SKELTON[1], David Cohen[2], Zvi Schwartz[2], BARBARA BOYAN[2]. [1], , [2]Virginia Commonwealth University, United States

Matrix vesicles (MVs) are nano-sized extracellular vesicles that are produced by bone and cartilage cells and become anchored in the extracellular matrix (ECM). They are historically involved in mineralization during endochondral bone formation, but further research has revealed that they are heterogeneous and are enriched with proteins and microRNA, suggesting a role in cell regulation and intercellular communication. The role and mechanism of action of MVs, particularly in bone, remains to be elucidated. In the present study we examined the regulation of osteoblasts by osteoblast-derived MVs and explored the role of caveolae as the endocytic pathway used in their uptake.MVs were isolated from confluent cultures of human MG-63 osteoblast-like cells grown in growth medium (GM) by centrifuging trypsin digests of the ECM at 100,000xg. Additional MVs were isolated in the same manner from MG-63 cells grown in osteogenic differentiation medium (OM) for 10 days. MG-63 cells in GM were treated with either MV(GM) or MV(OM) for 24 and 48 hours followed by assessment of osteoblastic differentiation and production of inflammatory markers. MG-63 cells were also pre-treated with methyl-?-cyclodextrin (?-CD) prior to MV treatment for 48 hours and evaluated for MV uptake to assess the use of caveolae-mediated endocytosis.Treatment with MV(GM) reduced alkaline phosphatase specific activity and interleukin-6 (IL-6) production at 24 and 48 hours and osteocalcin and vascular endothelial growth factor (VEGF) production at 48 hours with no changes in DNA content. MV(OM) caused a similar reduction in alkaline phosphatase at 48 hours and osteocalcin and IL-6 at 24 and 48 hours. In addition, treatment with MV(OM) caused a significant increase in IL-10 production at 48 hours. Pre-treatment with ?-CD prevented the incorporation of MV(GM)s into the cells and prevented the decrease in alkaline phosphatase specific activity, suggesting inhibition of the MV effect when caveolae are disrupted.In conclusion, our results indicate that MVs have a direct regulatory effect on osteoblasts after their incorporation into these target cells through the caveolae system. They suggest that MV composition is sensitive to the culture conditions, resulting in different cellular responses. Osteoblast-derived MVs may contribute to bone formation and remodeling in a more nuanced manner modulating the rate of osteoblast differentiation to ensure formation occurs at the correct location.

DLL4 deletion in endothelial cells affects fracture healing *Hitoshi Tanigawa[1], Sanja Novak[1], Sierra Root[1], Kurt Hankenson[2], Ivo Kalajzic[1]. [1]Uconn Health, Center for Regenerative Medicine and Skeletal Development, United States. [2]Department of Orthopaedic Surgery, University of Michigan Medical School, United States

Fracture healing involves interactions of different cell types and signaling cascades. Both in homeostasis and healing angiogenesis is coupled with osteochondrogenesis. Notch signaling has been known as an important regulator of skeletal cell proliferation and differentiation. Our previous study showed that activation of Notch signaling promotes fracture healing. Aim of this study was to determine the effects of Notch ligand Dll4 (Delta-Like-ligand 4) deletion in endothelial cells on the fracture healing process.We performed single cell RNA-seq from cells isolated from intact and periosteum, day 3 after fracture (DPF) in ?SMACre+/NICD1 and Cre-/NICD1 mice. Live, mesenchymal CD45- cells were sorted and single cell RNA-seq performed (10x Genomics). Our analysis identified endothelial cells (EC), satellite and muscle cell clusters and trajectories from skeletal progenitors into chondrocytes, and osteoblasts.Expression of Notch ligands Dll4 and Jag2 was restricted to EC while Jag1 was expressed in mesenchymal cells. We did not detect significant expression of Dll1 and 3 in periosteum. Notch1 has strong expression in EC, and in committed mesenchymal progenitors and preosteoblasts, satellite and muscle cells while low level of Notch2 is present in all CD45- cells within the callus.Based on gene expression analysis, we decided to use conditional knockout of Dll4 (Dll4?) in EC, using Cdh5/CreERT2. Fracture healing was assessed in 8-10-week-old male mice. Cre activity was induced by intraperitoneal injection of tamoxifen (75mg/kg) on 0, 2 and 4 DPF and healing evaluated by performing real time qPCR, histology and ?CT.Dll4 deletion in EC confirmed by real time qPCR, led to decreased expression of Hey1, Hes1 and OCN compared to Cre- mice. Cre+ mice have smaller callus with less cartilage 1 week post fracture (WPF). At this point, proportion of EdU+ cells within the smaller Cre- callus was higher than in Cre+ mice, displaying phenotype of delayed healing. However, there was no significant difference in bone volume at 3 WPF analyzed by ?CT, as Jag1 ligand could have potential to compensate for Dll4.We showed a negative effect on the early fracture healing process when Dll4 is deleted in EC. This data suggests that early Notch signaling through endothelial Dll4 expression is important for healing initiation (bigger callus with more cartilage) and potentially osteoprogenitor differentiation (increased OCN) in fracture healing process.

Investigating Correlated Changes to Bone Repair Physiology in Mice Selectively Bred for Accelerated Bone Growth *Colton Unger[2], Sarah Manske[2], Campbell Rolian[2]. [2]University of Calgary, . [2]University of Calgary, Canada

Bone fracture repair is a rare form of true tissue regeneration in mammals, and recapitulates many aspects of endochondral ossification seen in developing long bones. During both processes, multipotent progenitors undergo cell migration, differentiate into both chondrogenic and osteogenic lineages, induce vascularization, and subsequently produce, remodel, and mineralize cartilaginous scaffolds into bone. Transgenic studies in mice have shown that many genes involved in endochondral ossification also play important roles in bone repair. However, the full extent to which these processes overlap is poorly understood. To better understand the nature of endochondral ossification in bone repair, we employed the Longshanks mouse. Longshanks mice produce 15-20% longer tibiae than random bred Controls in the same developmental timeframe, a phenomenon driven in part by enhanced endochondral ossification. We hypothesized that if bone repair and development are largely overlapping at the gene regulatory and cellular levels, then there would be correlated changes in the bone repair dynamics of Longshanks adults. In other words, we predict that bone growth and repair are so fundamentally similar, that selection to alter one process will tend to indirectly alter the other. To test this, we induced experimental tibial fractures in sex-balanced and age-matched Longshanks and Control mice and monitored their recovery over six weeks using longitudinal live-µCT imaging during key milestones in fracture repair. In parallel, we analyzed callus tissue composition through histological analysis of a cross-sectional cohort of Longshanks fractures throughout the repair process. We show that mice with enhanced endochondral ossification rates in development also produce larger, more robust fracture calluses during the endochondral ossification phase of fracture callus repair compared to Controls. Moreover, we show that differences in fracture mineralization correlate with differences in the cellular properties of Longshanks calluses, which mimic observed trends in their developing long bone growth plates. These findings demonstrate that bones that grow faster, also heal faster, and highlights a deep conservation of endochondral ossification in both repair and development that may be leveraged to help heal fractures better in clinical settings.

Kidney-tonifying traditional Chinese medicine (TCM) formula Er Zhi Wan (EZW) promotes myogenesis in myoblasts of aging osteosarcopenic animal model *CHRISTINA POON[1], Chun Au-Yeung[2], Yan Zhang[3], Man-Sau Wong[4]. [1]THE HONG KONG POLYTECHNIC UNIVERSITY, Hong Kong. [2]The Hong Kong Polytechnic University, Hong Kong. [3]Longhua Hospital, affiliated to Shanghai University of Traditional Chinese Medicine, China. [4]Hong Kong Polytechnic University, Hong Kong

The co-existence of osteoporosis and sarcopenia (also known as osteosarcopenia) in the older adults contributes to their higher risk for falls and fragility fractures due to reduced support from skeletal muscles. However, pharmaceutical remedies for treatment of osteosarcopenia are currently unavailable. Traditional Chinese medicine (TCM) has long been used for strengthening tendon and bone. Er Zhi Wan (EZW) is a TCM formula which contains two herbs, Fructus Ligustri Lucidi (FLL) and Ecliptae Herba (EH) at a ratio of 1:1 (w/w). Both herbs were recognized for their actions in tonifying "kidney yin" to exert potent bone protective activity. The role of muscle-bone crosstalk contributes to the pathogenesis of osteosarcopenia, however, the regulation of intracellular events of primary myoblasts, muscle satellite cells (MuSCs), and vitamin D metabolism still remains elusive. Thus, the present study aimed to determine if EZW could exert in vivo protective effects against age-related muscle loss by promoting myogenesis in MuSCs isolated from osteosarcopenic animal model. Vitamin D diet group will be included as the positive control to determine if the effects of EZW on myogenesis are comparable to the current available recommended vitamin D supplementation. Aging (10-month-old) male senescence-accelerated mouse prone 8 (SAMP8) and the control mice senescence accelerated mouse resistant 1 (SAMR1) without sarcopenia were randomly arranged and treated with EZW (14 g/kg/day), vitamin D supplementation diet (5.7 IU/g) or vehicle (saline) for 8 weeks. The primary MuSCs from hindlimbs of those mice were isolated by enzymatic dissociation and cultured into primary myoblasts. We have demonstrated that EZW could exert stimulatory effects on myogenesis in MuSCs by promoting myogenic differentiation, in which they significantly increased both number and area of myotubes ($p<0.05$). EZW was found to significantly upregulate the expressions of the myogenic markers (MHC, MyoD, Myogenin and Pax7) in differentiated myoblasts ($p<0.05$), which are essential for muscle regeneration and repairing. This study provides the evidence for supporting the use of EZW for management of age-related osteosarcopenia. Further study will determine the mechanisms that involved in mediating the multi-targets actions of EZW on muscle-bone crosstalk.Acknowledgements:This work was supported by the Health and Medical Research Fund of Hong Kong Health Bureau (19200411) and PolyU Dean's Reserve internal fund (1-ZVXG). We also thank the University Research Facility in Life Sciences at The Hong Kong Polytechnic University for the technical support.

The Sodium Alginate Effect: Improving Tissue Printing from a Cellular Point of View *Ahmed Yacoub[1], Kamal Awad[2], MARCO BROTTO[3], Venu Varanasi[2]. [1]Bone Muscle Research Center, United States. [2]The University of Texas at Arlington , United States. [3]University of Texas-Arlington (UTA), United States

Introduction: Volumetric muscle loss requires external support to facilitate the healing. Biomaterials can mimic the mechanical behavior of muscles and be used as muscle grafts. They can provide improved functionality, compatibility, and regeneration, making them promising solutions for muscle regeneration. Gelatin methacrylate (GelMA) is a hydrogel material used in tissue engineering, but it has some limitations such printability, shape fidelity, and degradation. One promising strategy is to incorporate sodium alginate into GelMA hydrogels to overcome its limitations. This study investigates the advantages of this approach, including improved stability and mechanical properties, which could ultimately make GelMA hydrogels more suitable for a lot of tissue engineering applications.Methods: The methodology employed for this investigation includes rheology, 3D printing, and cell cultures. The rheological testing utilized a frequency sweep test, which provided information on the storage and loss modulus of the materials and their behavior under shear stress1. GelMA-alginate blends were extruded using a BioX 3D printer and crosslinked using UV light2. Cell viability was assessed using a LIVE/DEAD assay3. All experiments were tested with n=3 and in triplicates.Results: Firstly, we evaluated the rheological characteristics of muscle to determine the optimal properties of hydrogels that closely resemble the extracellular matrix of skeletal muscle. All formulations showed shear thinning behavior. GELMA + 1%, 2%, and 4% Alg exhibited an increase in the storage modulus. Storage modulus of the tested hydrogel attained a value of 950 +/- 56.5 Pa, which is consistent with the storage modulus of skeletal muscle. All GelMA alginate bio-inks exhibit superior printability when compared to GelMA alone. Live/dead assay demonstrated superior cell viability for GelMA+1%-alginate, compared to other tested formulations.Conclusion: The study showed that incorporating sodium alginate into GelMA hydrogels improves mechanical properties and stability for tissue engineering, specifically for muscle and neuronal cells. These findings are a significant advancement in the field of regenerative medicine, as they offer new possibilities for creating more effective and durable tissue constructs for transplantation and drug delivery.1- Zhang, J., et. Al., 2018. ACS Biomater. Sci. Eng. 4, 3036-3046.2- Gao, T., et. Al., 2018. Biofabrication.3- Siller, I.G., et. Al., 2019. Materials.

Molecular Phenotyping of Bone Forming Cells *Atenisa Caci[1], Nicholas Ditzel[2], Moustapha Kassem[1], Alexander Rauch[1]. [1]Molecular Endocrinology & Stem Cell Research Unit (KMEB), Department of Endocrinology and Metabolism, Odense University Hospital, Odense, Denmark and Department of Clinical Research, University of Southern Denmark, Odense, Denmark., Denmark. [2]Faculty of Health Science, Biomedical laboratory, University of Southern Denmark, Odense, Denmark, Denmark

Background: Bone Marrow stromal cells (BMSCs), are capable of multilineage differentiation. However, hBMSCs are heterogenous, not only in vivo due to the local niche, but also under standard culture conditions as clonal cell lines differ greatly in their potential to form bone.Purpose: Characterize the transcriptional heterogeneity of clonal MSC lines with distinct bone forming potential in vivo to define gene signatures that favor bone forming potential and to test the secretory capacity to transfer bone-forming potential from high to low-bone forming clones.Methods: Determine the cellular heterogeneity of clonal cell lines (high/low bone forming) using scRNA-seq analysis and quantify both in vitro and in vivo osteogenic potential of high, low, or mixtures of high and low bone-forming clones.Results: Cells with low bone-forming potential show higher osteogenic differentiation in vitro, which sought us to hypothesize that these cells either lack a positive signal required for or have a negative signal that prevents bone formation in vivo (A). At the single cell level, clones with similar bone forming potential show an alike cellular heterogeneity that is distinct between high and low bone forming clones and distinct to the parental hBM-MSC-TERT4 cells (B, bar plots). Bone-forming potential is characterized by the presence of cells with high regulation of cytoplasmic ribosomal proteins and PI3K-AKT mTOR signaling and the absence of HIPPO and VEGFA-VWGFR2 signaling. Bone formation assays in immunodeficient mice show that the presence of HBF cells in mixed cultures has a positive effect on bone formation in vivo beyond the linear relationship of cell numbers between high and low bone-forming clones (C).Conclusion: PI3K-AKT mTOR pathway activity seems to be beneficial for high bone-forming potential which can transferred on non-bone forming clones via secretory or cell-to-cell adherence mechanisms.

Identification and characterization of novel skeletal stem cell populations in mice and humans *Daniel Coutu[1], Stephanie Farhat[2], Bahaeddine Tilouche[3], Spencer Short[3]. [1]Ottawa Hospital Research Institute, Canada. [2]Univeristy of Ottawa, Canada. [3]University of Ottawa, Canada

Skeletal tissues possess an amazing capacity to regenerate. However, this regenerative capacity decreases with age and comorbidities. In older individuals, skeletal tissues heal slowly and imperfectly despite advances in orthopedic surgery and rehabilitation. Current experimental approaches involve tissue engineering and stem cell-based regenerative therapies. Indeed, stem cells are responsible for growth, maintenance, and repair of skeletal tissues. However, they remain poorly characterized at the cellular and molecular levels which is a clear limitation for their clinical use. Our aim was to identify and characterize novel skeletal stem cell populations in murine and human tissues. To achieve this, we used genetic lineage tracing, spectral 3D confocal imaging, computational image analysis, single cell transcriptomics and in vitro assays on mouse and human tissues. We show that the adult mouse skeleton contains self-renewing, multipotent skeletal stem cells (SSCs) with osteogenic, chondrogenic and adipogenic potential. These bona fide SSCs express Sox9 and are located in the resting zone of the growth plates and in periosteum. We further show that they persist after epiphyseal fusion in mature and old animals. Transcriptome analysis revealed that these cells express other putative SSCs markers, as well as genes involved in skeletal development, stem cell self-renewal, and fate decision. This data provides testable

drug targets to pharmacologically manipulate SSCs fate decisions in situ. We showed that human tissues contain SSCs akin to murine tissues. This is the first experimental proof of self-renewal in postnatal SSCs in vivo. These findings provide actionable insights for the use of culture-expanded stem cell product for regenerative medicine product or pharmacological targeting of these stem cells in situ.

The Decreased Expression of Sestrin 2 Contributes to a Decline in Osteogenesis and an Increase in Adipogenesis of Bone Marrow Mesenchymal Stromal Cells in Aged Individuals *Jeong-Hwa Baek[1], Hyun-Jung Park[2], Do Yeun Kim[2]. [1]Seoul National University, School of Dentistry, Republic of Korea. [2]Seoul National University School of Dentistry, Republic of Korea

Sestrin 2 belongs to the sestrin family of stress-induced proteins, which exert antioxidant activity by regulating AMPK and mTOR signaling. Although previous reports have shown that sestrin 2 is associated with the aging process, its role in the differentiation of osteoblasts and adipocytes remains unclear. Therefore, in this study, we investigated whether aging regulates the expression levels of sestrin 2 in bone marrow-derived mesenchymal stromal cells (BMSCs) and whether sestrin 2 has a regulatory effect on the differentiation of osteoblasts and adipocytes from BMSCs. Human BMSCs obtained from old donors (between 70 and 82 years old) showed cellular senescence characteristics such as higher levels of ?-galactosidase staining and expression of p16, p21, and ?H2AX proteins compared to the BMSCs from young donors (18 and 22 years old). RNA-seq analysis showed that the expression of SESN2 in old BMSCs was significantly lower than that in young BMSCs. Quantitative RT-PCR and western blot analysis confirmed the decreased expression level of sestrin 2 in old BMSCs. To examine the effect of decreased sestrin 2 expression on osteogenic and adipogenic differentiation, we induced sestrin 2 knockdown in mouse BMSCs using siRNAs. Knockdown of sestrin 2 suppressed the mRNA expression of osteogenic marker genes (Alpl, Ibsp, and Bglap), alkaline phosphatase activity, and matrix mineralization. Furthermore, sestrin 2 knockdown enhanced the mRNA expression of adipogenic marker genes (Cebpa, Pparg, Adipoq, and Plin1) and oil red O staining. These results suggest that the aging-associated down-regulation of sestrin 2 expression contributes to the enhanced adipogenic potential but reduced osteogenic potential of BMSCs.

Transcriptional Plasticity of Human Bone Marrow Stromal Cells for the Osteogenic and Adipogenic Lineage in vitro *Ali Jamil[1], Moustapha Kassem[2], Alexander Rauch[1]. [1]University of Southern Denmark, Denmark. [2]Odense University Hospital, Denmark

Both aging related and idiopathic osteoporosis show a strong inverse association between bone mass and bone marrow adiposity. Human bone marrow-derived (mesenchymal) stromal cells (hBM-MSCs) are progenitors capable of differentiating into bone forming osteoblasts and fat storing adipocytes. A preferential lineage speciation of hBM-MSCs into adipocytes on the cost of osteoblasts has been suggested as an underlying cause of osteoporotic bone fragility. However, whether activating the transcriptional networks of the osteogenic or adipogenic lineage modulates the multi-lineage potential of the cell, i.e. the capacity to change cell fates, has not been studied in detail. The aim of this study was to quantify the cellular and transcriptional plasticity of hBM-MSCs.Immortalized and primary hBM-MSCs were either subjected to osteogenic or adipogenic differentiation or exposed to single or multiple rounds of switching between osteogenic and adipogenic differentiation cocktails. Gene expression was quantified at the bulk and single cell level and by real time PCR for selected markers. Cellular differentiation was quantified by histochemical staining at the population and fluorescent staining at the single cell level.Immortalized hBM-MSCs show strong plasticity at the bulk and single cell expression level upon cross-differentiation, and fully differentiated cells either direct- or cross-differentiated towards the same lineage are almost indistinguishable (fig. 1A-B). Trajectory analysis in scRNA-seq data suggest that cells committing to one lineage remain capable to activate gene signatures of the other lineage confirmed by the generation of adipocytes with osteogenic characteristics upon osteogenic stimulation. Surprisingly, activation of a lineage selective gene program in hBM-MSCs does not reduce but rather enhance their differentiation capacity to the opposing lineage. In line, cross-differentiating primary hBM-MSCs that are refractory to osteogenic stimulation allowed the cells to mineralize (fig. 1C). Finally, multiple consecutive turns (8 x 4 days) of osteogenic and adipogenic stimulation leads to hybrid cells capable of mineralization and lipid droplet formation with high ALP activity.This study highlights a strong molecular plasticity between the transcriptional networks of osteoblast and adipocyte differentiation and that initiation of lineage speciation is associated with an increase rather than decrease in the multilineage potential of hBM-MSCs.

Lgr6 regulates multiple pathways during osteoblastogenesis *Justin King[1], Archana Sanjay[2], Kurt Hankenson[3], IVO KALAJZIC[4], Matthew Wan[4]. [1]University of Connecticut School of Medicine, . [2]UCHC, United States. [3]University of Michigan, United States. [4]University of Connecticut Health Center, United States

The periosteum is crucial for proper bone healing and harbors skeletal stem and progenitor cells (SSPCs). We recently reported that leucine-rich repeat-containing G protein-coupled receptor 6 (Lgr6) is upregulated in the periosteum following fracture and is essential for promoting a robust periosteal response for proper fracture healing. To further understand Lgr6's involvement in fracture healing, we examined published single-cell RNA sequencing (scRNA-seq) data of periosteal cells from intact and three-day-old fractured tibiae. We found robust Lgr6 expression in SSPC clusters, exclusively in the injured samples. Lgr5 expression was not detected, and Lgr4 had minimal expression in uninjured and injured samples. Interestingly, Rspo2 and Rspo3, well-known ligands of Lgr6, displayed minimal expression in all clusters. Among growth factors essential for fracture healing, Bmp2 expression paralleled the Lgr6 expression pattern. We also investigated published scRNA-seq datasets of Cxcl12+ and LepR+ stromal cells isolated from intact and injured whole bones, uncovering minimal or no expression of Lgr6 and Bmp2 in all datasets. We conducted bulk RNA-sequencing on Lgr6-null and wild-type (WT) BMSC osteogenic cultures. KEGG analysis showed significant downregulation of the TGF-? signaling pathway gene set ($p<0.001$), which encompasses BMP signaling. In agreement, RT-qPCR indicated reduced expression of Bmp2 and BMP target genes. In subsequent mechanistic studies, Lgr6-null cells exhibited a diminished response to Bmp2 treatment, characterized by weakened SMAD1,3,5 phosphorylation and decreased expression of Id1 and Noggin in Lgr6-null cultures. However, the canonical Wnt (cWNT) signaling response was unimpaired in Lgr-null cultures. The addition of recombinant Bmp2, Wnt3a, or Rspo2, individually or combined, failed to restore impaired osteogenesis in Lgr6-null cultures. The spatiotemporal interplay between the Wnt and BMP pathways in regulating osteogenesis is important; studies suggest that Bmp2 operates downstream of cWnt, facilitating cells in passing the Sp7+/Col1a1+ "checkpoint." In light of our findings, Lgr6, a known Wnt pathway modulator, also regulates Bmp2 signaling during osteogenesis, demonstrating Lgr6's necessity for proper fracture healing and offering mechanistic insights into the signaling pathways controlling osteogenesis. Our findings contribute foundational knowledge to developing anabolic therapies for orthopedic applications.

iPSC-derived Osteoblasts for Musculoskeletal Regenerative Medicine

*Feini Qu[1], Omolabake Oyebamiji[1], Farshid Guilak[1]. [1]Washington University in St. Louis, United States

Humans have limited regenerative potential of musculoskeletal tissues following limb loss. To this end, successful attempts to regrow missing limbs could significantly improve the prognosis for amputees. The murine digit has been used to study mammalian limb regeneration, where stem/progenitor cells regrow the digit tip after distal amputation, but the mechanisms controlling skeletal elongation and patterning remain unclear. We hypothesize that the expression of a limb-like developmental program in osteoprogenitors is required for proper bone morphogenesis after digit amputation. To address this question in vitro, we sought to develop a procedure to derive osteoblasts from murine induced pluripotent stem cells (iPSCs). To this end, we differentiated murine iPSCs toward a mesenchymal state using a high-density micromass to produce pre-differentiated iPSCs (PDiPSCs; Fig. 1A). PDiPSCs (passage 3) in monolayer were exposed to the following media conditions: growth (Control; DMEM-HG base with basic fibroblast growth factor), osteogenic (Osteo; ?-MEM base with l-ascorbic acid, dexamethasone, ?-glycerophosphate), or osteogenic with supplements (Osteo+; Osteo with insulin, transferrin, and sodium selenite, nonessential amino acids, 2-mercaptoethanol). As a positive control, MC3T3 murine pre-osteoblasts (passage 7) were cultured in growth (Control; ?-MEM base) and Osteo media. At 0, 14, 21, and 28 days after osteogenic culture, cells were fixed and stained with Alizarin Red and Oil Red O to assess calcium deposition and lipid accumulation, respectively. We found that both PDiPSCs and MC3T3s produced mineralized cultures when exposed to standard osteogenic media (Osteo), which increased over time as measured by Alizarin Red staining (Fig. 1). While additional supplements to the Osteo media (Osteo+) significantly enhanced PDiPSC osteogenesis, Alizarin Red staining remained lower than MC3T3s in Osteo media at 21 and 28 days (Fig. 1C). Osteo+ media also increased adipogenesis, as evident by Oil Red O staining (Fig. 1B). In contrast, there was no mineral detected in PDiPSCs and MC3T3s cultured in their respective Control media over time. However, PDiPSCs exposed to Control media readily accumulated lipid, a feature that was absent in MC3T3s. These data indicate that PDiPSCs may be driven toward osteogenesis and/or adipogenesis depending on the soluble cues present, representing a novel in vitro platform to probe the mechanisms of osteogenic differentiation.

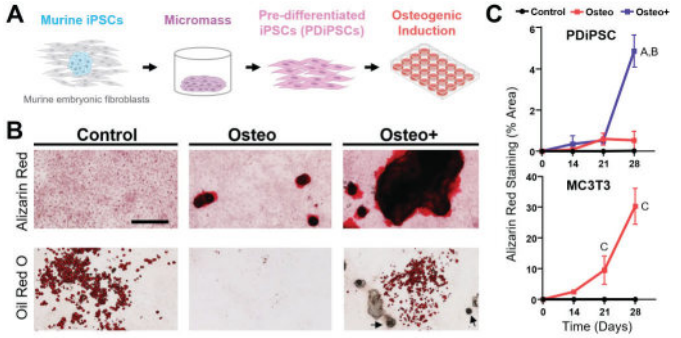

Fig. 1. (**A**) Schematic of iPSC differentiation. (**B**) PDiPSCs stained with Alizarin Red and Oil Red O after 28 days of culture. Arrows show mineralized nodules. Scale: 0.5 mm. (**C**) Alizarin Red staining (% area) over time (n=3-4/group, mean ± SD). A=p<0.05 vs. Control. B=p<0.05 vs. Osteo. C=p<0.05 vs. all other groups.

Differential Regulation of Calvarial vs Long Bone Skeletal Stem Cells in Bone Homeostasis and Osteogenesis Imperfecta

*JEA GIEZL SOLIDUM[3], YOUNGJAE JEONG[4], Francisco Heralde III[3], Dongsu Park[4]. [3]Department of Biochemistry and Molecular Biology, College of Medicine, University of the Philippines Manila, United States; [4]Baylor College of Medicine, ; [3]Department of Biochemistry and Molecular Biology, College of Medicine, University of the Philippines Manila, Philippines; [4]Baylor College of Medicine, United States

Reconstruction of craniomaxillofacial (CMF) defects is important but clinically challenging in patients with Osteogenesis Imperfecta (OI) or CMF deformities. Recently, calvarial suture skeletal stem cells (SuSSCs), including PRX1+ SuSSCs, were identified as a main stem cell popultaion for adult CMF bone regeneration. While much is known about skeletal stem cells in long bones, how the molecular and regulatory mechanisms of SuSSCs are different from long bone SSCs during skeletal development and injury healing have not yet been well elucidated. Further, their differences in normal and OI conditions are essentially unknown. Given that PRX1 is a common marker for calvarial and long bone SSCs, we compared PRX1+ SuSSCs with PRX1+ long bone SSCs to identify the differential function and molecular signatures during postnatal skeletal development and OI bone regeneration. By using inducible Prx1-CreER-EGFP+/-; Rosa26-tdTomato (WT) and G610c (a moderate OI) mouse models, we performed in-vivo imaging, immunofluorescence (IF) analysis, and single-cell (sc)RNA sequencing analysis. We found that PRX1+ SuSSCs and long bone SSCs differentially contribute to bone healing in both WT and OI mice. Further, in-vivo imaging of calvaria injury showed delayed migration of SuSSCs and delayed healing in OI mice. IF staining also showed less proportion of osteoblast progenies in the tibia injury site in OI mice. Single cell analysis revealed that calvarial and long bones have unique progenitor clusters with PRX1 and skeletal stem/progenitor cell (SSPC) marker expression. Consistent with development, long bone specific clusters express chondrogenic markers. Interestingly, calvaria specific clusters have higher expression of TGF?, FGFR, Twist1, and WNT-inhibitory pathways compared to long bones, suggesting potential targets for calvarial bone regeneration and repair. Overall, PRX1+ SSPCs contribute to injury repair in both WT and OI mice, with delay in OI bone healing. Further study of the molecular profiles and underlying mechanisms of PRX1+ SSPCs in WT and OI mice is warranted to provide valuable insghts to develop effective therapeutic options for CMF and long bone regeneration in healthy and OI conditions.

Enrichment of osteogenic lineage cells from pluripotent stem cells and integration with dynamic stress-relaxing hydrogels for bone tissue regeneration

*Hongqiang Yu[1], Eileen Gentleman[1], Karen J Liu[1], Agamemnon E Grigoriadis[1]. [1]King's College London, United Kingdom

The ability to regenerate bone efficiently for tissue engineering purposes is dependent on robust bone grafting systems that are composed of productive cells and instructive biomaterials. Through formation and enrichment of mesodermal populations by precise temporal control of exposure to specific growth factors, we have identified a novel osteochondral progenitor population from mouse embryonic stem cells (mESCs) which gives rise to both chondrocytes and osteoblasts. Interestingly, exposure to BMP4 in a defined window during mesoderm enrichment completely abolished chondrogenic lineage commitment and enriched the population towards committed osteoprogenitors. Flow cytometry, western blot and qPCR analysis confirmed that BMP4 treatment converted Sox9/Runx2 double-positive cells to a population of Runx2 single-positive cells that expressed lateral plate mesodermal markers that are destined to contribute to the appendicular skeleton.To investigate the translatable potential of this BMP-induced osteogenic population, we encapsulated cells into stress-relaxing alginate hydrogels. Viscoelasticity is the natural property of many tissues and stress-relaxing hydrogels have been shown to enhance MSC osteogenic differentiation. We compared single cell and spheroid encapsulation of BMP-induced ESC-derived osteogenic cells in both RGD and non-RGD peptide functionalized hydrogels. Spheroids encapsulated in stress-relaxing hydrogels showed significantly enhanced ostoegenic differentiation compared to spheroids generated in liquid culture, demonstrating that self-assembled spheroids provide the best structure to maximize the osteogenic potential when encapsulated in dynamic hydrogels. We investigated the potential mechanosensing mechanisms underlying this enhanced differentiation and observed increased F-actin bundle and decreased N-cadherin expression in encapsulated spheroids, concomitantly with elevate levels of YAP expression. As YAP is a major mechanotransducer and is thought to directly regulate Runx2 expression, we further demonstrated increased Runx2 nuclear localization in encapsulated spheroids. Taken together, we've successfully established efficient differentiation of a pluripotent stem cell-derived osteogenic population in a dynamic hydrogel, which provides a robust system that serves as a powerful tool for not only bone regeneration but for understanding the essential parameters in directing stem cell fate and exploring cell-biomaterial interactions.

SAT-278

The Effect of Protein Supplementation on Markers of Bone Metabolism following Repeated Whole-Body Resistance Exercise in Men and Women: A Randomised Controlled Trial *Julie Greeves[1], Joanne Mallinson[2], Sophie Wardle[1], Philip Atherton[2], Paul Greenhaff[2], Dan Wilkinson[2], Jonathan Tang[3], William Fraser[3], Thomas O'Leary[1]. [1]UK Ministry of Defence, United Kingdom, [2]University of Nottingham, United Kingdom, [3]University of East Anglia, United Kingdom

This study examined acute, dose-dependent effects of protein supplementation on markers of bone metabolism in young healthy adults following two repeated same-day bouts of whole-body resistance exercise in a randomised controlled trial. Resistance-trained men (n = 24) and women (n = 24) aged 18 to 35 y performed two within-day whole-body resistance sessions in the morning (Ex 1) and afternoon (Ex 2), separated by 4 h. Exercises comprised 3 × 8 repetitions at 75% 1 rep max (2 min rest between sets) involving latissimus dorsi pull down, single-leg press, and chest press. Participants (8 men and 8 women per group) were randomly assigned to drink either 15 g, 30 g or 60 g whey protein immediately after each exercise session. Resting venous blood samples were drawn after an overnight fast at 0 h (before Ex 1), 4 h (before Ex 2), 8 h and 24 h. Samples were analysed for ?CTX, P1NP, BALP, OC, RANKL, OPG, Sclerostin (SOST), PTH, adjusted-calcium. The dose-dependent effects of protein supplementation were analysed using Linear Mixed Effects Models. p values were adjusted using the Holm-Bonferroni method and significance was accepted at $p < 0.05$. ?CTX decreased between 0 h and 4 h, and 0 h and 8 h ($p < 0.001$); P1NP decreased between 0 h and 24 h ($p = 0.008$); OC decreased between 0 h and 4 h, and 0 h and 8 h ($p < 0.001$); and sRANKL decreased between 0 h and 4 h, 0 h and 8 h, and 0 h and 24 h ($p < 0.001$). OPG decreased between 0 h and 8 h ($p = 0.008$). PTH decreased between 0 h and 8 h ($p=0.003$) (mean (+/-SD) in Table 1). No significant changes were observed for BALP or SOST. Protein supplementation ingested immediately after two repeated same-day resistance exercise sessions did not increase markers of bone formation at any dose. A decrease in markers of bone resorption, molecular signalling makers of bone metabolism, and PTH are likely due to responses in circadian variation.

Table 1. Bone metabolic markers over time for each protein dose. Data are mean ± SD.

SAT-280

Effects of glucose-dependent insulinotropic polypeptide on bone metabolism: a systematic review and meta-analysis of randomized controlled trials *Wang Shin Lei[1], XianYan Chen[1], Andrea Kelly[2], Carlos Isales[3], Joseph Kindler[4]. [1]University of Georgia, United States, [2]The Children's Hospital of Philadelphia, United States, [3]Medical College of Georgia at Augusta University, United States, [4]The University of Georgia, United States

Glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1) are gut-derived hormones that not only augment post-prandial insulin production for glucose control, but also regulate bone metabolism. Bone-resorbing osteoclasts possess receptors for incretins, and clinical trials have tested the effects of acute incretin administration on bone metabolism. These studies support an anti-resorptive effect of incretins, but results from these trials have not been systematically evaluated and summarized. We performed a systematic review and meta-analysis summarizing randomized controlled crossover trials testing the effect of GIP/GLP-1 administration on bone resorption in adults. A systematic search of PubMed was performed for studies published between January 2000-2023 that reported baseline carboxy-terminal collagen crosslinks (CTX) and percent change in CTX relative to baseline following placebo and incretin administration. Among the 168 records that were originally identified, 24 underwent full-text review, and 9 met criteria for inclusion in this analysis. Two studies performed GLP-1 administration (n=27) and seven trials performed GIP administration (n=77, 100% male), so a meta-analysis was only performed for GIP. Among the GIP studies, most included healthy subjects, with the exception of two that included 22 people with diabetes. Five studies performed intravenous infusion (n=59) and two performed subcutaneous injection (n=18). For each study, baseline CTX and percent change in CTX following GIP and placebo administration were extracted, and a mean difference (MD) between the two treatments was computed. A random-effects meta-analysis of MDs was performed using the 'R package meta' in R. GIP administration was associated with a greater decrease in CTX compared to placebo ($P<0.01$, Fig. 1), but there was relatively high heterogeneity ($I2=87.2\%$, $P<0.01$). Comparing the MD between studies of people with diabetes (MD: 0.12, 95% CI: 0.08-0.16) vs. without diabetes (MD: 0.19, 95% CI: 0.15-0.23), the decrease in CTX following GIP administration was greater in those without diabetes ($P=0.03$). Route of GIP administration (infusion vs. injection) was not associated with the effect estimate. Egger's test revealed an absence of publication bias ($P=0.014$). In summary, GIP has a bone anti-resorptive effect, which may be modified in people with diabetes. Involvement of GIP in diabetes-related bone pathology requires further attention.

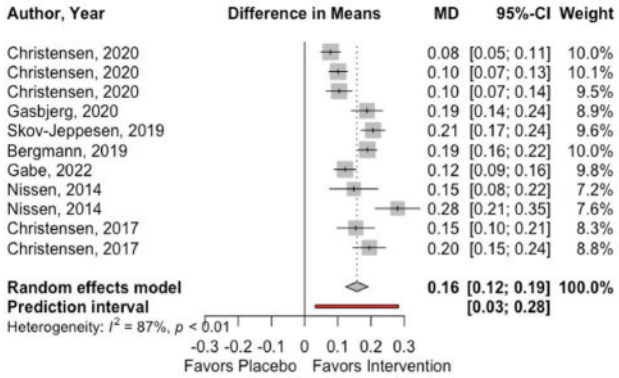

Fig. 1. Forest plot of total MD. Data represents overall study-level MD. Grey squares and horizontal lines represent the MD of each study and their 95% confidence interval. The sizes of the grey squares are proportionate to the study-level weights. Dashed line represents the overall pooled estimate. MD, mean difference, 95%-CI, 95% confidence interval.

SAT-281

Prevention of bone loss in mice by suppression of adipocyte-like cell differentiation by phenolic acids *Perry Caviness[1], Oxana Lazarenko[2], Michael Blackburn[2], Christopher Randolph[3], Jovanny Zabaleta[4], Jin-Ran Chen[5]. [1], [2]Arkansas Children's Nutrition Center, United States, [3]Arkansas Children's Research Institute, United States, [4]Louisiana State University Health Sciences Center, United States, [5]Arkansas Children s Nutrition Center / UAMS, United States

Phenolic acids, such as hippuric acid (HA) and 3-(3-hydroxyphenyl) propionic acid (3-3-PPA), are present in the human body throughout life from microbiome digestion of polyphenols and may be involved in facilitating bone development and protection from degeneration. Currently the mechanisms by which these chemicals prevent bone deterioration are unknown. In this report, we show that HA and 3-3-PPA suppression of bone resorption is slightly less effective than zoledronic acid (ZA) in an ovariectomy (OVX) induced osteoporotic mouse model but is still able to recover µCT parameters back to sham levels (BV/TV% for tibia trabecular bone; Sham: 3.11 +/- 0.60, OVX-PBS: 2.33 +/- 0.44, OVX-HA: 3.17 +/- 0.51, OVX-3-3-PPA: 3.17 +/- 0.24, OVX-ZA: 4.06 +/- 0.60). ZA treatment, unlike HA or 3-3-PPA treatment, was shown to fuse the tibial growth plate in mice. We hypothesize that HA and 3-3-PPA inhibit bone resorption through suppression of adipose tissue formation in bone marrow. HA and 3-3-PPA treatments were shown to significantly decrease bone marrow adipocyte-like cell formation in OVX bone tissue (Average # of adipocyte-like cells at 20X magnification; Sham: 49.63 +/- 14.93, OVX-PBS: 82.75 +/- 19.30, OVX-HA: 44 +/- 9.17, OVX-3-3-PPA: 43.38 +/- 15.01, OVX-ZA: 21.86 +/- 9.66). Decreased number of adipocyte-like cells is likely through decreased expression of lipoprotein lipase (Lpl) as determined by RNA-seq analysis. Gene expression of the key adipogenesis regulator, peroxisome proliferator activated receptor gamma (PPAR?), was shown to be upregulated in OVX mice and downregulated after HA or 3-3-PPA treatments. In addition, ChIP experiments show that the association between PPAR? and Lpl promoter region in pre-adipocyte-like cells (ST2 and mouse Calvaria) was significantly suppressed following HA, 3-3-PPA or ZA treatment (ST2 fold enrichment; DMEM: 0.53 +/- 0.13, Adipogenic media (AM): 1.62 +/- 0.15, AM + HA: 0.84 +/- 0.11, AM + 3-3-PPA: 0.53 +/- 0.22, AM + ZA: 0.61 +/- 0.37) (Mouse calvaria fold enrichment; DMEM: 0.46 +/- 0.07, AM: 1.04 +/- 0.29, AM + HA: 0.43 +/- 0.12, AM + 3-3-PPA: 0.45 +/- 0.27, AM + ZA: 0.49 +/- 0.12) Contrasting HA and 3-3-PPA, ZA significantly increased the number of TRAPase positive cells and suppressed bone cell proliferation, likely through increased apoptotic pathways. These findings suggest HA

or 3-3-PPA may be alternative options for protecting against bone deterioration without the potential negative side effects induced by ZA.

Optimizing Nutrition Education at an Osteoporosis Centre: The Bites for Bones Randomized Controlled Pilot Trial *Julia MacLaren[1,] Heidi Piovoso[2,] Adrienne Feasel[3,] Charlie Hasselaar[6,] Sarah Rose[6,] April Matsuno[3,] Tanis R. Fenton[6,] Catherine B. Chan[5,] Gregory Kline[6,] Emma Billington[6, 1], Canada. [2]Albert Health Services, Canada. [3]Alberta Health Services, Canada. [6]University of Calgary, Canada. [5]University of Alberta, Canada. [6]University of Calgary,

Nutrition recommendations for bone health frequently target single nutrients in isolation and often do not address strategies to obtain these nutrients as part of a balanced diet. The emerging field of Culinary Medicine (CM) offers a pragmatic approach to improve dietary quality and health outcomes, but CM interventions are untested for bone health. The purpose of this pilot trial was to assess the feasibility of implementing and evaluating a dietitian-led virtual CM intervention for bone health as an adjunct to usual care at our specialty osteoporosis centre. This study received ethics approval. A total of 40 adults age >=45 years, referred to our centre for assessment of fracture risk, were randomized to receive either usual care (didactic nutrition education from a dietitian) or usual care plus a CM program. The CM program consisted of a 1.5-hour virtual (Zoom) group session, co-facilitated by two dietitians. Participants were provided a recipe package and had the option of cooking along or viewing the session as a demonstration. Six weeks after the CM session the CM group were offered an optional virtual follow-up with a dietitian where they could ask further questions regarding home cooking and nutrition. The usual care group was invited to attend the CM program after study completion (i.e. wait-list control). At baseline and 3 months, participants completed surveys asking about home cooking patterns and confidence in eating well for bone health and were asked to complete 2 dietary recalls. The CM group also completed a program acceptability survey immediately following the CM session. Primary feasibility outcomes were: recruitment (target : 100% of participants recruited in 6 months), adherence (target: >85% of participants received allocated intervention), and retention (target: >85% of participants provided follow-up data). Feasibility data are shown in the Table . We achieved our target recruitment of 40 participants (95% female, median age 68 years) in 2 months. Targets were also met for adherence and retention (shown in bold); sub parameters reflect difficulties participants experienced in completing the dietary recalls, with only 5 participants (12.5%) completing all 4 recalls. Our findings indicate that evaluation of a CM program as an adjunct to usual care at our specialty osteoporosis centre is feasible, although, to achieve adequate retention, future studies will require data collection processes that are less onerous for participants.

Table. Feasibility of delivering and evaluating a dietitian-led virtual Culinary Medicine (CM) program for bone health

Feasibility Outcomes	Target, n	Achieved, n (%)	Target achieved (Yes/No)
Recruitment			
Recruited in 6 months	**40**	**40 (100%)**	**Yes**
Adherence			
All participants	**40**	**38/40 (95%)**	**Yes**
CM group			
Attended CM session	20	18 (90%)	Yes
Attended optional follow-up session	-	12 (60%)	-
Usual care group			
Did not attend any CM programming during study	20	20 (100%)	Yes
Retention			
Completed all surveys	**40**	**32 (80%)**	Yes
Completed baseline survey	40	35 (87.5%)	Yes
Completed 3 month survey	40	32 (80%)	Yes
Completed post-CM session survey (CM group only)	20	17 (85%	Yes
Completed baseline dietary recall x2	40	11 (27.5%)	No
Completed 3 month dietary recall x2	40	5 (12.5%)	No
Completed all dietary recalls	40	5 (12.5%)	No

The Role of Vitamin D Sulfates in Breastmilk *Carmen Reynolds[1,] Roy Dyer[1,] Sara Oberhelman-Eaton[1,] Brianna Konwinski[1,] Ravinder Singh[1,] Thomas Thacher[1. 1]Mayo Clinic, United States

Vitamin D is essential to infants for normal calcium metabolism and bone development, but the concentration of vitamin D3 (VitD3) in breastmilk is low or undetectable unless mothers receive high-dose vitamin D supplement. However, infant serum 25-hydroxyvitamin D3 (25OHD3) correlates with maternal serum 25OHD3, suggesting that alternative vitamin D metabolites may contribute to the infant's nutrition. Serum 25OHD3 is also observed conjugated to a polar sulfate group that increases metabolite solubility. In milk, such sulfate-conjugated vitamin D metabolites (D-Sulfates) could disperse into the aqueous phase for advantages such as enhanced stability or alternate digestion. We hypothesized that D-sulfates, vitamin D3-sulfate (VitD3-S) and 25-hydroxyvitamin D3-sulfate (25OHD3-S), are present in breastmilk and that these metabolites increase with high-dose VitD3 supplementation. We measured D-sulfates in breastmilk from 10 healthy lactating women >=2 weeks after delivery, before and after high-dose VitD3 supplementation. Those with premature birth (<37 weeks gestation), history of sarcoidosis or renal disease, or consuming VitD >=600 IU/day for 30 days prior were excluded. Breastmilk and serum were collected at baseline and after 28 days (d28) of supplementation with VitD3 5000 IU/day. VitD3-S and 25OHD3-S were measured by a newly developed LC-MS/MS method optimized for milk assessments. Subjects were enrolled in the fall and early winter (Oct-Dec). All women had baseline 25OHD3 values >=25 ng/ml and mean +/- SD serum 25OHD3 increased from 32.0 +/- 5.5 ng/mL at baseline to 42.7 +/- 4.5 ng/mL (d28; P <0.001). The D-sulfates in serum were 35.4 +/- 6.0 ng/mL 25OHD3-S and 2.3 +/- 0.2 ng/mL VitD3-S and did not increase from the supplement. In milk, baseline VitD3-S was 12.6 +/- 7.1 ng/mL and 16.3 +/- 9.4 ng/mL on d28 (P=0.3). Baseline 25OHD3-S was 3.5 +/- 2.2 ng/mL and 4.3 +/- 2.5 ng/mL on d28 (P = 0.4). Milk VitD3-S was positively correlated with milk 25OHD3-S (r=0.87, P<0.0001), but neither correlated with serum analytes (25OHD3, VitD3-S, or 25OHD3-S). In conclusion, VitD3-S and 25OHD3-S are present in milk from mothers who are not deficient in serum 25OHD3. These D-sulfates do not correspond to serum analytes or supplementation, thereby suggesting that a regulatory mechanism may exist within mammary glands.

SAT-285

Vitamin C deficiency deteriorates bone microarchitecture and mineralization in a sex-specific manner in adult mice *Stephane Blouin[1,] Farzaneh Khani[2,] Phaedra Messmer[1,] Paul Roschger[1,] Markus Hartmann[1,] Andre van Wijnen[3,] Roman Thaler[4,] Barbara Misof[1. 1]Ludwig Boltzmann Institute of Osteology at Hanusch Hospital of OEGK and AUVA Trauma Centre Meidling, 1st Med. Dept. Hanusch Hospital, Austria. [2]Department of Orthopedic Surgery, Mayo Clinic, United States. [3]University of Vermont, United States. [4]Mayo Clinic, United States

Vitamin C is essential for bone health and low vitamin C serum levels associate with an increased risk for skeletal fractures. However, if and how vitamin C affects bone mineralization is still unknown. Using micro-computed tomography (μCT), histologic staining as well as quantitative backscattered electron imaging (qBEI) we assessed the effects of

vitamin C on femoral structure and microarchitecture, bone formation and bone mineralization density distribution (BMDD) in the vitamin C incompetent Gulo-/- mouse model. For this purpose, 20 week old, vitamin C supplemented mice were compared to age-matched counterparts where dietary vitamin C intake was abrogated from week 15. We found that the cortical thickness of the diaphyseal shaft as well as bone volume around the growth plate are severely decreased in vitamin C depleted Gulo-/- mice (e.g., BV/TV of primary spongiosa -43%, p<0.001). Concurrently, the amount of newly formed bone tissue is clearly reduced as visualized by histology and by calcein labeling of the active mineralization front. Furthermore, the BMDD analysis reveals a shift to higher calcium concentrations, including higher average and peak calcium concentrations in the epiphyseal and metaphyseal spongiosa (e.g. average calcium concentration increases by 10%, p<0.001, in female Vitamin C depleted versus Vitamin C supplemented mice) suggesting increased bone tissue age. Importantly, many of the observed effects are significantly more pronounced in female mice indicating a higher sensitivity of their skeleton to vitamin C deficiency. In summary, our results unveil that vitamin C plays a key role in bone formation, propose low vitamin C levels as a contributing factor for the higher prevalence of bone degenerative diseases in females and suggest leveraging this vitamin against these conditions.

Prevalence for urinary calcium level among people in 9 provinces of China: a multi-center cross-section study *Li Shen[1], Zhenlin Zhang[2]. [1]Shanghai Sixth People's Hospital, China. [2]Shanghai Sixth People's Hospital, China

Objective: Population-based data of urinary calcium level in Chinese population is lacking. We aimed to investigate the urinary calcium level and obtain the profile of urinary calcium level according to gender and age.Methods: This is a multi-center, cross-section study, involving the method of multi-stage stratified sampling. Eligible participants (>=18 years) of Chinese ethnicity were enrolled from 9 provinces in China (9 centers). Dietary information was collected through questionnaire survey. 24-hours urine collection (24HUC) were collected and analyzedResults: A total of 1081 subjects with mean ages of (46.89+/-18.27) years (age range: 19-91 years) were included in the final analysis, of whom 434 (40.1%) were men and 674 (59.9%) were women. The median 24-hour urinary calcium excretion were 2.10mmol/24h(Q1-Q3: 1.29-3.37mmol/24h), there was no statistically significant difference in urinary calcium excretion between men and women. The total number of subjects with low urinary calcium excretion(<=2.5 mmol/24h) in this study was 641(59.5%), of which 234(54.0%) were men and 407(63.1%) were women. The total number of subjects with high urinary calcium excretion(>7.5 mmol/24h) in this study was 46(4.3%), of which 28(6.5%) were men and 18(2.8%) were women. The prevalence of 24-hour urinary calcium excretion in different provinces are shown in Figure 1, and the level difference in different provinces were statistically significant (P<0.001). The profile according to age showed that urinary calcium excretion were the highest at the age of 31-45 years in men[3.64mmol/24h(95%CI=2.92-4.35mmol/24h)] and over 46 years. However,it quickly decreased. In women, the highest urinary calcium excretion level was age of 46-60 years [2.99mmol/24h(95%CI=2.49-3.49 mmol/24h)], and over 60 years, it decreased with age. Conclusion: Low urinary calcium excretion was found to be high in China, which requires addressing as a public health priority. Further study is needed to understand the epidemiology of urinary calcium level and Influencing factors in more details to tailor intervention programs.Keywords: 24-hour urinary calcium level, calcium level, epidemiology, cross-sectional studyAcknowledgement: We thank the Chugai Pharma China Co., Ltd for funding this study

The landscape of osteoblast dysregulation in osteoporosis revealed by single cell 'omics *Ryan Chai[2], Marcelo Sergio[2], Torsten Gross[3], Juliana Cudini[3], Lorenzo Ramos-Mucci[3], Amaia Vilas Zornoza[3], Jake Taylor-King[3], Edith Hessel[3], Sarthak Chopra[4], Nathaniel Bradford[5], Horng Lii Oh[6], Peter Croucher[2], Rebecca McIntyre[3]. [2]Garvan Institute of Medical Research, . [2]Garvan Institute of Medical Research, Australia. [3]Relation Therapeutics, United Kingdom. [4]St. Vincent's Hospital, Australia. [5]St Vincent's hospital, Australia. [6]St Vincent's Hospital, Australia

Osteoporosis is a common skeletal disease of older age that is thought to affect ~200 million people worldwide. Despite the large healthcare burden of fracture surgery and the significantly increased post-surgery mortality (~20% lower than expected for up to 10 years post-fracture), only a small fraction of osteoporotic individuals are therapeutically treated. With the global population aging, there is an urgent need to identify novel therapeutic targets and early disease biomarkers.Here, we present a comprehensive single cell atlas of human femoral head and neck from both osteoporotic patients and non-osteoporotic controls. We established a pipeline to process bone cores for single cell RNA-seq (scRNA-seq), ATAC-seq (scATAC-seq), DEXA, microCT and histopathology. For scRNA-seq, we removed the majority of CD45-positive immune cells and CD235a-positive cells by cell sorting to improve resolution of the bone-lineage cells. We performed unsupervised clustering to identify 27 clusters of cells, inferred cell-cell communication and performed trajectory analysis to identify the multiple stages of osteoblast differentiation from mesenchymal stromal cells (MSCs) through to mature osteoblasts and early osteocytes. We cross-referenced expression profiles against genes known to regulate bone mineral density and found that the vast majority of the genes involved in the monogenic form of osteoporosis, osteogenesis imperfecta, were expressed highly in osteoblasts at a specific stage of differentiation. We characterized these cells further using flow cytometry and histopathology. These findings represent the first data describing the cellular landscape of patients with osteoporosis and identified osteoblast populations that may be associated with disease pathogenesis/abnormal bone mass. Our results to date provide a vast resource and enable prioritization of genes and disease-relevant pathways in key disease effector cell types, greatly facilitating the development of novel therapeutics and disease biomarkers.

The Impact of Genomic Structural Variations on Osteoporosis Risk: Insights from Whole-Genome Sequencing *Kuan-Jui Su[1], Yong Liu[1], Anqi Liu[2], Jonathan Greenbaum[1], XIAO ZHANG[2], Zhe Luo[1], Qing Tian[1], Li Wu[1], CHUAN QIU[3], Hui Shen[4], Hong-Wen Deng[4]. [1]Tulane Center for Biomedical Informatics and Genomics, United States. [2], . [3], United States. [4]Tulane University, United States

Genomic structural variations (SVs) are large-scale differences in the genome that can lead to genetic diversity. While small-scale copy number variations are known to affect osteoporosis, a heritable metabolic bone disorder characterized by low BMD, the role of large-scale SVs in osteoporosis susceptibility is not well understood. This study aims to investigate the diverse patterns of SVs and their potential association with osteoporosis in the human genome. Whole-genome sequencing was performed on 4982 subjects from the Louisiana Osteoporosis Study, including 50% males, 23% Black, and 57% White participants, to analyze genomic deletions, duplications, insertions, and inversions using an ensemble-SV method. A gene-based burden test was applied to determine the association between the presence of SVs within a gene and hip, femoral neck (FNK), and lumbar spine (SPN) BMD. We used a false discovery rate procedure for multiple tests correction. We also performed post-analytic interrogation using webTWAS, GWAS Catalog, ROADMAP epigenome, and enrichment analysis. Additionally, we explored the sex- and race-specific effects of SVs on bone traits through stratification. We identified a total of 31,304 high-confidence SVs, comprising four SV types. Among the pooled samples, we found 243 unique BMD-related SVs. Over than 50% of these SVs were simultaneously associated with two skeletal sites in combined and sex/race-specific analyses, but none of the SVs were found to be simultaneously associated with all three bone traits. Furthermore, we noted a higher number of FNK-related SVs compared to HIP and SPN-BMD SV associations. We found that many BMD-related SVs were located near centromeres/telomeres, which have been suggested as relevant to human diseases as sources of genomic instability or repositories of haplotypes containing causative mutations. Additionally, we discovered 55 GWAS bone signals that co-occurred with BMD-related SVs. Our analysis also identified 157 GO terms and 32 KEGG pathways and annotated with several enhancers and promoters in osteoblasts, myoblasts, CD14+monocytes, and other cell types (Fig 1). Overall, our study highlights how different sets of SVs can influence BMD at different skeletal sites as well as common enriched biological functions that could provide new insights into the pathophysiology of osteoporosis.

Metabolomics signatures associated with fracture prediction; cox proportional hazard model and random forest survival analysis *Sohyun Jeong[1], Paul Okoro[1], Sarah Berry[2], Douglas Kiel[3], Yi-Hsiang Hsu[4]. [1]Marcus Institute for Aging research and Hebrew seniorlife, United States. [2]Hebrew SeniorLife/Beth Israel Deaconess Medical Center, United States. [3]Hinda and Arthur Marcus Institute for Aging Research Hebrew SeniorLife, United States. [4]HSL Institute for Aging Research, Harvard Medical School, United States

Measurement of multiple metabolites has shown some success in understanding bone metabolic processes that contribute to skeletal health. We aimed to identify metabolomics signatures that are associated with the risk of fracture. We leveraged large-scale UK Biobank data which has high-throughput NMR-based measures of 249 metabolites spanning 14 lipoprotein subclasses, fatty acids, low-molecular weight amino acids, ketone bodies, and glycolysis metabolites. A total of 121,733 individuals with metabolomics profiling were selected. Missing metabolite values (0.1%) were imputed by assigning half of the minimum positive values. We had a 2-step approach; 1) Cross-sectional study between individuals with fracture events within 6 months before/after blood sampling and those with no fracture history (case;295, control;115,862); significantly different metabolomics (Log2FC, pval <.05) were determined using Limma, 2) Cohort study in individuals with no fracture history before blood sampling (n=119,081); metabolomics selected in the first step were considered as predictors of 6-month and 1-year fracture outcomes; cox proportional hazard model adjusting for age at sampling, sex, BMI, genetic European ancestry, hypertensive disease, diabetes (Type1/Type2), lipid disorder and chronic kidney disease and random forest survival analysis (randomForestSRC R package) were conducted. Mean age was 57.14 (+/-8.13) and 54% were female. Among 249 metabolomics screened, 20 were selected in the first step. Next in the cohort study, none of the metabolomics were significantly associated with 6-month fracture outcome. However, at 1-year follow-up,"Phospholipids to Total Lipids in Small HDL percentage" (HR:3.99, pval<.001), "Cholesterol to Total Lipids in Small HDL percentage" (HR:4.84, pval:0.005), and "Monounsaturated Fatty Acids to Total Fatty Acids percentage" (HR:1.44, pval: 0.008) were significantly associated with increased fracture whereas "Monounsaturated Fatty Acids" (HR: 0.067, pval:0.019) was associated with decreased fracture risk. Additionally, we put 4 significant metabolomics with all covariates in random forest survival analysis. The model fitted well to predict 1-year fracture risk with OOB CRPS (Continuous Ranked Probability Score), 0.0014 and OOB performance error, 0.460. We demonstrated 4 lipoprotein and fatty acid related metabolomics were associated with fracture risk at 1 year of follow up and previous studies support the association.

Identification of a Novel, MSC-Induced Macrophage Subtype via Single-Cell Sequencing: Implications for IVDD Therapy *JINSHA KOROTH[1], CASEY CHITWOOD[1], RAMYA KUMAR[1], WEI-HAN LIN[1], THERESA REINIKE[1], ARIN ELLINGSON[1], CASEY JOHNSON[1], LAURA STONE[1], BRENDA OGLE[1], ELIZABETH BRADLEY[1]. [1]University of Minnesota, United States

Intervertebral disc (IVD) degeneration is a common pathological condition associated with lower back pain. Recent evidence suggests that mesenchymal signaling cells (MSCs) promote IVD regeneration, but the mechanisms are poorly defined. MSCs encounter drastic oxygen tension declines when injected into the avascular IVD. IVD degeneration likewise associates with altered oxygen tension via vasculature invasion, and macrophage infiltration; thus, understanding how different oxygen tensions affect interactions between MSCs and macrophages may offer clues as to how MSCs act therapeutically. To gain insight, we investigated how conditioned medium (CM) derived from MSCs cultured in hypoxia altered macrophage subsets. We cultured human, bone marrow-derived Stro3+ MSCs in hypoxia (2% O2) or normoxia and collected CM. We then cultured human bone marrow-derived macrophages (e.g., Cd11b+/Cd14+ cells) with IFN-y for 24 hours, followed by either hypoxic or normoxic Stro3+ MSC CM. We also cultured macrophages in hypoxic MSC CM in the presence of IL-4. After 24 hours in CM, we collected cells for scRNA-seq analyses. Bioinformatic analyses confirmed multiple subpopulations of macrophages within human bone marrow. To gain insight into how MSCs exposed to different oxygen tensions affected macrophage subsets, we first performed comparison analyses between macrophages cultured in hypoxic and normoxic MSC CM. Integration of these two data sets showed large overlap between most macrophage subsets; however, we identified a unique macrophage cluster induced by hypoxic MSC CM. This cluster represented approximately 2-3% of macrophages (Fig 1A, B). Gene Ontogeny (GO) analyses revealed enrichment in several Reactome Pathways, including IL-10, Ccl5/Ccr5, G alpha (i) Signaling and Rho GTPases within this unique cluster (Fig 1C, D). To determine if factors from MSC CM simulated IL-4, we integrated the data from macrophages cultured in hypoxic MSC CM with and without IL-4 addition. Integration of these two data sets showed considerable overlap, demonstrating that hypoxic MSC CM simulates the effects of IL-4. Interestingly, macrophages cultured in normoxic MSC CM did not significantly show the unique cluster within our comparison analyses; thus, normoxic conditions did not approximate the effects of IL-4. Our study identifies a unique macrophage subset induced by MSCs within hypoxic conditions, and offers clues towards mechanisms by which MSCs promote IVD regeneration.

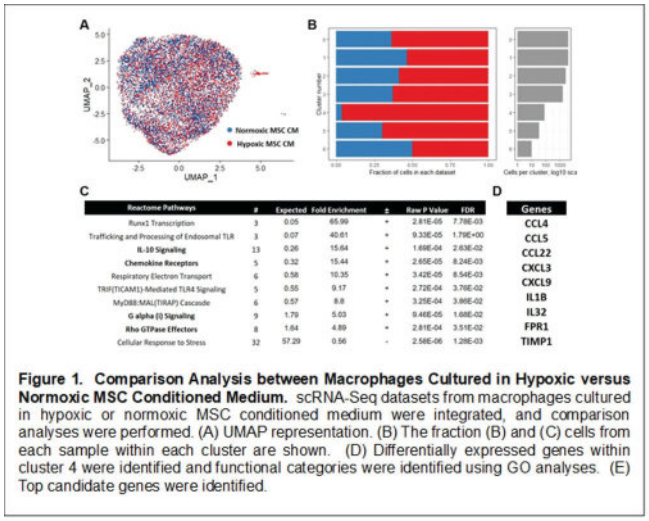

Figure 1. Comparison Analysis between Macrophages Cultured in Hypoxic versus Normoxic MSC Conditioned Medium. scRNA-Seq datasets from macrophages cultured in hypoxic or normoxic MSC conditioned medium were integrated, and comparison analyses were performed. (A) UMAP representation. (B) The fraction (B) and (C) cells from each sample within each cluster are shown. (D) Differentially expressed genes within cluster 4 were identified and functional categories were identified using GO analyses. (E) Top candidate genes were identified.

Identification of Osteoporosis Biomarkers and Biological Interactions Using Multi-omics Data Integration *Anqi Liu[2], Lindong Jiang[2], Kuan-Jui Su[2], XIAO ZHANG[2], YUN GONG[2], CHUAN QIU[3], Zhe Luo[2], Qing Tian[2], Zhengming Ding[2], Hui Shen[2], Hong-Wen Deng[2]. Osteoporosis is a medical condition characterized by a decrease in bone density and a deterioration of bone microarchitecture, which increases the risk of fractures. The development of high-throughput technologies and integrative strategies has created new possibilities to explore the underlying pathophysiological mechanisms associated with osteoporosis. Currently, omics-based technologies have been put forward to enhance our comprehension of the biological mechanisms contributing to decreased bone mineral density (BMD). While each omics technology can capture a portion of biological information, integrating multiple types of omics data can provide a more holistic picture of the underlying biological processes. In this study, we produced multi-omics data from our own Trans-omics Integration of Multi-omics Studies for Male Osteoporosis Study (including single nucleotide variations, copy number variations, mRNA gene expression, miRNA, DNA methylation, metabolomics, lipidomics and clinical data) from 181 subjects with high (n=57) and low (n=124) BMDs. We employed a multi-omics integrative method using multi-view graph convolutional networks for high BMD and low BMD classification. This method jointly explored omics-specific learning with graph convolutional networks and cross-omics correlation learning with view correlation discovery network (VCDN) for effective multi-omics data classification. In conclusion, we identified 105 important biomarkers associated with

low BMDs from various omics. We revealed functional interactions among the 36 annotated genes from 105 biomarkers and pinpointed osteoporosis-related pathways related with other biomarkers. The identification of osteoporosis biomarkers and the understanding of their biological interactions would be transformed into consistent benefits for the effective prevention, intervention, and treatment for osteoporosis.

Multi-Omics Data Integration Revealed Osteoporosis-Associated DNA Methylation and Transcription Variations in Human Peripheral Blood Monocytes *XIAO ZHANG[2], YUN GONG[2], Kuan-Jui Su[3], Anqi Liu[2], CHUAN QIU[4], Zhe Luo[3], Qing Tian[3], Melanie Ehrlich[3], Hong-Wen Deng[3], Hui Shen[3, 2], , [2], United States, [3]Tulane University, United States, [4], United States

Osteoporosis (OP) is a common bone disorder characterized by low bone mineral density (BMD) and increased risk of fractures in both women and men. About one third of worldwide fractures occur in men and OP in men has received little attention. Despite extensive research efforts, the underlying molecular mechanisms driving OP remain poorly understood. Multi-omics integration has emerged as a promising approach to address this issue by integrating data from various molecular layers, such as epigenomics (DNA methylation) and transcriptomics (RNA-seq and miRNA-seq). In this study, we integrated a set of 519 independent male (both Caucasians and African Americans) subjects' multi-omics data derived from peripheral blood (classical) monocytes using Multi-Omics Factor Analysis (MOFA) to study osteoporosis risk in men. We determined nine factors and identified known and novel putative genes and BMD-associated features associated with OP, with the model explains > 10% of the variation in the DNA methylation annotated in CpG islands, active enhancer- and promoter-chromatin region in monocytes. One of the identified factors prioritized a CpG site (chr19:4,053,428/hg19) which annotated to active enhancer-chromatin in monocytes and located in intron 2 of ZBTB7A. The encoded protein, ZBTB7A, is known to play a role in osteoclast differentiation. Through the integration analysis, we identified significant and novel OP-associated coding and non-coding genes whose expression is epigenetically dysregulated.

Trabecular bone texture is sensitive to Strontium Ranelate treatment and improves the prediction of knee osteoarthritis progression: Data from the SEKOIA Trial *Ahmad Almhdie-Imjabbar[1], Hechmi Toumi[1], Eric Lespessailles[2], [1]Translational Medicine Research Platform, PRIMMO, University hospital center of Orleans, France, France, [2]Centre Hospitalier Universitaire d'Orleans, France

Trabecular bone texture (TBT) analysis of subchondral bone on conventional knee X-ray has been shown to be a promising method to identify patients at risk for knee osteoarthritis (KOA) progression.The aim of this study was to investigate an approach combining the use of TBT, with a set of radiological severity scores and clinical covariates, to predict radiological progression (joint space narrowing (JSN) >= 0.5 mm over 3 years) and radioclinical progression (JSN >= 0.5 mm and lack of improvement in WOMAC pain <= 20% over 3 years) in the Strontium-ranelate (SR) Efficacy in Knee Osteoarthritis trIAl (SEKOIA). The study also examined the longitudinal effects of the SR treatment on TBT variations.This study included 905 patients from the SEKOIA dataset. Radiographs were automatically segmented to determine 16 regions of interest (ROIs). Several statistical models were developed using logistic regression to evaluate the performance gain in including not only clinical covariates (age, gender and BMI), WOMAC pain scores and radiological KL grades and minimum joint space width, named hereafter TBT-excluded models, but also TBT descriptors, named hereafter TBT-included models.The TBT-included models were predictive of radiological progression and the AUC was 0.64 (95% CI: 0.57-0.70), significantly outperformed TBT-excluded models (AUC=0.52, 95% CI: 0.46-0.59, p-value=0.002). The performance of TBT-included models in prediction of radioclinical progression (AUC=0.62, 95% CI: 0.52-0.73) also outperformed, but not statistically significantly, those of TBT-excluded models (AUC=0.58, 95% CI: 0.49-0.68).The highest increase in TBT was 3% in specific ROIs, in both the placebo and treated group (Strontium Ranelate). The highest variations were observed in the horizontal direction, in the extreme medial and lateral ROIs, see Figure 1.The proposed combined model provides a good performance in the prediction of radiological and radioclinical progression over 3 years, in the setting of a multicenter international trial. The current study confirms the ability of the TBT-included models to predict KOA progression in different databases. TBT provides a responsive outcome measure for subchondral tibial bone microarchitecture in longitudinal KOA trial.

Evaluation of a Novel Computed Tomography Application to Monitor Knee Osteoarthritis *REECE BLAY[2], Grace Roskam[2], Yvonnne Golightly[2], Laura Bilek[3], [2]University of Nebraska Medical Center, , [2]University of Nebraska Medical Center, United States, [3]UNIVERSITY OF NEBRASKA MEDICAL CENTER, United States

PurposeKnee osteoarthritis (KOA) affects nearly 1 in 5 adults over the age of 45 in the United States. Its prevalence is rapidly increasing in recent decades, partly due to the obesity epidemic. Identifying the pathologic mechanism of KOA development requires the detection of early changes in bone. No validated tool exists to examine the role of bone in the initiation of KOA in those at risk for the disease. X-ray is not sensitive enough to detect changes, and advanced imaging techniques such as CT and MRI are not routinely used in practice, as they require a significant amount of time to capture images. There is a need for a quick, accessible, and low-radiation tool to accurately assess bone at the knee in people at risk of KOA development. This methodological study evaluates the effectiveness of a peripheral quantitative computed tomography (pQCT) scan to assess bone density of the proximal tibia and distal femur.MethodsParticipants include adults over the age of 23 who can transfer independently into and out of the pQCT. Pregnant women and those who had prior surgery on their right knee were excluded. Participants underwent two trials during a single visit, with images of their right knee captured using a Stratcom XCT3000 pQCT. The knee angle was kept neutral with straps and padding to stabilize the patient's position. A radiographic technician identified the image reference lines of the femur and tibia (densest area of the medial subchondral endplate) using a scout image. The femur was scanned at a distance 2 mm proximal to the femoral reference line, and the tibia was scanned 12 mm distal to the tibial reference line. These sites represent subcortical and trabecular bone, respectively. Between trials, participants exited the pQCT. The process was repeated to capture a second image. Each trial took approximately 12 minutes. Endpoints include total, trabecular, and cortical density of the medial and lateral condyles of the femur and total, medial, and lateral hemispheres of the tibia. Bland Altman analysis assessed bias (95% CI) between pQCT scans.ResultsThe study sample included 52 participants (mean age 50 years, 81 % female, BMI 27.98 kg/m2). Bland Altman Bias (95% CI) between pQCT scan trials is reported in Table 1.ConclusionpQCT is a reliable modality to assess tibial and medial femoral bone at the knee. Since KOA changes occur primarily in the tibia, the reliability of pQCT to monitor bone changes in this area is significant.

Table 1: Bland Altman Bias (95% CI) between pQCT scan trials, N=52

Scan Location	Density Measure	Bland Altman Bias (95% CI)
Medial Femoral Condyle (2mm)	Total	0.77 (0.66 to 0.88)
	Trabecular	0.67 (0.57 to 0.77)
	Cortical	-0.4 (-0.44 to -0.36)
Lateral Femoral Condyle (2mm)	Total	3.92 (3.29 to 4.55)
	Trabecular	4.49 (4.09 to 4.89)
	Cortical	1.96 (1.64 to 2.29)
Total Tibia (12mm)	Total	0.58 (0.54 to 0.62)
	Trabecular	0.59 (0.56 to 0.62)
	Cortical	1.99 (1.81 to 2.18)
Medial Tibial Hemisphere (12mm)	Total	-0.31 (-0.36 to -0.26)
	Trabecular	-0.47 (-0.51 to -0.42)
	Cortical	0.22 (0.13 to 0.30)
Lateral Tibial Hemisphere (12mm)	Total	-0.35 (-0.40 to -0.31)
	Trabecular	-0.17 (-0.22 to -0.13)
	Cortical	0.42 (0.31 to 0.54)

Osteoarthritis is a joint degenerative disease, the alteration in cartilage and underlying bone could concurrently change the microstructure and mechanical performance of osteoarthritic femoral heads due to the dynamic nature of human bones. Bone adaptation occurs in the direction of loading as stated by Wolff's law. Although some evidences suggest bone structure heterogeneity in regions under different degrees of loading [1], little is known about mineral deposition in response to load alteration at microscopic level across femoral head. Synchrotron Radiation Computed Tomography (SRCT) offers the advantage of three-dimensional visualization, precise mineralization quantification and mineral distribution of the whole femoral head. This study uses SRCT technique to compare the bone mineral density (BMD) between regions subjected to different degrees of loading, with a specific focus on the stressline observed along principal compressive trabeculae [Figure 1].Osteoarthritic femoral heads collected from patients of 42, 59, 69, 89 years old were scanned with SRCT at beamline 05ID-2 at the Canadian Light Source. Images at different bit depth were used for microstructural and density analysis. Bone cores of 10 mm in diameter were then drilled from the superior, medial and inferior region of femoral heads with descending order of loading magnitude. Cores were cut, ground, polished and scanned under scanning electron microscope (SEM) for quantitative backscattered electrons (qBSE) analysis. qBSE offers two dimensional quantitative calcium content analysis from grayscale values, which was compared and correlated with the grayscale values of the matched SRCT slice in an attempt to confirm the observed stressline spanning down the main loading direction.SRCT data from patients at age 59 and 89 demonstrated that the superior region exhibits the highest mean volumetric BMD (1.74 g/cm^3) whereas the inferior region showing the lowest (1.50 g/cm^3). Regions with pronounced color intensity on the heatmap showed higher BMD. Preliminary analyses also suggested a correlation between qBSE and SRCT, indicating higher degree of mineralization along the principal compressive trabeculae.Reference: [1] G. Li, L. Chen, Q. Zheng, Y. Ma, C. Zhang, and M. H. Zheng, "Subchondral bone deterioration in femoral heads in patients with osteoarthritis secondary to hip dysplasia: A case-control study," J. Orthop. Transl., vol. 24, pp. 190-197, Sep. 2020, doi: 10.1016/j.jot.2019.10.014.

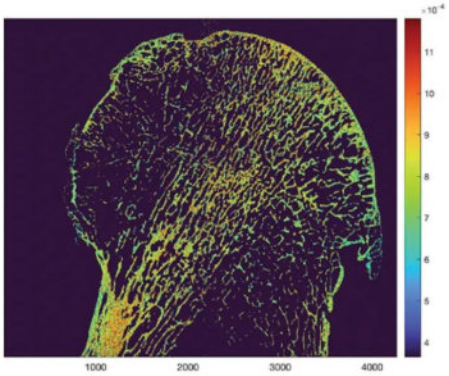

Figure 1.Heatmap of femoral head slice with pronounced stress line in the direction of loading. Grayscale values outside of the range of 2 standard deviations from the mean are excluded. X-axis shows the pixel scale with a pixel size of 13.07um. The grayscale of SRCT is represented by color intensity,where red represents high grayscale an d blue represents low grayscale.

Single-Cell Transcriptomic Analysis Reveals Molecular Complexity and Key Genes Involved in Osteoarthritis *Zhengwu Xiao[1], Chong Cao[2], Yan Chen[2], Junxiao Yang[1], YUN GONG[3], Xiao Zhang[3], Kaizhi Wen[1], Hui Shen[3], Lijun Tan[2], Hong-Wen Deng[3], Hongmei Xiao[1]. [1]Central South University, China. [2]Hunan Normal University, China. [3]Tulane University, United States

Osteoarthritis (OA) is the most common multifaceted degenerative joint disease which is characterized by degeneration and loss of cartilage and bone. These alterations are mediated by various bone-related cells, such as osteoblasts (OBs) in bone, and potential cell subtypes (cellular heterogeneity). Despite extensive research efforts, the underlying molecular mechanisms driving OA remain poorly understood, especially at single cellular level. In this study, we performed comparative single-cell transcriptomics (scRNA-seq) analysis on freshly isolated OBs obtained from femur head of three OA individuals and three controls with femoral neck fractures. We obtained a total of 42,855 cells and revealed three distinct OB subtypes (pre-, metaphase, and mature OBs) through gene expression profiling, which each with unique functional roles. The pre-OBs exhibit to participate in angiogenesis and adipocyte differentiation; the metaphase OBs may regulate neutrophil-related immune responses; and, the mature OBs display ossification properties. Differential gene expression analysis revealed three upregulated genes (APOE, PTGDS, and CFD) in OA. Using weighted gene co-expression network analysis (WGCNA), we identified a critical gene co-expression network associated with OA, which featuring CFD as the central hub gene. Our findings shed light on the molecular intricacies of OA in OBs and its subtypes, uncovering potential biological processes and essential genes that may guide future diagnostic and therapeutic research.

Higher CAROC Fracture Risk is Associated with Progressive Knee Symptoms in Postmenopausal Women: the AMBERS Cohort Study *Andy Kin On Wong[1], Shannon Reitsma[2], Ali Naraghi[3], Rakesh Mohankumar[3], Alexandra Papaioannou[4], Jonathan Adachi[5]. [1]University Health Network, Canada. [2]Division of Rheumatology, Medicine, McMaster University, Canada. [3]Joint Department of Medical Imaging, University Health Network, Canada. [4]McMaster University , Canada. [5]St. Joseph s Hospital/McMaster University, Canada

Purpose: To examine fracture risk's impact on knee osteoarthritis (OA) symptom progression in postmenopausal women.Methods: The Appendicular Muscle and Bone Extension Research Study (AMBERS) recruited women 60-85 years old at baseline through primary care in Hamilton, Canada. Participants completed a total hip DXA and a single slice peripheral QCT scan at the 66% site (0.500x0.500x2.3mm, 38 kVp energy, 0.3 mA current) at baseline. Muscle was separated from subcutaneous fat and bone using fixed thresholds (40 mg/cm3) on pQCT scans after filtration (F03F05F05). Muscle density (MD) was computed as mass/volume. At year 5 and 6 of follow-up, the Knee OA Outcomes Scores (KOOS) and Gender Role Expectations in Pain (GREP) questionnaires were completed. Information on use of corticosteroids, pain medications for the knee, and history of diabetes were collected annually. The Canadian Association of Radiologists and Osteoporosis Canada (CAROC) Fracture Risk category (low, moderate, high) was determined using DXA femoral neck

T-score, sex, and age.Statistical analyses: KOOS subcategory change from year 5 to 6 was dichotomized according to whether the decrease (more symptoms) exceeded the respective minimum detectable change (MDC) (1) or not (0), and used as the outcome in logistic regression. The primary exposure was CAROC fracture risk category. All models adjusted for MD as a secondary exposure, covariates: age, BMI, use of corticosteroids, knee pain medication, and history of diabetes. GREP score was reversed and normalized to its maximum value and used as a weight to mitigate gender bias in willingness to report pain, pain endurance, and sensitivity.Results: Among 284 women with complete data (age: 75.0+/-6.0 yrs, BMI: 29.56+/-5.69kg/m2, Total Hip T-score: -0.89+/-1.80), KOOS subcategory decreases beyond MDC ranged from 18.0% (symptoms) to 35.6% (quality of life). Overall, 8.8% of women were at high and 54.2% at moderate CAROC fracture risk. Odds for worsening knee symptoms beyond MDC was higher for every unit greater CAROC category, ranging from 1.51 (symptoms) to 2.33 (quality of life)-fold (Table 1). Each standard deviation lower MD was also predictive of worse KOOS scores (Odds ratios: 1.13 to 1.85). These effects remained significant with minimal effect size differences after accounting for use of antiresorptives. Conclusions: Having a higher fracture risk is associated with greater likelihood of experiencing worse knee symptoms in postmenopausal women.

		CAROC Fracture Risk Category			Muscle Density		
KOOS Subcategory	N	OR	Lower	Upper	OR	Lower	Upper
Knee Pain	284	1.69	1.20	2.38	1.57	1.12	2.19
Symptoms	284	1.51	0.96	2.38	1.13	0.72	1.78
Activities of Daily Living	284	1.56	1.09	2.23	1.82	1.29	2.58

IntroductionBone plays a major role in the pathology of OA, a common musculoskeletal disease [1]. For the assessment of OA, radiography and magnetic resonance imaging are the main imaging modalities considered. However, CT has advantages over those imaging modalities for bone imaging. Particularly, its capability of producing high resolution three-dimensional image reconstructions that enable standardised bone structure analysis. Therefore, we aimed to systematically review CT parameters for osteoarthritic subchondral bone assessment and gain an overview of current practices and standards in the realm of OA imaging with CT.MethodsMedline, Embase and Cochrane Library databases were searched from 2010 to January 2023 with bespoke search strategies. Two independent reviewers screened the search results against inclusion/exclusion criteria; studies utilising CT for subchondral bone assessment in vivo/ex vivo of human adults (>18 years) with OA were deemed eligible. Data was extracted and combined in a qualitative summary and formal narrative synthesis.ResultsIn the 202 included studies, imaging of subchondral bone in OA was performed with four CT groups (Fig. 1a) across nine anatomical locations (Fig. 1b). The reported subchondral bone parameters measuring related OA features were classified in six categories: (i) microstructure, (ii) bone adaptation, (iii) gross morphology, (iv) mineralisation, (v) joint space, and (vi) mechanical properties (Fig. 1c).Figure 1 | Reporting frequency overview of a) CT groups, b) anatomical locations, and c) parameter categories. ConclusionsCT is gaining increasing popularity for the assessment of OA. CT parameters with clinical relevance for osteoarthritic subchondral bone assessment were identified, as well as measurements with the potential to become clinically meaningful. To ensure the sensibility and reproducibility of these parameters, quantification is imperative. Additionally, reporting consistency and standardised measurement protocols are required to improve their value in future OA research and clinical practice.References1. **Comparison between UK Biobank and Shanghai Changfeng suggests distinct hip morphology may contribute to ethnic differences in the prevalence of hip osteoarthritis ***Jiayi Zheng[1], Monika Frysz[2], Benjamin Faber[2], Huandong Lin[3], Raja Ebsim[4], Jieyu Ge[1], Yanling Yong[5], Fiona Saunders[6], Jennifer Gregory[6], Richard Aspden[6], Nicholas Harvey[7], Bing-Hua Jiang[5], Timothy Cootes[4], Claudia Lindner[4], Xin Gao[3], Sijia Wang[1], Jonathan Tobias[2]. [1]Chinese Academy of Sciences, China. [2]University of Bristol, United Kingdom. [3]Fudan University, China. [4]The University of Manchester, United Kingdom. [5]Zhengzhou University, China. [6]University of Aberdeen, United Kingdom. [7]University of Southampton,

Background: Joint morphology is a key risk factor for the development of hip osteoarthritis (HOA) and could explain established ethnic differences in HOA prevalence. Therefore, we aimed to compare hip morphology and prevalence of radiographic HOA (rHOA) in the predominantly White UK Biobank (UKB) and exclusively Chinese Shanghai Changfeng (SC) cohorts.Methods: Left hip iDXA scans (GE Lunar) were used to quantify rHOA, from a combination of osteophytes and joint space narrowing, and hip morphology. Using an 85-point Statistical Shape Model (SSM) we evaluated cam/pincer morphology and acetabular dysplasia based on alpha angle (AA) and lateral center-edge angle (LCEA), respectively. Composite hip shape was derived from the first ten SSM modes, which explain 86.3% of hip shape variance. Measures of hip geometry were also obtained (femoral neck width (FNW), hip axis length (HAL) and femoral head diameter (DFH)). Results were adjusted for differences in age, height and weight.Results: Complete data were available for 5,924 SC and 39,020 White UKB participants. rHOA prevalence was considerably lower in female (2.3% versus 13.1%) and male (12.0% and 25.1%) SC versus UKB participants. Cam morphology, rarely seen in females, was less common in SC compared with UKB males (6.3% versus 16.5%). Inspection of composite SSM modes, scaled to the same overall size, revealed SC participants to have a wider femoral head compared to UKB participants. FNW and HAL were smaller in SC compared to UKB, whereas DFH was similar, and DFH/FNW ratio was higher in SC.Conclusions: The prevalence of rHOA was lower in SC compared with UKB participants. Several differences in hip shape were observed, including the frequency of cam morphology, FNW and DFH/FNW ratio. These characteristics have previously been identified as risk factors for HOA, and may contribute to observed differences in HOA prevalence.

Comparison of bone structure between weight-bearing and non-weight-bearing bones in patients with rheumatoid arthritis: A study using HR-pQCT and 3D-SHAPER on DXA *Ikuko Tanaka[1], Shigenori Tamaki[2], Yusuke Suzuki[2], Takashi Kato[3], Hisaji Oshima[4]. [1]NAGOYA Rheumatology Clinic, Japan, [2]Nagoya Rheumatology Clinic, Japan, [3]National Center for Geriatrics and Gerontology, Japan, [4]Tokyo Medical Center, Japan

Background and purposeIn rheumatoid arthritis (RA), anti-CCP antibodies (ACPA) and inflammatory cytokines activate osteoclasts, resulting in increased systemic bone resorption. Recently, the introduction of an analysis software, 3D-SHAPER (3DS) on DXA systems has made it possible to simulate quantitative CT-like three-dimensional bone structural analysis of the proximal femur. The purpose of this study was to investigate the bone structure in RA patients by analyzing the bone structure of non-weight bearing bones (the distal radius) by HR-pQCT and weight-bearing bone (the proximal femur) by 3DS.MethodsSubjects were 80 patients with ACPA-positive RA (RA group, 61+/-12 years old, male/female=3/77) and 147 patients with ACPA-negative non-RA diseases (control group, 63+/-12 years old, male/female=5/142). They underwent DXA scans (Horizon A, HOLOGIC) of the lumbar spine and the proximal femur and HR-pQCT scans (XtremeCT II, Scanco Medical) of the distal radius. Three-dimensional bone structure analysis was performed on the DXA data of the proximal femur using 3DS to obtain the structural measurements of the cortical and trabecular bones. HR-pQCT images were used to obtain structural parameters of the cortical and trabecular bones of the distal radius on the side where no synovitis was observed in the wrist joint on previous ultrasound examinations. The bone measurements were compared between the RA group and the control group.ResultsThere were no significant differences in bone mineral density at the lumbar spine or proximal femur, but it was -2.5% lower on average in the RA group than in the control group. 3DS showed a decrease in cortical volumetric bone mineral density (mean -2.0%, p<0.05) and cortical surface bone mineral density (mean -3.7%, p=0.06) in the RA group compared to the control group. HR-pQCT showed a decreasing tendency in cortical bone porosity (mean -14.3% p=0.15) and cortical bone thickness (mean -1.8%) in the RA group. In the trabecular bone, there was no apparent difference in any of the measurements by 3DS and HR-pQCT between RA and the control group.ConclusionThe bone structural measurements were more reduced in the distal radius than in the proximal femur in the RA group compared to the control group. The results indicate that in the RA group, structural strength loss may be more likely to occur in the weight-bearing bones than in the non-weight bearing bone.

Caveolin-1 microdomains modulate parathyroid hormone receptor type 1 signaling and osteogenic actions in bone cells *Sara Heredero-Jimenez[1], Eduardo Martin-Guerrero[1], Joan Pizarro-Gómez[1], Irene Tirado-Cabrera[1], Arancha R. Gortázar[1], Juan A. Ardura[1]. [1]Department of Basic Medical Sciences, Bone Physiopathology Laboratory, Universidad San Pablo?CEU, CEU Universities, Alcorcón, Madrid, Spain

Caveolin-1, a key component of caveolae, regulates the trafficking and signaling of some cell surface receptors. Parathyroid hormone (PTH) receptor type 1 (PTH1R) modulates osteoblast and osteocyte actions during bone remodeling and formation after activation by ligands such as the PTH-related protein (PTHrP). Activated PTH1R may lead to different biological actions depending on its association with different membrane or intracelular molecules. Since PTH1R presents a potential caveolin-1 binding domain we hypothesize that PTH1R trafficking, signaling and gene expression responses are regulated by interactions with caveolin-1 in cells of the osteoblastic lineage. Mouse osteoblastic MC3T3-E1 and osteocytic MLO-Y4 cells were transfected with GFP-PTH1R, mCherry-Caveolin-1 or specific caveolin siRNAs and stimulated or not with PTHrP (1-37). Using confocal microscopy we performed live-cell time-lapse imaging and fluorescence recovery after photobleaching analysis to evaluate PTH1R and caveolin-1 trafficking and receptor-caveolin-1 interactions, respectively. Intracellular calcium accumulation was evaluated by Fluo-4AM microscopy and cAMP levels were analyzed with an ELISA kit. ERK1/2 was assassed by western blotting. Caveolin-1, runx2, osteocalcin, bone alkaline phosphatase, OPG and RANKL mRNA expression were studied in osteoblastic cells and in femora of C57BL/6 mice ranging from 2-18 months of age by qPCR.Caveolin-1 interacts with PTH1R at membrane-bound vesicles in osteoblastic cells. This interaction causes PTH1R temporarily retention at caveolin-1 microdomains upon receptor activation by PTHrP, delaying receptor internalization. Moreover, caveolin-1 overexpression modified PTHrP-dependent signaling and actions in osteoblastic cells by decreasing intracellular calcium accumulation, increasing cAMP levels and inducing runx2, osteocalcin, bone alkaline phosphatase and OPG gene overexpression. In contrast, caveolin-1 silencing caused over-phosphorylation of ERK1/2 kinase, over-production of calcium, reduced expression of runx2, osteocalcin and alkaline phosphatase and increased the percentage of dead cells. Analysis of bone-related genes in femora of mouse of different groups of age revealed that the gene expression of caveolin-1 positively correlated with that of runx2, osteocalcin and OPG.Our observations suggest that PTH1R signaling and osteogenic actions are regulated by caveolin-1 in cells of the osteoblastic lineage.

Omega-6 and Omega-9 Fatty Acids Negatively Impact Osteoblast Function Before and After Mineralization *Beatriz Bermudez[1], Veronica Butler[2], Michael David[2], David Karasik[3], Cheryl Ackert-Bicknell[4]. [1]University of Colorado Denver, United States, [2]University of Colorado Anschutz Medical Campus, United States, [3]Azrieli Faculty of Medicine, Bar-Ilan University, Israel, [4]University of Colorado, United States

Western diets are increasing in prevalence around the world and contain significant amounts of omega-3 (?-3) and omega-6 (?-6) fatty acids (FA). Therefore, these FAs and omega-9 FAs are commonly consumed, and current studies show mixed effects on bone health and fracture risk. Osteoblast function relies on energy generated through oxidative phosphorylation and therefore changes in cell metabolism due to the availability of various FA could impact osteoblast function. This study aimed to examine how specific ?-3, ?-6, and ?-9 FAs influence osteoblast mineralization, metabolism, and differentiation using the MC3T3-E1 pre-osteoblast cell line. Before differentiation, we quantified the effect of FAs on proliferation and cellular energetics, and then after differentiation, we looked at mineralization and cellular energetics. Cells were treated for 48 hours with vehicle (VEH) (?-3 VEH: ethanol, ?-6, ?-9 VEH: cell culture media) or with linoleic acid (?-3, 40 uM), alpha-linolenic acid (?-6, 250 uM), and oleic acid (?-9, 100 uM), respectively. Proliferation was assessed by quantifying a fluorescent ki67 marker. Immunofluorescent images were taken to count the percent of ki67 positive cells using QuPath software. A Mito Stress Test assay was conducted using a Seahorse XFe96 Analyzer to measure oxygen consumption and extracellular acidification rates after FA treatment. Mineralization was quantified over ten days using the IRDye 800CW BoneTag. Data are presented as the mean +/- SEM with significance set at p<0.05. Proliferation was reduced in MC3T3-E1 cells by 58% with ?-3 FA, 11% with ?-6 FA, and 32% with ?-9 FA. Maximal respiration before differentiation was reduced in cells treated with all FAs when compared to VEH-treated cells (Figure 1A-C) and ATP production (5.46+/-0.14 vs. 4.55+/-0.12 pmol/min) before differentiation was reduced in cells treated with ?-6 FA compared to VEH-treated cells. Proton leak after mineralization was reduced in cells treated with ?-6 FA (1.43+/-0.06 vs. 1.23+/-0.06 pmol/min) compared to VEH-treated cells. Mineralization was decreased at all time points in cells treated with ?-6 and ?-9 FAs (Figure 1D-F). Our results suggest that reducing the intake of ?-6 and ?-9 FAs has the potential to improve bone health since we found that acute treatment of FAs has a detrimental effect on osteoblast function before differentiation. In addition, ?-6 and ?-9 FAs negatively influence the osteoblasts after mineralization.

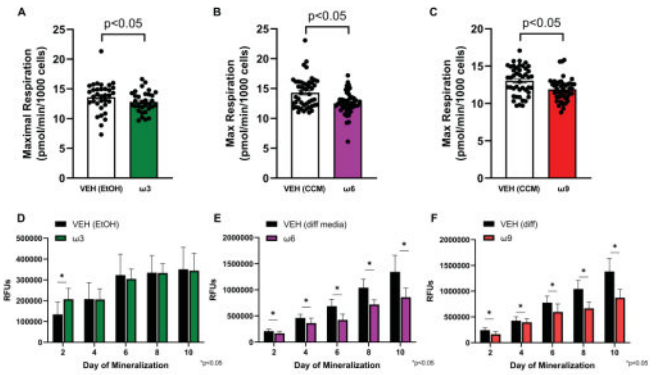

Figure 1: MC3T3-E1 cells after 48 hour treatment of alpha-linolenic acid (ω-3), linoleic acid (ω-6), and oleic acid (ω-9). Maximal Resipration before differentiation in cells treated with (A) ethanol vehicle or ω-3 fatty acid, (B) media vehicle or ω-6 fatty acid, and (C) media vehicle or ω-9. Mineralization after differentiation in cells treated with (D) ethanol vehicle or ω-3 fatty acid, (E) media vehicle or ω-6 fattyacid, and (F) media vehicle or ω-9 fatty acid.

Thrombospondin Status Affects Gene Expression in MSC-Osteoblasts from Adult Mice *Andrea Alford[1], Meredyth Bowman[1]. [1]University of Michigan, United States

The matricellular extracellular matrix (ECM) proteins thrombospondin (TSP) 1 and 2 affect bone mass and quality in growing mice. Our preliminary data suggest that TSP2 expression increases with age. In MSC-osteoblast cultures, conditioned medium TSP2 protein per cell layer DNA content increased between 5-9 months and 12 months of age (322.70+/-84.5 vs. 67.84+/-11.4 p<0.0001; N=5-6 female mice/age). However, contributions of TSP1 and 2 to osteoblast and osteocyte physiology in the adult and aging skeleton are not known. Marrow derived mesenchymal stem cells (MSC) from 10-month-old male TSP1-/- (N=6), TSP2-/- (N=3) TSP1/TSP2 double knockout (DKO, N=6), and wildtype (WT, N=3) mice were used to study effects of TSP status on osteoblast phenotype. RNA interference was employed to determine impacts of acute TSP2 knockdown in MSC from 2-year-old male mice (N=3). DMP1, OPG, RANKL, col1a1, col1a2, alkaline phosphatase, runx2 and PHEX expression were determined by rtPCR. Beta-actin was the house keeping gene. Significance (p<0.05) was determined using students t-test or ANOVA and Tukey test. Data are mean and SD.Mineralization was qualitatively reduced in TSP2-/- and DKO cultures, but not in TSP1-/- cultures (Figure 1). DMP1 expression was reduced in DKO, but it trended up in TSP2-/- MSC (p=0.11. Figure 1). TSP2-shRNA also led to elevated DMP1 expression compared to LacZ-shRNA in MSC from 2-year-old male WT mice (3.21+/-1.0 vs. 1.0+/-0.7 (n.s) at day 3 post-transduction and 6.88+/-3.0 vs. 0.87+/- 0.05 (p<0.01) at day 14 post-transduction. PHEX gene expression was reduced in DKO MSC, but not TSP1-/-, TSP2-/-MSC or in MSC transduced with TSP2-shRNA. OPG and RANKL were elevated ~2-fold over WT in TSP1 (p<0.0001 for both) but not TSP2-/- or in TSP2-shRNA treated MSC. OPG and RANKL were also elevated in DKO MSC (p<0.01), but the magnitude of the increases were reduced compared to TSP1-/- (~40% over WT for both).Our data suggest that TSP1 and 2 make unique and cooperative contributions to osteoblast and osteocyte gene expression in the adult and aging skeleton. The data also suggest overlap between the consequences of global TSP2 deficiency and acute reduction of TSP2 gene expression.

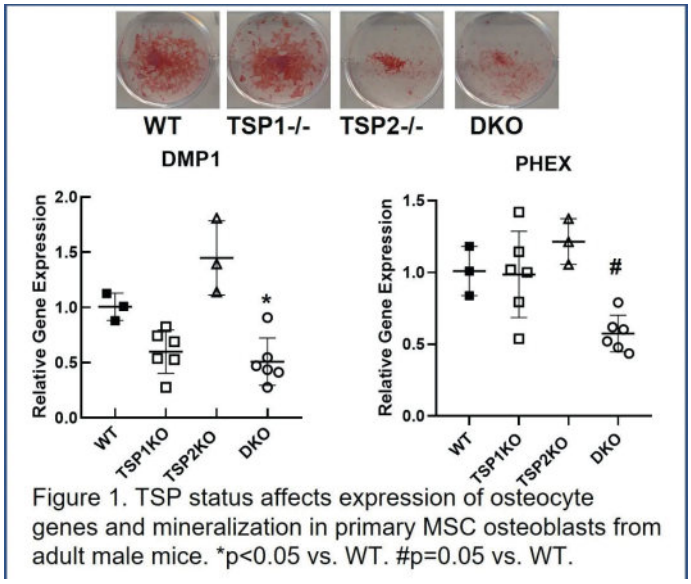

Figure 1. TSP status affects expression of osteocyte genes and mineralization in primary MSC osteoblasts from adult male mice. *p<0.05 vs. WT. #p=0.05 vs. WT.

SAT-315

Mapping the local protein interactome of PHEX in osteoblasts by proximity biotinylation *Chirada Dusadeemeelap[1], Takuma Matsubara[1], Shoichiro Kokabu[1], William Addison[1]. [1]Kyushu Dental University, Japan

Inactivating mutations in PHEX cause impaired matrix mineralization and hypophosphatemia in X-linked dominant hypophosphatemic rickets (XLH). PHEX is a Type II membrane protein with an extracellular endopeptidase catalytic domain. To better understand the molecular mechanisms and protein-protein interactions which dictate PHEX's critical functions and underly XLH, we used proximity-dependent biotin identification (BioID) combined with mass spectrometry (MS) to define the PHEX interactome in osteoblast cells. BioID utilizes the fusion of a mutant form of BirA biotin ligase to a bait protein thereby permitting the specific labeling of proximal proteins in live cells within a delimited time period. Unlike classical affinity-purification proteomic approaches, BioID is well suited for the identification of insoluble matrix proteins, transient or weak associations and the membrane-anchored topology of PHEX.Protein fractionation, immunofluorescent imaging, PNGaseF analysis and PHEX activity assays confirmed that fusion of the biotin ligase to the C-terminal extracellular domain of PHEX (PHEX-BIOID) did not adversely affect PHEX subcellular localization, transmembrane orientation, glycosylation or endopeptidase activity in MC3T3-E1 osteoblast cells. MC3T3-E1 cells stably expressing PHEX-BIOID were differentiated for 12 days, treated with biotin for 24 hours and candidate factors identified by biotin-affinity capture and MS analysis. We discovered a PHEX proximity interaction network consisting of 21 proteins. Notably, several candidates with documented roles in endochondral bone morphogenesis, extracellular structure organization and collagen fibril organization were identified. Gene ontology analysis also revealed factors with underappreciated roles in integrin activation and cell adhesion molecule binding. Coimmunoprecipitation validated direct interaction of PHEX with selected candidate factors.In summary, our study provides a comprehensive map of the local PHEX interactome and provides a resource for unraveling the molecular mechanisms underlying PHEX-related functions and XLH disease. We show that the BioID approach is a powerful tool to explore membrane-matrix relationships in osteoblasts.

The Effects of Hypochlorous Acid Antiseptic Solution on Cultured Osteoblast Proliferation *Madison Gregory[1], Ryan Moon[1], Patrick Brooks[1], Joshua Smith[1], Amanda Brodeur[1]. [1]Missouri State University, United States

Stabilized hypochlorous acid (HOCl) solutions have broad microbicidal activity at very low concentrations. With low toxicity to human tissues, these solutions are increasingly used as antiseptics in wound treatments. Contaminated orthopedic injuries such as compound fractures have a high rate of chronic infection despite operative irrigation and use of parenteral antibiotics. HOCl may be useful as an operative irrigant in this setting, yet the effects of hypochlorous acid on bony tissue and osteoblasts are unknown.Investigating the potential role of HOCl irrigation for contaminated orthopedic wounds, cultured osteoblasts were incubated with varying concentrations of a commercially available stabilized HOCl solution (Pure&Clean, Nixa, MO). Osteoblast survivability and proliferation was assessed. The LD50 of HOCl solution was assessed for Staphylococcus aureus, the most common pathogen in post-traumatic osteomyelitis, as well as for other common bacterial contaminants

of compound fractures. Bacterial cultures were exposed to hypochlorous acid at various concentrations and remaining colony forming units were calculated.Osteoblast cells were incubated in differing concentrations of HOCl and counted at varying durations following exposure. This work suggests that osteoblasts exposed to various concentrations of HOCl solution maintain proliferation in the short term. At the highest concentrations tested of up to 100 ppm, osteoblast survivability is not negatively impacted by HOCl, and survivability may be enhanced by its presence. Through culturing techniques and experimentation, osteoblast survivability appears more dependent on buffering conditions of incubation solutions. This work suggests that osteoblast growth media promotes greater survivability than HEPES and PBS. Finally, the potent bactericidal effects of hypochlorous acid were confirmed by reaching the LD50 against Staphylococcus aureus, Escherichia coli, and Pseudomonas aeruginosa at solution concentrations of less than 10 ppm.HOCl has bactericidal effects at extremely low concentrations yet does not show toxicity to osteoblasts in culture at concentrations used in some commercially available HOCl antiseptics. Overall, this study contributes to the growing body of research that HOCl may be safe as an irrigation solution for living cells, and potentially osteoblasts. Further investigation into the feasibility of HOCl irrigation of contaminated orthopedic tissues is warranted.

Discovery of a novel tubulin isotype switch in microtubule cytoskeleton during osteoblast differentiation. *Shreya Patel[1], Marcus Winogradzki[1], Waddell Holmes[1], Niyati Patel[1], Ahmad Othman[1], Ryan Ross[1], Jitesh Pratap[1]. [1]Rush University Medical Center, United States

Differentiation of osteoblasts (OB) involves remarkable changes in gene expression, cytoskeletal proteins, and secretory activity. A network of microtubules (MT) supports intracellular vesicular trafficking and secretion. However, specific changes in the MT structure and function during differentiation are currently unknown. We show that disruption of MT structure inhibits differentiation. MTs are composed of heterodimers of ?- and ?-tubulins. The ?- and ?-tubulin isotypes and their post-translational modifications control the properties and functions of the MTs, a concept known as the 'tubulin code'. The objective of our study was to understand the changes in tubulin code during OB differentiation. First, we examined the expression levels of the 7 tubulin isotypes in primary mouse calvarial OB, fetal human OB, and mouse IDG-SW3 differentiation models via qRT-PCR and western blots. We found a robust increase in the mRNA and protein levels of TUB ?2, while a decrease of TUB ?3, indicating a novel tubulin isotype switch during differentiation. We validated these findings in vivo using mouse femurs revealing differential staining of OB in the endosteum and periosteum regions, suggesting a spatiotemporal function of TUB ?2 and TUB ?3 isotypes. The expression levels and integration of the isotypes into the MT polymer control its stability and regulate the interaction of MT-associated proteins. We then examined the post-translational modifications of tubulins and found a significant increase in the acetylation levels of Lys-40 of the ?-tubulin during differentiation. Acetylation prevents MT breakage and makes them more stable. Our immunofluorescence studies showed a differential subcellular distribution of TUB ?2 and TUB ?3 and their colocalization with acetylated MTs. These changes in the tubulin code indicate specific modifications in MTs to promote subcellular vesicular trafficking and secretion of matrix proteins. To understand the regulation of the code, we analyzed ChIP-Seq data from differentiating OB. We found increased recruitment of Runx2 on the TUB ?2 gene locus, revealing a novel role of Runx2 in controlling the isotype switch. Taken together, we discovered a tubulin isotype switch reflecting increased MT stability during differentiation. Our findings show a novel regulation of OB differentiation via tubulin code. Understanding the control mechanism of the tubulin code may lead to the development of targeted therapies for osteoporosis and osteopenia.

Osteoblasts and Bone Nodules in vitro enhance understanding of how osteoblasts produce bone matrix: mechanism of bone labeling by calcium binding fluors *Quitterie Larrouture[2], Irina Tourkova[2], Deborah Nelson[3], Paul Schlesinger[4], Harry Blair[2]. [2]University of Pittsburgh, . [2]University of Pittsburgh, United States. [3]University of Chicago, United States. [4]Washington University , United States

Osteoblasts in vivo form an epithelial-like layer with tight junctions between cells. Bone formation involves mineral transport into the matrix and acid transport to balance pH in the bone with extracellular fluid. To study how osteoblasts mineralize in vitro, we cultured stromal stem cells (SSCs) on perforated polyethylene terephthalate membranes. SSCs prepared from murine bone marrow were used to investigate alternative conditions whereby osteoblast differentiation would better emulate in vivo bone development. SSCs were characterized by flow cytometry with CD44, Sca-1 and CD105 positive labeling and CD45 negative. Initially the SSC produced a monolayer; at 2.5 weeks we noted resistance of 100+/-10% ohms.cm2 across the cell layer. Calcein is commonly used as a marker for identification of bone growth in vivo, however, the mechanism is not well understood. Osteoblasts accumulate the fluorescent calcium binding protein (calcein), possibly via ATCC1, the only MDR transporter in avian osteoblasts greenscreen. In culture, the osteoblasts accumulate calcein, on their apical surface where mineral formation is observed which is the opposite site of the PET membrane. We incubated plates with 5 μM calcein and with 10 μM of the non-fluorescent inhibitors of multidrug resistance protein transport vinblastine or diltiazem. This showed calcein transport in the initial layer of osteoblasts that behaves as a tight epithelium is inhibited by two known inhibitors of the MDR mechanism. Mineralization was validated with paracellular alkaline phosphatase activity and mineral deposition. Cross-section of bone nodule formed by mineralizing osteoblasts revealed its structure with osteocyte-like cells within the nodule, surrounded by a dense collagenous matrix. The surface of the bone nodule is covered by cuboidal osteoblast-like cells. Membrane attached osteoblasts in vitro had abundant mitochondria consistent with active transport that is mediated in vivo by surface osteoblasts. These findings suggest that osteoblasts produce bone matrix on their apical side, transport protons from the apical side to the basolateral side and release the protons in the ECF. This in vitro model is a major advancement in modeling bone in vivo for understanding of osteoblast bone matrix production.Figure 1: Mineralizing osteoblasts cultured with calcein fluorescence and non-fluorescent MDR inhibitors. Bone nodule at 2 weeks of differentiation on PET membrane, 20x.

Analysis of the molecular influence of Wnt1 using osteogenic cell lines *Wenbo Zhao[1], Michael Amling[1], Timur Alexander Yorgan[1], Thorsten Schinke[1]. [1]University Medical Center Hamburg-Eppendorf, Germany

Mutations of WNT1 have been identified to cause either early-onset osteoporosis or osteogenesis imperfecta type XV, and the key role of Wnt1 for skeletal integrity was further confirmed by the analysis of corresponding mouse models. Moreover, although we observed a remarkable osteoanabolic influence of Wnt1 in transgenic mice with inducible Wnt1 expression in osteoblasts, the underlying mechanisms still remain to be established.To identify putative receptors of Wnt1 in osteoblasts and transcriptional targets mediating this response, we treated mesenchymal ST2 cells, MC3T3-E1 cells or primary murine osteoblasts with a recombinant Wnt1/Sfrp1 complex. Long-term treatment (15 days) with reWnt1/Sfrp1 during osteogenic differentiation significantly promoted osteogenesis of mesenchymal ST2 cells but not of MC3T3-E1 or primary osteoblasts. Based on these findings we analyzed the expression of all known Fzd genes encoding putative components of a Wnt1 receptor complex. We observed remarkably higher expression of Fzd2 and Fzd4 in Wnt1-responsive ST2 cells, when compared to MC3T3-E1 or primary osteoblasts. We additionally investigated the expression of all Fzd genes during osteogenic differentiation in primary osteoblasts, where we observed a general pattern of higher expression in early stages, especially for Fzd1, Fzd2 and Fzd9.In order to explore down-stream effects of Wnt1, we performed genome-wide expression analysis of short-term (6h) reWnt1/Sfrp1 treated ST2 cells. Here we observed significantly higher expression of known Wnt target genes (such as Apcdd1), but also of Osteomodulin (Omd) and Periostin (Postn). Importantly, the two latter genes were also identified to be strongly induced in another genome-wide expression analysis, where we analyzed ST2 cells 3 days after the transfection of a Wnt1 expression plasmid.Our data not only demonstrate that two established osteogenic cell lines display different responsiveness to Wnt1 administration, but also suggest that Wnt1 primarily acts on osteoblast progenitors. Based on our molecular findings, it now remains to be verified, if Omd and Postn are relevant downstream mediators of Wnt1 to promote bone formation, and if one of the Fzd genes with relatively higher expression in ST2 cells encodes a physiologically relevant Wnt1 receptor.

?-catenin phosphorylation by ?2-adrenergic activation: New insights into sympathetic inhibition of osteoblasts *Leah Worton[3], Anna Curtin[2], Edith Gardiner[3]. [3]University of Washington, United States. [2]The University of Washington, United States. [3]University of Washington,

The sympathetic nervous system modulates bone mass by increasing bone resorption and inhibiting bone formation through osteoblastic ?2-adrenergic receptor (?2AR). ?-adrenergic activation in osteoblasts stimulates cAMP/PKA signaling upstream of the tran-

scriptional inhibition of proliferation/differentiation and support of osteoclastogenesis. The present study expands the signaling/mechanism by which this activation regulates osteoblast function. All data were generated from at least 3 independent culture studies and are presented as percentage change from the mean. Treatment of differentiating MC3T3 pre-osteoblastic cells with the ?-adrenergic agonist isoproterenol (ISO) resulted in decreased mineralization (-36%, p<0.001); this was mirrored in primary BMSCs from WT but not ?2AR KO mice. Further, ?-adrenergic stimulation in MC3T3 cells with ISO increased cell attachment (+165%, p<0.001) and reduced transwell migration (-45%, p<0.05). This decrease in migration was confirmed in osteoblastic outgrowth cells from WT mice (-48%, p<0.001) but negated in ?2AR KO cultures. Activation of ?-adrenergic signaling in MC3T3 cells also resulted in a higher cytoskeletal G/F-actin ratio, with F-actin decreased by ISO treatment (-85%, p<0.001). Investigating this inhibition of osteogenic signaling we found increased phosphorylation of ?-catenin at serine residues 552 and 675 downstream of ?2AR activation with ISO (p<0.05). These phosphorylation events were inhibited by pre-treatment with the ?-adrenergic antagonist propranolol or PKA inhibitor H89, suggesting that ?-catenin phosphorylation downstream of ?2AR is via G-protein coupled signaling. These phosphorylation events were also dependent on activation of PAK4 kinase. ISO did not affect GSK3? phosphorylation, activation of ?-catenin at S33/S37/T41, or canonical Wnt target gene expression. Co-immunoprecipitation suggested enhanced interaction of pS552/675 ?-catenin with Cadherin 11/?E-catenin after ISO treatment. This ?2-adrenergic response in osteoblasts may divert ?-catenin from its canonical Wnt pathway transcriptional role, instead promoting cadherin interaction at the cell membrane, reducing actin polymerization and cell migration and enhancing cell attachment, thereby modulating osteoblast function. These data reveal ?-catenin as a novel downstream effector of ?2-adrenergic signaling, which has not previously been reported in osteoblasts or any other cell type.

Effects of PTH on Osteoblast Bioenergetics in Response to Glucose *VICTORIA DEMAMBRO[1], Li Tian[2], Dr. Clifford ROsen[3], Anyonya Guntur[1]. [1]MaineHealth Institute for Research, United States. [2]West China Hospital, Sichuan University, China. [3]Maine Medical Center, United States

Parathyroid hormone acts through its receptor, PTHR1, expressed on osteoblasts, to control bone remodeling. Metabolic flexibility for energy generation has been demonstrated in several cell types coupled to substrate availability. Recent studies have identified a critical role for PTH in regulating glucose, fatty acid and amino acid metabolism thus stimulating both glycolysis and oxidative phosphorylation. Therefore, we postulated that PTH stimulates increased energetic output by osteoblasts either by increasing glycolysis or oxidative phosphorylation depending on substrate availability. To test this hypothesis, undifferentiated and differentiated MC3T3E1C4 calvarial pre-osteoblasts were treated with PTH to study osteoblast bioenergetics in the presence of exogenous glucose. Significant increases in glycolysis with acute ~ 1hr PTH treatment with minimal effects on oxidative phosphorylation in undifferentiated MC3T3E1C4 in the presence of exogenous glucose were observed. In differentiated cells, the increased glycolysis observed with acute PTH was completely blocked by pretreatment with a GLUT1 inhibitor (BAY-876) resulting in a compensatory increase in oxidative phosphorylation. We then tested the effect of PTH on the function of complexes I and II of the mitochondrial electron transport chain in the absence of glycolysis. Utilizing a novel cell plasma membrane permeability mitochondrial (PMP) assay, in combination with complex I and II specific substrates, slight but significant increases in basal and maximal oxygen consumption rates with 24hr PTH treatment in undifferentiated MC3T3E1C4 cells were noted. Taken together, our data demonstrate for the first time that PTH stimulates both increases in glycolysis and the function of the electron transport chain, particularly complexes I and II, during high energy demands in osteoblasts.

Irisin Enhances Mitochondrial Function in Differentiating Osteoclast Progenitors *Eben Estell[1], Tsunagu Ichikawa[2], Cliff Rosen[1]. [1]MaineHealth Institute for Research, United States. [2]University of New England College of Medicine, United States

Irisin is a signaling factor released from muscle during exercise1 known to modulate bone remodelling2,3. We have shown that irisin influences the resorptive processes of remodelling by stimulating osteoclastogenesis. The ability of brief initial irisin exposure to yield increased osteoclast numbers later in culture points to a rapid action on the progenitor4. Osteoclasts and their progenitors support the high energy demands of differentiation and resorption with increased mitochondrial glucose metabolism compared to other cells5. We have previously demonstrated via mitochondrial stress testing that irisin enhances mitochondrial respiration in the osteoclast progenitor, elevating basal oxygen consumption rate and significantly increasing maximal and spare energy capacity. The present study further investigates this mechanism with the hypothesis that enhanced respiration is due to an overall increase mitochondrial biogenesis in the osteoclast progenitor. Primary murine osteoclasts were differentiated in vitro from bone marrow progenitors as previously described5 for 48 hours with or without 10 ng/mL irisin prior to visualization of cellular content of mitochondria and reactive oxygen species via fluorescence microscopy. Irisin treatment resulted in a significant increase in mitochondrial content as quantified by relative fluorescence intensity of the MitoTracker Red CMXRos dye, averaged for the body of individual cells (Figure 1a-c). Similarly, irisin treatment resulted in a significant increase in intercellular levels of reactive oxygen species, as quantified by cellular fluorescence of the CellROX Green dye (Figure 1d-f). Together these data support previous mitochondrial stress test results by showing that irisin enhances mitochondrial content and production of reactive oxygen species, an output of mitochondrial respiration that plays a vital signaling function during osteoclastogenesis6. This enhancement of mitochondrial function may thus be a driving mechanism in the stimulation of osteoclastogenesis by irisin, providing both an energy source and key intercellular signaling factors to differentiating progenitors. Ongoing work weeks to elucidate the utilization of different metabolic processes during osteoclastogenesis, and the influence of irisin thereupon. References: 1) Bostrom et al. Expression of Ubiquitin-Specific Peptidase 4 (USP4) and its Impact on Bone Resorption in Human Osteoclasts *Victor Goguen-Couture[1], Papa Yaya Badiane[1], Michèle Roy[1], Jean-Philippe Brosseau[2], Sophie Roux[1]. [1]Rheumatology, Department of Medicine, Sherbrooke University, Canada. [2]Department of Biochemistry and Functional Genomics, Sherbrooke University, Canada

Alternative splicing (AS) plays a central role in protein diversity and may regulate OC activity. Using a PCR-based screening strategy, we previously identified an alternative splicing event in USP4 (encoding ubiquitin-specific protease 4) significantly associated with the overactive phenotype of osteoclasts in Paget's disease of bone (Klinck et al, 2014). USP4 is a de-ubiquitinase that exhibits specificity for both degradative (Lys48) and regulatory (Lys63) ubiquitin chains. In other systems, some USP4 targets involve signaling components, such as TAK1, TRAF6 or PDK1, all components known to be critical in osteoclasts. In mice and humans, two isoforms of USP4 are produced by AS, differing by 47 residues (exon7), which may regulate substrate selectivity as their relative abundance varies between tissues and also alters the subcellular distribution of USP4. In addition, most of the phosphorylation sites of USP4 are located in exon 7, suggesting a different regulation for the isoforms of the protein. Since USP4 had never been studied in osteoclasts, our first objective was to investigate the localization and the roles of USP4 in human osteoclasts. We used cord blood monocytes as osteoclast precursors in in vitro long-term cultures (N=5). We first confirmed USP4 protein

expression by western blot, as well as its subcellular localization by immunofluorescence in bone resorbing osteoclasts. The impact of USP4 on osteoclast activity was studied by comparing osteoclast transfected at D17 of three-week cultures with USP4-specific DsiRNAs or a negative control, or left untransfected, allowing an average 60% decrease in USP4 expression in presence of USP4-specific vs control DsiRNA. Inhibiting USP4 induced a significant 2/3 decrease in bone resorption compared with negative controls, with an associated decrease in the number of multinucleated cells. The impact of isoforms on nuclearity and resorption is being evaluated. Thus, USP4 may have a potential role in the regulation of osteoclast bone resorption in human osteoclasts, although the exact mechanism and the osteoclast targets remain to be elucidated, as does the impact of spliced isoforms.

Vitamin A Enhances Periosteal Osteoclastogenesis by Stimulating Macrophage/Osteoclast Progenitor Cell Proliferation *Petra Henning[1], Anna Westerlund[1], Karin Horkeby[1], Vikte Lionikaite[1], Sofia Movérare-Skrtic[1], H. Herschel Conaway[1], Ulf H. Lerner[1]. [1]Sahlgrenska Academy at University of Gothenburg, Sweden

A deleterious effect of elevated levels of vitamin A on bone health has been reported in numerous clinical studies. Mechanistic studies in rodents have shown that numbers of periosteal osteoclasts are increased, while endocortical osteoclasts are simultaneously decreased by vitamin A treatment. These observations indicate that osteoclastogenesis on the endocortical and periosteal surface of bone is differentially controlled by vitamin A. The present study investigated the in vitro effect of all-trans retinoic acid (ATRA), the active metabolite of vitamin A, on osteoclast differentiation using periosteal osteoclast progenitors. Mouse calvarial bone cells were cultured in media containing ATRA, with or without the osteoclastogenic cytokine RANKL, on plastic dishes or bone discs. Whereas ATRA did not stimulate osteoclast formation alone, the compound robustly potentiated the formation of RANKL-induced bone resorbing osteoclasts. This effect was due to stimulation by ATRA (EC50 ~3nM) on the numbers of macrophages/osteoclast progenitors in the bone cell cultures, as assessed by mRNA and protein expression of several macrophage and osteoclast progenitor cell markers, such as M-CSF receptor, RANK, F4/80 and CD11b, as well as by FACS-analysis of CD11b+/F480+/Gr1- cells. The stimulation of macrophage numbers was independent of increased M-CSF and IL-34. These observations demonstrate a novel mechanism by which vitamin A enhances osteoclast formation specifically on periosteal surfaces.

Downregulation of receptor activator NF-kB (RANK) expression by CpG methylation of its gene promoter in aging model. *Riko Kitazawa[1], Ryuma Haraguchi[2], Sohei Kitazawa[3]. [1]Ehime University, Graduate School of Medicine, Japan. [2]Ehime University Graduate School of Medicine, Japan. [3]Ehime University, Japan

The precise mechanism of senile osteoporosis, which occurs in the elderly regardless of gender, remains largely unknown. We investigated the regulation of the receptor RANK gene expression by methylation using a high-passaged mouse osteoclast progenitor cell line, RAW264.7, as an in vitro model of aging. A comprehensive DNA methylation analysis was implemented with the use of low- and high-passaged RAW264.7 and bone marrow stromal cell line, ST2. CpG-island located in a regulatory region of RANK gene was maintained in a hypomethylated state in RAW264.7 cells, but accumulated in ST2 cells, suggesting that hypermethylation of CpG-island in RANK gene promoter is involved in its cell type-specific expression. In the RAW264.7 cells after prolonged passaging, receptor RANK expression was downregulated, resulting in decreased sRANKL-induced osteoclastogenesis and expression of TRACP and CTSK. Epigenome study of high-passaged RAW264.7 cells revealed that genes important in osteoclastogenesis, such as NFATc1, MITF, AP-1, and PU.1, did not change methylation status. On the other hand, methylation-specific PCR and bisulfite mapping confirmed hypermethylation of a small fraction of CpG-island (methylation at 22 out of 25 sites) in high-passaged cells. ICON probe-mediated in situ demonstration of methylated-cytosine at this CpG site revealed that the percentage of cells with methylation in the RANK gene increased in a passage-dependent manner in RAW264.7 cells. Conversely, upon treatment with demethylating agent 5-azacytidine, high-passaged RAW264.7 cells showed restoration of RANK expression, osteoclastogenesis, TRACP and CTSK expression. Ex vivo cultures of splenic macrophages from young (10.5W) and aged (12M) mice also showed that CpG methylation was predominant and RANK expression and osteoclastogenesis were reduced in the aged animals. In macrophage lineage cells, including osteoclast progenitors, overall DNA methylation was not significantly affected by passage loading, but for the RANK gene, its downregulation by methylation was observed in some aging osteoclast progenitor cells in both cell line RAW264.7 and mouse individuals. Reduced RANK expression by age-related accumulation of DNA methylation (type A methylation), albeit seen in some population of osteoclast precursor cells, may be involved in low-turnover bone in aged populations.

AhR ligands regulate subchondral bone remodeling via osteoclast differentiation *Yuri Yoshikawa[1], Takashi Izawa[2], Yusaku Hamada[1], Yuuki Namba[1], Gohji Kozaki[1], Hiroshi Kamioka[3]. [1]Department of Orthodontics, Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama University, Japan. [2]Okayama University Grad Sch, Japan. [3]Okayama University Graduate School of Medicine, Dentistry, and Pharmaceutical Sc, Japan

Bone loss due to smoking represents a major risk factor for fractures and bone osteoporosis. Signaling through the aryl hydrocarbon receptor (AhR) and its ligands contributes to both bone homeostasis and inflammatory diseases. The aim of this study was to investigate possible mechanisms which mediate bone loss in the TMJ due to smoking. In particular, whether benzo[a]pyrene (B[a]P), a carcinogen of tobacco smoke, induces expression of the AhR target gene, Cyp1a1, in mandibular condyles. Possible functions of an endogenous ligand of FICZ, were also investigated in a TMJ-osteoarthritis (OA) mouse model. B[a]P was administered orally to wild-type and AhR?/? mice and bone metabolism was subsequently examined. Therapeutic functions of FICZ were detected with ?CT and histology. Exposure to B[a]P accelerated bone loss in the mandibular subchondral bone. This bone loss manifested with osteoclastic bone resorption and upregulated expression of Cyp1a1 in an AhR-dependent manner. In a mouse model of TMJ-OA, FICZ exhibited a dose-dependent rescue of mandibular subchondral bone loss by repressing osteoclast activity. Meanwhile, in vitro, pre-treatment with FICZ reduced RANKL-mediated osteoclastogenesis. B[a]P regulates mandibular subchondral bone metabolism via the Cyp1a1. The AhR ligand, FICZ, can prevent TMJ-OA by regulating osteoclast differentiation.

A novel biomaterial for functional and analytical recapitulation of osteoclastogenesis in vitro *Yongkuk Park[1], Jungwoo Lee[2]. [1]University of Massachusetts Amherst, . [2]University of Massachusetts-Amherst, United States

Osteoclasts, the multinucleated bone-resorption cells that exclusively develop on the bone surface during bone remodeling, is a primary target for osteoporosis drug development as their relatively increased activity leads to bone loss. Accurate in vitro recapitulation of osteoclast biology is essential for screening potential toxicity and predicting pharmacological responses. Recent animal studies have revealed the critical roles of osteoblasts in regulating osteoclast function and the longer lifespan of osteoclasts than previously thought, partly through fission and recycling. However, existing osteo-culture and assay platforms are limited in reproducing these newly identified processes. Here, we introduce a novel in vitro osteoclast differentiation and functional assay platform utilizing osteoid-inspired demineralized bone paper (DBP), a thin slice of demineralized compact bone matrix. DBP supports rapid, structural mineral deposition by osteoblasts while retaining optical transparency for imaging. Osteoblasts and bone marrow monocytes coculture on DBP under biochemical stimulation recapitulated in vivo-relevant osteoclastogenesis. Longitudinal fluorescent monitoring substantiated osteoclast fusion, mineral resorption, and fission. Finally, a simulated clinical scenario of bisphosphonate treatment demonstrated with significantly reduced the number and lifespan of osteoclasts due to mineral-bound bisphosphonate. The DBP-based bone model can significantly facilitate the development of osteoclast-targeting drugs and understanding various aspects of bone remodeling biology with high fidelity and analytical power.

Osteoclast Deletion of Kalirin, a Dual GTP Exchange Factor Protein, Decreases Bone?Mass *Katie Chester[1], Daniel Godfrey[1], Jung Min Hong[1], Mauro Tudares[2], Angela Bruzzaniti[3]. [1]Indiana University School of Dentistry, United States. [2]Indiana Unversity School of Dentistry, United States. [3]Indiana University School of Dentistry , United States

Kalirin is a multi-faceted protein with dual GTP/GDP activity which has previously been characterized in neurons, but its skeletal role remains unclear. Our group reported that Kalirin global knock-out mice exhibit profound decrease in bone mass, with females demonstrating more bone loss than males, compared to sex- and age-matched wild-type littermates. To investigate the contributing cellular mechanisms, we examined Kalirin deletion in osteoclasts (OCs) by crossing Kalirin flox/flox (Kal) mice with Cathepsin K (CatK) and TRAP Cre-recombinase mice. Male and female Kal-CatK-Cre and Kal-TRAP-Cre and Cre- littermates underwent in-vivo Lunar Piximus Densitometer analysis at 8-, 14- and 26-weeks (n=7-10). Changes in femoral bone mineral content (BMC), bone area and bone mineral density (BMD) were determined. Female Kal-CatK-Cre mice showed a significant decrease in BMC (-7.0%), bone area (-3.3%) and BMD (-4.0 %) at 14-weeks, with no statistical changes observed at 8- and 26-weeks. No significant changes were observed in male Kal-CatK-Cre mice at the ages examined. To assess OC formation in vitro, non-adherent bone marrow cells were differentiated with RANKL and MCSF, resulting in increased OC formation in Kal-CatK-Cre, compared to Cre- mice. Consistent with the Kal-CatK-Cre data, Kal-TRAP-Cre females showed a significant decrease in BMC (-6.3%) and bone area (-7.5%) ($p<0.05$) at 14-weeks. These results indicate that Kalirin regulates OCs and bone mass in female mice. In addition, other bone cell types or alternative physiological mechanisms contribute to the regulation of total bone mass by Kalirin. Expanded longitudinal assessment of mice with cell-targeted deletion of Kalirin will elucidate the individual or combinatory mechanisms regulating Kalirin's effects on overall bone mass.

Human Osteoclast Assays for Identifying Antiresorptive Treatments with Different Mechanisms of Action *Katja Fagerlund[1], Mervi Ristola[1], Jenni Mäki-Jouppila[1], Jukka Rissanen[1]. [1]Pharmatest Services Ltd, Finland

Several agents are approved for the treatment of osteoporosis, of which antiresorptive treatments primarily target osteoclasts by reducing their lifespan or activity. Zoledronic acid, a third generation nitrogen containing bisphosphonate, accumulates in bones where it binds to hydroxyapatite crystals. For years, zoledronic acid has been used to prevent or treat osteoporosis and regarded as the standard of care for patients with advanced cancer and bone metastasis to prevent skeletal complications. As an alternative therapeutic option, denosumab has also been found to be potent antiresorptive for treatment of osteoporosis and effective in delaying skeletal-related events in advanced cancer. Denosumab, a human monoclonal antibody against receptor activator of nuclear factor kappa-B ligand (RANKL), blocks the RANKL/RANK signalling pathway. In this study, effects of zoledronic acid and denosumab on osteoclast differentiation and bone resorption activity were studied using human osteoclast precursor cells that were cultured on bovine bone slices in 96-well plates for 7 days in the presence of RANKL and M-CSF, allowing them to differentiate into mature osteoclasts. In the osteoclast differentiation assay, zoledronic acid (0.001 - 500 µM) and denosumab (0.01 - 10 µg/ml) were added into the culture medium at day 0. Tartrate-resistant acid phosphatase 5b (TRACP 5b) activity was measured in the culture medium at day 7 as an index of osteoclast differentiation. In the osteoclast activity assay, the test compounds were added into the culture medium at day 7, and the formed osteoclasts were allowed to resorb bone for 3 days. C-terminal crosslinked telopeptides of type I collagen (CTX-I) was measured in the culture medium at day 10 as an index of bone resorption. Denosumab and zoledronic acid showed strong concentration dependent inhibition of osteoclast differentiation and resorption activity. We conclude that this osteoclast culture system can be used for identifying new potential compounds affecting osteoclasts with different mechanisms of action.

Development of a Semi-Automated Digital Imaging Pipeline for Evaluation of Osteoclast Phenotypes in vitro *Anders Narum[3], MARGARET DURDAN[2], ANGELO GUILATCO[2], Christine Hachfeld[3], GABRIEL ALVARES BORGES[3], Megan Weivoda[3]. [3]Mayo Clinic, . [2]Mayo Clinic/University of Michigan, . [3]Mayo Clinic, United States

Osteoclasts (OCs) are myeloid-derived, bone-resorbing cells and are essential for healthy bone remodeling. In traditional in vitro osteoclastogenesis assays, OCs are quantified manually as multinucleated (>=3 nuclei) cells positive for Tartrate Resistant Acid Phosphatase (TRAP) activity. However, this method is time consuming and doesn't capture important characteristics of OC size, number of nuclei, and nuclear distribution that may be informative about OC functions and in vivo bone phenotypes. The goal of this study was to develop digital imaging analysis pipelines to automate the quantification of OC, including morphologic characteristics. Further, resorptive activity on bovine bone chipsOCs were generated from young (4 months) and old (32 months) male C57BL/6 mouse bone marrow macrophages using recombinant M-CSF and RANKL (n=3 per group). OC cultures were fixed after five days of differentiation; cells were TRAP stained and counterstained with Hoechst to assess nucleation. Whole wells were imaged using an EVOS automated fluorescent microscope. Images were run through a custom CellProfiler pipeline, identifying TRAP+ primary objects. Nuclei were detected as secondary objects and quantified per primary object (TRAP+ cell). Primary object morphometric data, including secondary object (nuclei) quantification was exported for analysis. Using this pipeline to compare young and old mouse derived OCs, we identified significant increases in the number of small (3-5 nuclei) and medium OCs (6-10 nuclei, p10 nuclei) was not significantly different; however, the area of large osteoclasts derived from old mice was trending larger than those from young mice. The overall morphometric parameters allow for principal component analysis and clustering of single OCs. These data are currently being tested for correlation with OC resorptive behavior on bovine bone chips in vitro as well as in vivo bone phenotype (micro computed tomography, histomorphometry, serum markers of bone remodeling). This semi-automated pipeline will facilitate the analysis of heterogeneity in OC and functional behavior and how these in vitro measures inform in vivo bone phenotypes.

Sclerostin and Wnt Signaling in Idiopathic Juvenile Osteoporosis *Renata Pereira[1], Isidro Salusky[2], Barbara Gales[2], Kathleen Noche[2], Lauren Albrecht[3]. [1]UCLA, United States. [2]University of California Los Angeles , United States. [3]University of California Irvine , United States

Idiopathic juvenile osteoporosis (IJO) is a condition characterized by low bone mass that can increase the risk of fractures in children. The molecular mechanisms underlying the initiation and progression of disease is incompletely understood, especially compared to adult osteoporosis, because it is uncommon. A key driver of osteoporosis in adults is sclerostin given its inhibitory roles on osteoblast activity and Wnt signaling. To evaluate the role of sclerostin in IJO, high-resolution confocal microscopy analyses were performed on bone biopsies collected from 13 pediatric patients. We report for the first time that sclerostin is increased in bone of IJO patients. Bone biopsies stained with sclerostin antibodies showed elevated expression across osteocytes and increased sclerostin-positive osteocytes. Skeletal sclerostin was associated with static and dynamic histomorphometric parameters. Further, colocalization analyses showed that bone sclerostin colocalized with phosphorylated ?-catenin, a hallmark of Wnt signaling that indicates Wnt inhibition. In contrast, sclerostin-positive osteocytes were not colocalized with "active" unphosphorylated form of ?-catenin. These results provide evidence that Wnt signaling plays a role in this disease and suggest that future studies of sclerostin in IJO could help in the development of biomarkers or therapies.

Nitric Oxide Contributes to Sclerostin Protein Degradation Following Mechanical Load *HEATHER BUCK[3], Joseph Stains[2], Olivia Torre[2], Jenna Leser[2], NICOLE GOULD[3], Christopher Ward[2, 3], United States. [2]University of Maryland School of Medicine, United States. [3],

Following sufficient fluid-shear stress (FSS), osteocytes produce NOX2-derived reactive oxygen species, inducing calcium influx via TRPV4 channels. Increased intracellular calcium results in calcium-calmodulin dependent protein kinase II (CaMKII) activation, which regulates the lysosomal degradation of sclerostin. Here, we extend our discoveries identifying nitric oxide (NO) as a regulator of sclerostin degradation downstream of mechano-activated Ca2+ influx.Pharmacological inhibition of nitric oxide synthase (NOS) activity in Ocy454 osteocyte-like cells prevents FSS-induced sclerostin degradation. Conversely, short-term treatment with a NO donor in Ocy454 cells (10µM, 5min) or isolated murine long bones (15min) is sufficient to induce the rapid lysosomal degradation of sclerostin. Together these data show that NO is necessary and sufficient for sclerostin protein control.To interrogate the hierarchy of NO production within the mechano-transduction cascade that controls sclerostin protein abundance, we subjected Ocy454 cells to FSS in the presence of NOX2 or TRPV4 antagonists. Blocking NOX2 and TRPV4 prevents FSS-induced NO production, supporting that NO production is downstream of these signal transducers. Consistent with this hierarchy, NO donation was insufficient to induce Ca2+ influx in Ocy454s. Inhibition of lysosomal acidification did not alter NO production in mechanically-stimulated Ocy454s. NOS3 was identified as the predominant NOS gene expressed in Ocy454s via qPCR. Preliminary data show that siRNA knockdown of NOS2 or NOS3 abrogates FSS-induced sclerostin degradation.Emerging data show that NO donation (1min) appears sufficient to drive CaMKII activation, while NOS2/3 knockdown may also alter CaMKII activation in response to FSS. Conversely, loss of sclerostin protein expression in isolated long bones following treatment with a NO donor is abrogated in CaMKII?? dKO mice relative to WT.In conclusion, it seems that NOS3- and NOS2-dependent NO plays an essential role in the post-translational

degradation of sclerostin protein, suggesting a link between mechano-activated NO production and physiological responses initiating de novo bone formation.

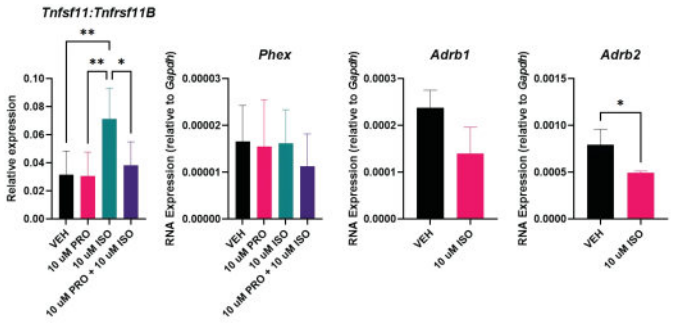
Sympathetic autonomic signaling promotes osteocyte-driven bone resorption

*Galen Goldscheitter[1], Alexandra Hooks[2], Evan Buettmann[3], Henry Donahue[3, 1], [1]United States, [2]Virginia Commonwealth University Department of Biomedical Engineering, United States, [3]Virginia Commonwealth University, United States

The sympathetic autonomic nervous system, which mediates the fight-or-flight response, has a complex role in skeletal health. Its primary effector, norepinephrine, acts on adrenergic receptors in bone. Of these, most evidence supports the role of ?1 and ?2 receptors in bone metabolism. Previous work demonstrated a catabolic effect of ?2 agonism. Further, studies suggest treatment with ?-adrenergic antagonists enhance the anabolic effect of loading via an unknown mechanism. Here, we show ?1/?2 agonism by isoproterenol (ISO) promotes a resorptive secretory phenotype in osteocyte-like cells, the primary mechanoresponsive bone cell, while ?1/?2 antagonism by propranolol (PRO) ablates this effect.OCY-454 cells were cultured at 33.5 °C to confluence in ?-MEM containing 10% FBS and 1% Penicillin/Streptomycin and exposed to vehicle (HBSS), PRO (10 ?M), and/or ISO (10 ?M) for 48 hours at 37 °C. Gene expression was measured via RT-qPCR.Treatment with the ?-receptor agonist ISO increased expression of Tnfsf11 (encodes RANKL) relative to Tnfrsf11B (encodes OPG). Treatment with PRO, alone, resulted in no change in expression. The effect of ISO was reversed when cells were co-treated with PRO. Treatment with ISO also reduced expression of ?2 adrenergic receptor (Adrb2), but not ?1 adrenergic receptor (Adrb1). No effect was seen on Phex expression, a component of the DMP1-FGF23 pathway and a marker of osteocyte differentiation.RANKL is an activator of osteoclast differentiation, and thus, a driver of bone resorption. It is inhibited by OPG which inhibits its binding on osteoclast precursors. Treatment with ISO increases relative expression of Tnfsf11 to Tnfrsf11B in osteocyte-like cells, key regulatory cells of bone metabolism. Suppression of this effect by PRO suggests this effect is driven by a primary ?1/?2-mediated mechanism. OCY-454 cells express both Adrb1 and Adrb2, and treatment with ISO decreases expression of Adrb2, but not Adrb1. Decreased receptor expression is a signal desensitization mechanism, thus suggesting ?2 is the primary mediator of this effect. Finally, ISO and PRO do not change Phex expression, suggesting this effect is not mediated by cellular differentiation state. These data introduce a novel mechanism of bone catabolism in response to sympathetic outflow; in which osteocytes secrete RANKL secondary to ?2 receptor agonism. This supports work done by other authors and suggests ?2 antagonism enhances osteogenic stimuli.



RT-qPCR of cell lysates from OCY-454 cells. Cells were treated with isoproterenol (ISO, 10 uM), propranolol (PRO, 10 uM) or vehicle (VEH) for 48 hours after reaching confluence. Statistical comparisons were made via one-way ANOVA and Tukey's post-hoc test (Tnsfs11:Tnfrsf11B, Phex) or student's t-test (Adrb1, Adrb2). * p < 0.05, ** p < 0.01

Hyperglycemia Induces Extensive Alternative Splicing Changes In Osteocyte-Enriched Cultures With Minimal Transcriptional Alterations

*Aseel Marahleh[1], Sherif Rashad[2], Hideki Kitaura[3], Jiayi Ren[3], Fumitoshi Ohori[4], Takahiro Noguchi[3], Itaru Mizoguchi[3]. [1]Tohoku University, Frontier Research Institute for Interdisciplinary Sciences, Japan. [2]Tohoku University, Graduate School of Biomedical Engineering, Japan. [3]Tohoku University, Graduate School of Dentistry, Japan. [4]Tohoku University Graduate School of Dentistry, Japan

Hyperglycemia is a hallmark of type II diabetes mellitus (T2D), and it is associated with reduced bone remodeling due to decreased bone resorption and bone formation. This state of reduced bone turnover leads to skeletal fragility and increased risk of fractures. Osteoblasts and osteocytes are the cells responsible for orchestrating the events necessary for bone remodeling to take place. Since bone cell gene expression was shown to be permanently impacted by high glucose, we reasoned that hyperglycemia would lead to extensive differential gene expression in osteocyte-enriched populations. First, we used Dmp1-Topaz neonatal calvaria, which express the topaz variant of GFP under the influence of the 8-kb Dmp1 promoter, to obtain osteocyte-enriched cultures through enzymatic digestion and cell sorting. Isolated cells were cultured under euglycemic (5.5 mM) and hyperglycemic conditions (25 mM) over 72 hours, where cell viability was comparable in both conditions as revealed by ethidium homodimer 1 staining. Second, RNA-seq data analysis revealed that high glucose diversifies the transcriptome by regulating RNA transcripts' splicing program rather than impacting gene transcription. Third, gene set enrichment analysis (GSEA) displayed a cellular environment of decreased adaptive response to oxidative stress and inflammation and increased susceptibility to apoptosis. Also, GSEA revealed a state of inhibited regulation of extracellular matrix (ECM) remodeling, including downregulation of biological processes involved in collagen catabolism and upregulation of the Hippo signaling pathway leading to YAP suppression which is implicated in poor bone accrual and poor mechanotransduction. Finally, computational analyses were performed for all five types of alternative splicing (AS) patterns and identified 2536 differential AS events between the two groups involving 719 genes, the most common of which were alternative spliced transcripts of Col1a1 and Col11a2. Additionally, we identified potential regulators of AS based on motif search analysis and found a significant enrichment in binding motifs of LIN28A/B, SRSF1 and HNRNP family and a significant depletion of KHDRBS1 and RBM41 motifs. In conclusion, we reveal that high glucose impacts AS events mostly without significant changes to gene expression, resulting in reduced cell adaptive response and an inhibited role in ECM remodeling.

RNA Sequencing Analysis of Osteoclast Related Genes in Osteocyte-like Cell Line Cultured in Hypoxic Environment.

*Kohei Narita[1], Hideki Kitaura[1], Fumitoshi Ohori[2], Takahiro Noguchi[1], Aseel Marahleh[1], Jinghan Ma[1], Kayoko Kanou[1], Mariko Miura[1], Jiayi Ren[1], Itaru Mizoguchi[1]. [1]Tohoku University, Japan. [2]Tohoku University Graduate School of Dentistry, Japan

Purpose: In orthodontic tooth movement (OTM), bone resorption occurs on the compression side by osteoclasts. In compression side, orthodontic force compresses the periodontal ligament, which affects blood vessels, causes hypoxia due to lack of blood flow. It is considered that osteocytes in the alveolar bone on the compression side are also in a hypoxia environment. Recently, it has been found that osteocytes play an important role in osteoclastogenesis. In fact, it has been reported that hypoxia increases the expression of RANKL in osteocytes and promotes osteoclastogenesis. However, it is unclear that the mechanism of hypoxia environment promotes osteoclastogenesis through osteocytes. The purpose of this study is to elucidate the effect of osteocytes in hypoxia environment on osteoclastogenesis by using RNA sequencing analysis. Materials and Methods: Osteocyte-like cells (MLO-Y4 cell) were seeded in a 10 cm dish and cultured for 24 hours. Then, they were cultured for another 24 hours under hypoxia conditions (2% O2) using a hypoxia culture kit as the hypoxic culture group. The normal oxygen group were also cultured for another 24 hours (20% O2). After culturing, total RNA was extracted from all samples and analyzed for purification of RNA by RIN (RNA Integrity Number). RNA sequencing was performed using NovaSeq6000 for gene expression analysis. In addition, gene expression was mapped to the mouse genome using DRAGEN and calculated TMP values. Statistical analysis was then performed between the hypoxic culture group and the normal oxygen culture group. Results and Discussion: RIN analysis confirmed that all samples from osteocyte-like cells had a high-quality RNA. The most upregulated gene in osteocyte-like cells cultured under hypoxia conditions was Ndor1, while the most downregulated gene was Ifnb1. Additionally, it was observed that increased expression of several osteoclast related genes, such as Tnfsf11. The results suggested that hypoxic cultured osteocytes increase various osteoclastogenic factors including RANKL. Conclusion: The expression of osteoclast related gene in osteocytes by hypoxic cultured was found. It has been suggested that osteocytes in hypoxic condition promote osteoclastogenesis.

Lack of osteoblast lineage autophagy does not alter the response to mechanical load *James Hendrixson[3], Robert Shaver[2], Alicen James[3], Jacob Laster[3], Julie Crawford[3], Jinhu Xiong[4], Melda Onal[3]. [3]University of Arkansas for Medical Sciences, United States. [2]University of Arkansas Fayetville, United States. [3]University of Arkansas for Medical Sciences, . [4]Univ of Arkansas for Medical Sciences, United States

Autophagy is a catabolic process by which cells recycle cytoplasmic content. Autophagy can play various cellular functions ranging from cellular stress response to cell differentiation. Previous studies have shown that mice lacking Atg7, an essential component of the autophagy pathway, from the entire osteoblast lineage exhibit very low cancellous and cortical bone mass associated with a 50% fracture rate. This phenotype was associated with a significant reduction in osteoblast number and bone formation. However, the underlying mechanisms are still unclear. Osteocytes are thought to serve as mechanosensing cells in bone and a reduction of the osteocyte network is thought to contribute to reduced mechanosensitivity. Notably, the deletion of Atg7 from the osteoblast lineage also caused a reduction in the osteocyte lacunocanalicular network. Additionally, mechanical strain has been shown to stimulate osteocyte autophagy in culture. Based on this, we hypothesized that autophagy contributes to mechanosensitivity by maintaining an intact osteocyte lacunocanalicular network. In support of this, Atg7floxed;Osx1-Cre (cKO) mice exhibited a low periosteal perimeter relative to control mice, a finding common to murine models with reduced mechanical response. To test our hypothesis, we isolated calvaria from cKO and Osx1-Cre (control) mice, and treated these ex vivo organ cultures with 10?M Yoda or vehicle for 24 hours. Yoda is a Piezo1 agonist, used to mimic mechanical strain in culture. Yoda treatment increased the expression of mechanosensitive genes such as Ptgs2 and Tnfsf11 independent of autophagy levels. However, transcriptional changes after a short-term mechanical stimulation in culture may not be representative of the long-term anabolic response to loading in vivo. Therefore, we tested if lack of autophagy altered the response to loading in vivo by performing tibial axial loading in 4-month-old cKO and control mice. The tibia of each mouse was loaded with equal compressive strain for 9 days within a 2-week period. MicroCT analysis revealed that mechanical loading increased cortical thickness similarly in both cKO and control mice. These results indicate that mice that lack autophagy respond normally to mechanical loading. Therefore, reduced mechanosensitivity is not responsible for the low bone formation levels and reduced periosteal perimeter of cKO mice.

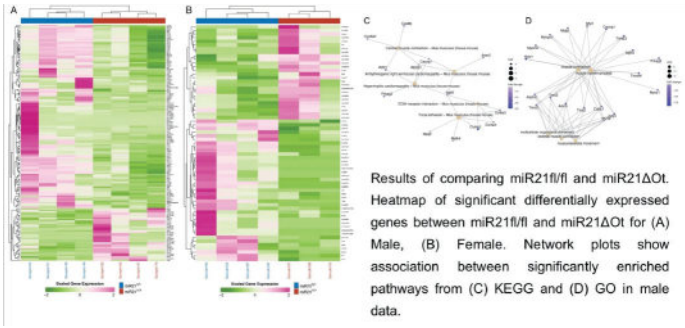
SAT-371

Sex dimorphic response to osteocyte miR21 deletion in calvaria bone as determined by RNAseq analysis. *Gang Peng[1], Padmini Deosthale[1], Hannah M. Messersmith[1], Lilian Plotkin[1]. [1]Indiana University School of Medicine, United States

Low microRNA (miR) 21 levels may explain the increase in osteocyte (Ot) apoptosis with Cx43 deletion and aging in female mice. Yet, further studies showed that miR21 exerts a sex-divergent role in osteocytes, regulating bone mass and architecture through non-cell autonomous effects on osteoblasts and osteoclasts, through sex-specific regulation of Ot cytokine production. Yet, miR21 deficiency improves bone strength in males and females, to a higher extent in male miR21-deficient mice. To understand the molecular basis for the sex-dependent or independent effects of miR21 deletion, mRNA was isolated from calvaria bones of males and females expressing miR21fl/fl (controls) or in which miR21 was deleted by 8kbDMP1-Cre (miR21?Ot mice). miR21 was 50% lower in mir21?Ot whole bone, compared to miR21fl/fl mice. 4 samples/sex and genotype were submitted for RNAseq. RNAseq reads were aligned to GRCm38 using HISAT and read counts for each gene were extracted with featureCounts. Following principal component analysis, Sample 173 (female miR21?Ot) was removed from the analysis. There were 152 genes with 1 absolute log2 fold change in the analysis of male data. Most of these genes were higher expression in miR21fl/fl group. With the 152 significant genes, the 8 male samples could be hierarchically clustered into miR21fl/fl and miR21?Ot groups. 2 of the genes, Actn3 and Myh4, had a false discovery rate <0.1. Gene enrichment analysis of significant genes on both KEGG pathways and GO gene sets shows the significant genes were enriched in muscle contraction. Some muscle related genes like Actn3 were included in multiple significant pathways. For females, only 65 genes had 1 absolute log2 fold change. The remaining 7 female samples can be clustered into miR21fl/fl and miR21?Ot groups by the 65 genes. Yet, no significant KEGG or GO pathways including >=5 significant genes were seen. Interestingly, we did not find any overlap of significant genes between male and female data. We conclude that deletion of miR21 has a stronger effect on male transcriptome, consistent with a positive effect on bone mass and remodeling, and a higher increase in bone strength compared to miR21fl/fl mice. Further, although there are some genes significantly changing in females, they are not enriched in any pathways. Either there are not difference between two groups in female or the effect size is small, and we need a larger sample size data to find differences.



Results of comparing miR21fl/fl and miR21ΔOt. Heatmap of significant differentially expressed genes between miR21fl/fl and miR21ΔOt for (A) Male, (B) Female. Network plots show association between significantly enriched pathways from (C) KEGG and (D) GO in male data.

[3]McGill University, Shriners Hospital for Children, 1003 Decarie Blvd, Montreal H4A 0A9, QC, Canada, Canada

Osteocytes reside in the mineralized bone matrix organized as a cell network. Their cell bodies are accommodated within pores called lacunae and their cell processes in channels called canaliculi. Lacunae and canaliculi together form the lacunocanalicular network (LCN). Besides facilitating transport, an important function of the LCN is to enable mechanosensation by osteocytes due to load-induced fluid flow through the LCN [1]. We follow the research strategy to detect differences in the LCN architecture and try to relate them to the network's function. In this study our aim is (i) to relate spatial heterogeneities of the LCN and material properties in whole mouse tibial cross-sections and (ii) to analyze differences in the LCN between different mouse strains.Our analysis included both tibiae of five BALB/c and four C57BL/6 mice (female, 12-week-old). After rhodamine staining the LCN in the whole tibial cross-section was imaged using confocal laser scanning microscopy (CLSM) and network properties were determined using a self-developed software. Quantitative backscattered electron imaging (qBEI) was employed to measure spatial differences in the calcium content in the same samples.In the tibial cross-sections of both mouse strains contiguous regions of high/low network density and high/low calcium content were identified, but these regions do not coincide. We asked the question whether differences in the network density are due to a different number of branching points in the network or due to a different number of branches emerging from a branching point. We found that spatial heterogeneities of the LCN were more strongly related to differences in the number of branching points. The LCN in C57BL/6 mice is denser compared to BALB/c and the difference can be explained by a network with more branching points.Spatial differences in network and material properties give important clues about the development of the bone. Since fluid flow through the LCN is influenced by its architecture, differences in the mechanoresponse between the two mouse strains have to be related to variations in their LCN.[1] van Tol et al., PNAS (2020).

High-glucose environment reduces the response to mechanical stimulation by affecting its communication with other cells in the bone marrow. *Arancha Gortazar[1], JUAN ANTONIO ARDURA[2], Joan Pizarro-Gomez[3], Irene Tirado-Cabrera[3], Sara Heredero-Jimenez[3]. [1]IMMA- School of Medicine, San Pablo CEU University, Madrid Spain, Spain. [2]MADRID, Spain. [3]IMMA- School of Medicine San Pablo CEU University, Spain

Osteocytes can detect mechanical stimuli and translate it in a biochemical signal. The response of osteocytes to mechanical stimuli has important effects on bone microenvironment. Diabetes mellitus (DM) is a highly prevalent disease with negative impact on the skeleton, which markedly increases fracture risk. Both in vivo and in vitro studies have indicated that Diabetes mellitus and high glucose concentration media reduce some of the beneficial effects of mechanical stimulation, such as bone formation or osteocyte survival. Osteocyte responses to mechanotransduction also influence other cells present in the bone marrow. Based on this, we hypothesize that hyperglycemia may modify the communication of osteocytes with bone marrow cells, including macrophages, lymphocytes, or mesenchymal cells.MLO-Y4 osteocytes were mechanically stimulated by fluid flow (FF) or not (static conditions, SC) at normal (5mM D-Glucose; NG) or high glucose (25 mM D-glucose; HG) concentration. Conditioned media (CM) and RNA were collected 18h after treatments. RAW 264.7 murine macrophage cells were stimulated with lipopolysaccharide (LPS) or IL-4 for 24h to induce M1 or M2 macrophage polarization, respectively. In these conditions we eval-

uated the effect of CM from osteocytes on macrophage polarization by qPCR analysis of M1 or M2 specific markers in normal or high glucose media. Migration studies were carried out using CM from osteocytes on C3H/10T1 mesenchymal cells and JURKAT lymphocytes . qPCRs were performed with SYBR green and specific primers for GAPDH, TNF-?, INOS and CD206.CM from osteocytes stimulated by FF or not (SC) did not modify LPS-induced M1 polarization in macrophages cultured in normal or HG conditions. In contrast, SC-CM potentiated while FF-CM inhibited M2 polarization induced by IL-4. Interestingly, CM from osteocytes treated in HG conditions completely reversed these effects. Moreover, HG significantly reduce M1 or M2 polarization induced by LPS or IL-4, respectively. In addition, FF-CM stimulated both mesenchymal C3H/10T1 and lymphocyte JURKAT cell lines migration in NG but not in HG conditions.Our results suggest that a high glucose environment weakens osteocyte communication with bone marrow cell populations, buffering osteocyte actions on mesenchymal and lymphocyte migration and macrophage polarization in response to mechanical stimulation.

A Comparison of Fixed versus Relative Offset Positioning for HR-pQCT *Annabel Bugbird[2], Rachel Klassen[2], Olivia Bruce[2], Lauren Burt[2], William Edwards[2], Steven Boyd[2]. [2]University of Calgary, , [2]University of Calgary, Canada

IntroductionIn HR-pQCT imaging, there are then two main approaches to define this scan position: (1) the fixed offset positioning, and (2) the relative offset positioning (relative to bone length). Differences between the use of these two methods may be problematic for comparison between studies and participants. It is thought that when using the fixed offset positioning, a shorter individual may result in an image captured more proximally, and in taller individuals an image captured more distally. The concern raised about a relative offset positioning method is that it assumes that the underlying bone structure scales linearly with bone length, which to the best of our knowledge has not been verified.The objectives of this study were (1) to determine how anatomical landmarks scale with whole bone length, and (2) to evaluate both a fixed and relative offset positioning for providing a consistent anatomical location for scan acquisition.MethodsUsing clinical computed tomography (CT) images of the radius (N = 25) and tibia (N = 42), 10 anatomical landmarks were selected along the bone's length. The location of these landmarks was then converted to a percent length along the bone, and the variation in the location of the landmarks was evaluated across all bones in the dataset. In addition, the absolute location of the HR-pQCT scan position using both offset methods were identified for all bones and converted to a percent length position. ResultsThere was a lack of allometric scaling in the landmarks across the dataset, with a range of 3.6% at the radius sites (Figure 1A), and 4.5% and the tibia sites. The range in the position of the scan at the radius was 0.6% and 0.3% (Figure 1B), and at the tibia 2.4% and 0.5%, for the fixed and relative offset, respectively.ConclusionIn summary, we demonstrate there is considerable normal variation in anatomical landmark positions in relation to bone length and that it is greater than the difference in scan position when comparing the fixed and relative offset positioning methods. This suggests that the difference between using the fixed or relative offset method is inconsequential as there is inherent variability in the scan location regardless of the offset method used. Therefore, there is no clear benefit of either offset method, and the intrinsic variation in the underlying architecture suggests that it is reasonable to compare studies and participants using different positioning methods.

SAT-377

Gaussian Process Regression Modeling for Real-Time Fracture Risk Prediction from 2D-DXA scans *Heesun Choi[1], Luca Quagliato[1], YOON-SOK (MARTIN) CHUNG[2], Taeyong Lee[1]. [1]Ewha Womans University, Republic of Korea. [2]Ajou University School of Medicine, Republic of Korea

Bone fracture risk assessment for osteopenia and osteoporotic patients is essential for the adoption of early countermeasures and avoid discomfort and hospitalization. Currently employed methodologies, such as FRAX®, provide calculation over a five to ten years period without showing the main variables influencing the prediction nor how they can be targeted in the short term. Thus, a lesser black-box approach where the fracture risk can be assessed in real time from a commonly employed analysis, such as dual-energy X-ray absorptiometry (2D-DXA), would help clinicians and patients alike. Accordingly, this study presents a real-time fracture risk assessment model, coupled with a feature augmentation algorithm, based on the results of a 2D-DXA scan.In this study, a ~10,000 adult Korean cohort, 70% female and 30% male ranging from 50 to 90 years of age where ~30% of the database is relevant of subjects who experienced an osteoporosis-related skeletal fracture. The 2D-DXA analyses performed on each patient allowed collecting 23 parameters, including the patients' age, BMI, gender, and fracture history, for a total of 25 scalar and one binary variable. To enhance the prediction accuracy, a feature augmentation algorithm (FAA) was developed and employed to allow for a better refinement of the parameters influence on the target function.The defined database was used to training of a Gaussian Process Regression (GPR) machine learning (ML) model, coupled with a Radial Basis Function (RBF) kernel, and validated through a 5-foldalidation and by considering various training-validation redistributed datasets. Unlike other ML models that predict exact values, the GPR algorithm, which is grounded on a Bayesian approach, presents a standard deviation of the predicted value.The GPR prediction, connected with the standard deviation, allows defining a 0-to-1 range with the associated standard deviation, allowing for the definition of the osteoporotic risk assessment, where a value close to zero represents no fracture risk whereas a value close to one a high risk. The GPR-RBF model already showed good accuracy in predicting fracture likelihood with an 89%, afterward improved to 96% thanks to the application of the FAA technique. In addition, the progressive integration of more augmented data in the training process allowed defining the limit beyond which the application of the FAA becomes counterproductive and leads to overfitting issues.

Soft Bone During Spine Surgery and Its Significance: Relationships Between Subjective Intra-operative Assessment of Bone Quality, Bone Mineral Density and Biomechanical Properties of Bone *Alexander Dash[1], Fernando Quevedo Gonzalez[2], Ryan Breighner[3], Emma Billings[4], Han Jo Kim[2], Matthew Cunningham[2], Darren Lebl[2], Emily Stein[2]. [1]Icahn School of Medicine at Mount Sinai, , [2]Hospital for Special Surgery, United States. [3]Hospital for Special Surgery/Weill Cornell Medicine, United States. [4]Hospital for Special Surgery ,

Spinal fusion surgery is one of the most common and complex orthopedic procedures. Complications occur in up to one-third of cases. While poor bone quality increases risk of post-operative complications, many patients are not evaluated for skeletal deficits pre-operatively. Further, artifact from spinal pathology may mask osteoporosis on spine DXA. As a result, patients with poor bone quality are often only identified when surgeons encounter "soft" bone while placing orthopedic hardware. Few studies have investigated whether this subjective assessment of intra-operative bone quality (SBQ) relates to objective measurements of skeletal integrity. The FUSED SPINE (The FUsion and Skeletal Evaluation in patients unDergoing SPINE surgery) is an ongoing prospective cohort study investigating relationships between pre-operative bone health, intra-operative measures and post-operative outcomes. This sub-study related bone mineral density (BMD) and biomechanical

properties to SBQ. We hypothesized that patients with lower BMD and stiffness by would have lower SBQ. Pre-operative assessments included areal BMD (spine, hip, forearm) by DXA, phantom calibrated spine vBMD by QCT and whole bone stiffness by finite element analysis. Intra-operatively, surgeons blind to QCT and FEA rated bone on a 3-point scale (poor, fair, good) based upon resistance to the insertion of pedicle screws. Analysis of variance compared imaging parameters to the surgeon's assessment. This cohort included 59 patients who underwent lumbar spine fusion. Mean age was 61 years (range 25-81), 51% were women, 80% non-Hispanic White. Mean Z-scores by DXA were within the normal range at all sites. Mean vBMD (L1-L2) was 164 mg/cm3. Intra-operative SBQ was rated as poor in 7 patients (12%), fair in 23 (39%), and good in 29 (49%). Patients rated as having poor SBQ were older than those with good bone (70 vs 57 yrs; p<0.05). Spine aBMD was not related to SBQ. Compared to patients with good SBQ, those with poor SBQ had lower aBMD at the hip, femoral neck and 1/3 radius (-29 to -37% lower, p<0.05 for all). Further, those with poor SBQ had lower vBMD (-34%, p<0.01) and whole bone stiffness (-63%, p<0.01) at L1 (figure). In summary, there were direct relationships between BMD, stiffness and SBQ in patients undergoing spine fusion surgery. Our findings suggest that these subjective determinations may have clinical importance as a means of identifying patients with compromised bone.

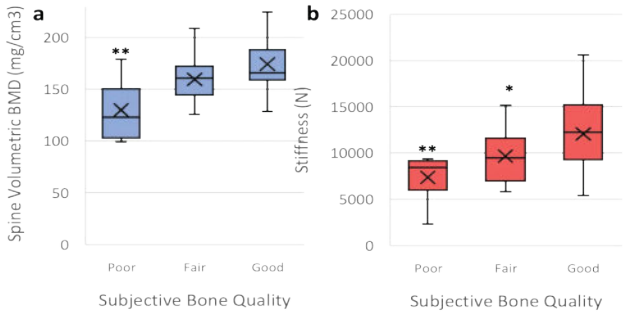

Figure: Volumetric BMD (a) and stiffness (b) at L1 according to subjective intra-operative bone quality assessment. Center line denotes median and X denotes mean values. Box encompasses 25th through 75th percentiles of dataset. *p <0.05 and **p<0.01 compared to good SBQ.

The utility of clavicle cortex index as a screening tool for low bone mineral density among spine and hip surgery patients *Yusuke Dodo[1], Ichiro Okano[1], Koki Tsuchiya[1], Soji Tani[1], Chikara Hayakawa[1], Ryo Yamamura[1], Hiroshi Maruyama[1], Yoshifumi Kudo[1]. [1]Showa University, Japan

Background: Low bone mineral density (BMD) has been considered as a risk factor for mechanical complications after spine and hip surgeries. Currently, the Dual-energy X-ray absorptiometry (DXA) is the gold standard for the evaluation of bone mineral density. However, DXA scan is not always readily available for spine surgery patients. In this study, we focused on clavicle cortical bone thickness that can be easily assessed on routine chest radiograph to predict low bone mineral density among spine surgery patients. Purpose: To investigate the associations between clavicle cortical thickness index and DXA-BMDs in various anatomical locations. Methods: The records of patients who underwent elective spine and hip surgery were retrospectively reviewed. The bilateral clavicles shown on the chest radiograph was divided equally into four equal portions (A: distal, B: middle-distal, C: middle-proximal, D: proximal) and the thickness of each cortical and trabecular bone was measured at each point. The clavicle index was defined as the following formula: (cortical + trabecular) / trabecular bone. Pearson's correlation coefficients were calculated to compare the clavicle cortical index at each point, unilateral and bilateral average values, and BMDs in the proximal femur, lumbar spine, and distal radius. The receiver operating characteristic (ROC) curve analysis was also performed to assess the predictive value of the index for diagnosing osteoporosis defined as BMD <70% of young adult mean value. Results: A total of 219 patients (61.2% female) with mean age of 68.03 years were included in the final analysis. Mild but significant correlations were found between the middle-distal clavicle cortex index (MCDI) and BMDs in the radius (r=0.409) but weak correlations in the femur (r=0.313) and spine (r=0.209). Female was a factor for stronger correlations between MCDI and BMD in the radius (r=0.63). In spine surgery patient, mild correlations were observed between MCDI and BMDs in the femur (r=0.42) and radius (r=0.432) but weak correlations in lumbar BMD (r=0.223). In hip surgery patient, mild correlations were observed between the MDCI and BMDs in lumbar BMD (r = 0.223) and radius (r=0.446) but weak correlations in femur BMD (r=0.186). The ROC analyses demonstrated that the areas under the curve (95%CI) of MCDI for osteoporosis diagnosis were moderately accurate: 0.69 (0.55-0.83) with femur BMD, 0.716 (0.57-0.861) with lumbar BMD, and 0.834 (0.737-0.931) with radius BMD. Conclusions: Our results indicated that the middle-distal clavicle cortex index was significantly correlated with BMDs especially in the radius among spine and hip surgery patients. The clavicle cortex index is calculated easily using a routine chest radiograph, hence, the index can be utilized as an osteoporosis screening tool for spine and hip surgery patients.

SAT-380

The Influence of Contrast on Opportunistic Computed Tomography Bone Mineral Density Analysis *KIRSTEN BOTT[2], Ainsley Smith[2], Richard Walker[2], Steven Boyd[2], Sarah Manske[2]. [2]University of Calgary, , [2]University of Calgary, Canada

Opportunistic computed tomography (CT) analysis leverages CT images acquired for clinical diagnosis for secondary analysis of bone, without the need for a phantom within the field of view. Recent developments implement phantomless internal density calibration, using tissues captured in the scan field of view (e.g., blood, adipose, muscle, bone) and air as density referents for bone mineral density (BMD) analysis. However, many routine clinical scans often use contrast enhancement which may interfere with the internal calibration process. Therefore, the aim of this project was to investigate the effect of contrast enhancement on opportunistic BMD analysis, with the goal of quantifying error and determining whether corrective measures may be applied. The influence of contrast enhancement was addressed using retrospective CT scans from hematuria patients (n = 225). Hematuria patients are typically healthy and undergo a protocol that includes multiphasic CT imaging, a) without contrast b) during the nephrographic phase and c) 10-minute delayed post-contrast imaging). The vertebra from a subset (n = 39) of the abdominopelvic CT scans were automatically segmented and identified using the freely available Anduin web tool (https://anduin.bonescreen.de). The internal referents were manually selected for air, adipose, muscle, and bone; blood was not included due to the contrast enhancement. CT images were calibrated based on the mass attenuation coefficients of the internal referents. The results indicated that BMD was lower in the nephrographic phase (149.7 +/- 35.4 mg/cm3; p < 0.001) and delayed phased (141.8 +/- 36.1 mg/cm3; p < 0.001) contrast CT scans compared to the nonenhanced CT scan (170.1 +/- 39.5 mg/cm3), with a less significant difference between the two post-contrast phase scans (p < 0.05). The BMD from nonenhanced CT scans was linearly correlated with BMD in both the nephrographic (r2 = 0.70) and delayed (r2 = 0.67) phase contrast CT scans. The strong relationship between the multiphasic CT imaging with and without contrast suggests a linear equation may be able to correct differences in BMD results with contrast. Similarly, previous research using asynchronous BMD calibration also reported a strong correlation. Development of a robust opportunistic CT protocol will allow for greater applicability to analyze available clinical data, including corrections for contrast enhanced CT scans to comprehensively analyze changes in bone.

Improving DXA Lumbar Spine BMD Outcomes with a new AI-Based Spine Segmentation Application *Guillaume Gatineau[1], El Hassen Ahmed Lebrahim[2], Karen Hind[2], Olivier Lamy[1], Elena Gonzalez Rodriguez[1], Lionel Beaugé[2], Didier Hans[3]. [1]Center of Bone Diseases, Rheumatology Unit, Bone and Joint Department, Lausane University Hospital, & University of Lausanne, Switzerland. [2]Medimaps group SA, Switzerland. [3]Center of Bone Diseases, Rheumatology Unit, Bone and Joint Department, Lausane University Hospital, & University of Lausanne, Switzerland, Switzerland

Introduction: Dual-energy X-ray absorptiometry (DXA) is commonly used to diagnose osteoporosis by measuring bone mineral density (BMD). However, DXA's accuracy in assessing lumbar spine BMD can be limited due to factors like degenerative changes, osteophytes, and artifacts. These limitations may lead to inaccurately high BMD values, resulting in misdiagnosis and undertreatment of osteoporosis. To overcome these challenges, a new AI-based spine segmentation (SpS) application has been developed by Medimaps Group, Switzerland, aiming to enhance the accuracy and efficiency of DXA-based spine BMD analysis. This study aimed to assess the effectiveness of this AI SpS application in improving DXA lumbar spine BMD outcomes. Methods: The study included 1,052 postmenopausal women (mean age=70.3+/-7.4 y, BMI=26.0+/-4.4 kg/m²) from the OsteoLaus cohort who

had a LS (L1-L4) DXA scan during the third visit (GE Lunar iDXA). Among these women, 568 had vertebral anomalies based on the ISCD criteria, which involves a +1 SD T-score difference between adjacent vertebrae. For this subgroup, LS BMD and T-score were analyzed using three SpS approaches: the default DXA manufacturer, an AI application, and the criterion set by a clinical expert. Statistical analysis involved Student's t-tests to compare outcomes. The impact of each SpS method on BMD classification (osteoporosis, osteopenic, or normal) was examined. Contingency tables were used to compare and analyze sensitivity and specificity for the Default and AI classifications. Kappa index was used to calculate the agreement levels of the default and AI SpS with the Expert's classification. Results: LS BMD outcomes differed significantly between Expert and Default SpS (p=0.005**, Table 1). No significant differences were found between Expert and AI SpS for LS BMD (p=0.098, Table 1). The prevalence of LS osteoporosis was 16.4% for Expert SpS, 9.3% for Default SpS, and 13.7% for AI SpS (Tables 2, 3). Osteoporosis classification sensitivity was 0.57 for Default SpS and 0.84 for AI SpS (Table 4). AI showed higher agreement with Expert (Kappa=0.892) compared to Default (Kappa=0.755) classifications.Conclusion: The AI SpS demonstrated improved LS BMD measurements and greater agreement of densitometric osteoporosis classifications with the extert compared with the default. These results suggest that AI SpS may be a valuable tool to improve the accuracy of LS BMD analysis and individual level diagnosis.

Table 1: Differences in LS BMD outcomes between the default, AI and expert (criterion) spine segmentation methods

		Mean (SD)		Mean (SD)	p-value
LS BMD	Expert	1.058 (0.186)	AI	1.077 (0.191)	0.096
LS BMD	Expert	1.058 (0.186)	Default	1.088 (0.174)	0.005 * *

Table 2: Lumbar spine BMD T-score classification using AI spine segmentation

		BMD T-score classification -Expert SpS		
		Normal	*Osteopenia*	*Osteoporosis*
BMD T-score classification - AI SpS	*Normal*	255	21	0
	Osteopenia	0	179	15
	Osteoporosis	0	0	78

Table 3: Lumbar spine BMD T-score classification using the manufacturer default spine segmentation

		BMD T-score classification - Expert SpS		
		Normal	*Osteopenia*	*Osteoporosis*
BMD T-score classification - Default SpS	*Normal*	248	38	0
	Osteopenia	2	162	40
	Osteoporosis	0	0	53

Table 4: Sensitivity and specificity outcomes for BMD T-score classification using default vs. AI SpS methods

SAT-382

Substantially Improved Identification of Patients At High Risk of Osteoporotic Fracture Through a Revised Risk Assessment Strategy: The Manitoba BMD Registry *Claus-C Glueer[1], Klaus Engelke[2], Friederike Thomasius[3], William Leslie[4]. [1]Christian Albrechts Universitaet zu Kiel, Germany. [2]University Hospital Erlangen, Germany. [3]Frankfurt Bone Health Center, Germany. [4]University of Manitoba, Canada

Purpose. Current strategies for case finding do not exploit the full potential for identification of patients at high(est) risk of fracture. A revised strategy is proposed emphasizing (i) hip fracture (HF) and vertebral fracture (VF) over other non-hip/non-vertebral osteoporotic fractures (oOF), (ii) a wider range of clinical risk factors (cRFs), (iii) spine aBMD and TBS in addition to total hip aBMD (iv) and prediction times of 3 and 1 years.Aim. To test whether this strategy leads to clinically relevant and statistically significant incremental improvement in fracture prediction.Methods. An expanded set of risk factors for HF or VF risk was selected based on systematic literature review (2267 publications, Oxford evidence criteria) and availability in the Manitoba BMD registry. Cox models to predict 3-yr HF, VF and oOF were built in 7 steps requiring significant improvement and clinically relevant increases in AUC>0.005 for each step : (0) base of 8 primary risk factors from FRAX (without secondary osteoporosis or DXA) (1) disaggregating FRAX prior fracture into subgroups of individual fractures ? (2) cRFs from FRAX secondary osteoporosis plus other bone disorders ? (3) cRFs from neurological disorders ? (4) adding total hip aBMD ? (5) adding lumbar spine aBMD ? (6) adding TBS; (7) comparison of the final 3-year fracture risk model with the same model for 1- and 10-yr fracture risk.Results. The sample included 56,129 women; over 3 years 292 HF, 260 clinical VF and 1556 oOF were recorded. Table shows improvement in AUC with each step adding significantly and at least AUC increase>0.005. Overall 3yr AUCs improved by +0.054 (from 0.830 to 0.884) for incident HF and by +0.068 from (0.727 to 0.795) for incident VF. Compared to 3yr risk models, imminent 1yr AUCs further increased to by +0.023 (to 0.907) for HF and by +0.055 (to 0.850) for VF. In contrast, the 10yr AUC was substantially lower at 0.825 (-0.059 vs 3yr AUC) for HF and at 0.771 (-0.024) for VF. For non-hip/non-vertebral oOFs, AUCs at all steps were consistently lower than for HF and VF.Conclusion. Four strategic changes, i.e. (i) focus on risk of hip and VF; (ii) novel clinical risk factors; (iii) including spine aBMD and TBS (for VF); (iv) assessing risk over 3-yr (and 1-yr imminent risk) instead of 10-yr all substantially improved risk profiling. The large improvement in AUC observed mandates consideration of a change in clinical approach to the identification of high-risk individuals.

SAT-383

The Association Between Body Mass Index and Fracture is Dependent on Femoral Neck BMD: An International Meta-Analysis *Nicholas Harvey[1], Helena Johansson[2], Eugene McCloskey[3], Enwu Liu[2], Marian Schini[4], Liesbeth Vandenput[2], Mattias Lorentzon[2], William Leslie[5], John Kanis[3], FRAX Meta-analysis Cohort Group[3]. [1]MRC Lifecourse Epidemiology Centre, University of Southampton, United Kingdom. [2]Mary McKillop Institute for Health Research, Australian Catholic University, Australia. [3]Centre for Metabolic Bone Diseases, University of Sheffield, United Kingdom. [4]Department of Oncology & Metabolism, University of Sheffield, United Kingdom. [5]Department of Medicine, University of Manitoba, Canada

We undertook an international meta-analysis to quantify the predictive value of body mass index (BMI) for incident fracture and to explore the relationship of this risk with age, sex, time since baseline and femoral neck bone mineral density (BMD). The analysis dataset comprised 1,824,804 men and women from 62 cohorts in 32 countries followed for a total of 17.6 million person-years. We investigated the relationship between BMI (kg/m2) and risk of any clinical fracture, any osteoporotic fracture, major osteoporotic fracture (MOF) and hip fracture alone using an extended Poisson model in each cohort. Covariates examined were age, sex, BMD and duration of follow up. The results of the different studies were merged by using the ?-coefficients (weighted by sample size). After adjustment for age and time since baseline, greater BMI was associated with lower risk of incident fracture in both men and women. For example, hazard ratio [HR (95% CI)] for MOF per kg/m2 greater BMI was 0.98 (0.97, 0.98) in women and 0.98 (0.97, 0.99) in men. Associations appeared similar by fracture outcome category and in the subset of cohorts in which BMD was measured. Here, after further adjustment for BMD, the relationships inverted such that greater BMI was associated with greater fracture risk. For example, for women HR (95%CI): 1.01 (1.00, 1.02) and for men 1.02 (1.02, 1.03). Dependent on sex and fracture category, the magnitude of associations varied by age and/or follow-up time. In the largest ever meta-analysis undertaken to date, greater BMI was protective for incident fracture without adjustment for femoral neck BMD, but a risk factor after accounting for BMD. Ongoing analyses will elucidate relationships by individual fracture site, BMI category and in non-linear models to inform the second version of the FRAX tool.

Use of 3D-DXA as a new tool to evaluate bone loss after bariatric surgery *C. Gómez-Vaquero[1], M. López Picazo[2], L. Humbert[2], M. Perez-Prieto[3], L. Hernandez-Montoliu[6], O. Jermakova[4], L. Huanuco[0], F. Guerrero-Perez[4], J. Osorio[6], L. Sobrino[0], N. Vilarrasa[4]. [1]Rheumatology. Hospital Universitari de Bellvitge, L'Hospitalet, Spain, Spain. [2]3D-Shaper Medical, Barcelona, Spain, Spain. [3]Endocrinology and Nutrition. Hospital Universitari de Bellvitge, L'Hospitalet, Barcelona, Spain. [6]Endocrinology and Nutrition. Hospital Universitari de Bellvitge, L'Hospitalet, Spain, Spain. [4]Endocrinology and Nutrition. Hospital Universitari de Bellvitge, L'Hospitalet, Spain, Spain. [0]Endocrinology and Nutrition. Hospital Universitari de Bellvitge, L'Hospitalet, Spain. [6]General and Gastrointestinal Surgery, L'Hospitalet, Spain, Spain. [0]General and Gastrointestinal Surgery, L'Hospitalet, Spain, Spain

Objective: To analyze changes in bone structure using 3D-DXA in patients with severe obese after different types of bariatric surgery (BS).Methods: Prospective, single center and non-blinded study in patients with obesity undergoing BS. BMD at lumbar spine (LS, L1-L4), femoral neck (FN) and total hip (TH) was measured by DXA (Horizon Wi; Hologic Inc., Waltham, MA, USA) prior and 12 months after surgery. Proximal femur 3D-DXA parameters including cortical and trabecular volumetric(v) BMD, cortical thickness (CTh) and surface(s) BMD at TH, FN, trochanter and shaft were analyzed using 3D-Shaper software v.2.12.1 (3D-Shaper Medical, Barcelona, Spain).Results: 153 patients, 81% female, aged 50+/-9 years and BMI 38+/-9 kg/m2 were evaluated. In 54.3% of them underwent Sleeve gastrectomy (SG), 29.4% Duodenal Switch/SADIS and 16.3% Roux-en-Y Gastric bypass (RYGB). Baseline characteristics were comparable between groups, except BMI that was lower in RYGB. Weight loss was greater after DS/SADIS compared to SG and RYGB (-34+/-12 vs 27+/-9 vs 27+/-11, p< 0.001). After surgery DMO losses were significantly greater at all sites in DS/SADIS and RYGB (p<0.001) compared to SG. In the whole cohort, significant changes from baseline were found in 3D-DXA measurements at the TH. Cortical sBMD decreased by -4.4+/-4.8%; Cortical vBMD by -1.4+/-2.8%; CTh by -3.1+/-3.9%; and Trabecular vBMD by -8.0+/-6.6 (p<0.05). Similar results were found at all hip regions except the neck where a 2.1+/-7.3% increase in CTh was found (increase from baseline statistically significant (p<0,05) only after SG). Cortical and trabecular BMD losses were greater in DS/SADIS and RYGB (p<0.01). Final Z-scores for Cortical sBMD and Trabecular vBMD were 0.96 (IC 95%: 0.73 to 1.19) and -0.17 (IC 95%: -0.32 to -0.02).Conclusion: Patients undergoing BS showed a significant decrease in LS and hip BMD assessed by DXA. 3D-DXA analysis showed greater decreases in trabecular vBMD, compared to cortical sBMD. More hypoabsortive techniques induced a greater bone loss. After one year, bone density remains within or above mean reference values from the general population.

An MRI-based Approach for Characterizing Bone Mineral Density and Cortical Porosity: Comparing Ultrashort Echo Time MRI with HR-pQCT *Andrea Jacobson[1], Christopher Newman[2], Thomas Siegmund[3], Joseph Wallace[4], Matthew Allen[5], RACHEL SUROWIEC[6]. [1]Department of Biomedical Engineering, Indiana University Purdue University Indianapolis, United States. [2]Department of Radiology and Imaging Sciences, Indiana University School of Medicine, United States. [3]School of Mechanical Engineering, Purdue University, United States. [4]Indiana University Purdue University Indianapolis (IUPUI), United States. [5]Anatomy, Cell Biology and Physiology, Indiana University School of Medicine, United States. [6]Indiana University Purdue University,

Current imaging modalities used to quantify cortical bone density and microarchitecture rely on X-ray radiation to image the mineral phase. However, recent work suggests ultra-short echo-time MRI (UTE-MRI) can innocuously characterize cortical porosity and potentially bone mineral density (BMD) based on MRI's signal intensity. Additionally, UTE-MRI can provide insight into bone water and matrix organization, making a comprehensive bone evaluation with a singular imaging modality feasible. Toward this goal, we sought to establish UTE-MRI's ability to characterize mineral density and microarchitecture at clinical field strength and compare this to high-resolution peripheral quantitative computed tomography (HR-pQCT).Femoral bone from ten fresh cadaveric specimens (83.5 +/- 10.1 yrs) underwent 3D radial UTE MRI using a short (0.04 ms) and long (2.8 ms) echo time (3.0 T, Siemens, 0.45 mm resolution), and HR-pQCT (XtremeCT II, SCANCO, 0.06 mm resolution) imaging (Fig1A-B). For UTE-MRI, specimens were imaged with the following phantoms: H2O, hydroxyapatite (CHA), and a series of D2O-doped water. Multi-modal images were registered, and a 4.5 mm region of interest was created from the HR-pQCT image and used across two multi-modal images per specimen (MATLAB) (Fig1C). Statistical relationships between the following outcomes were determined using Pearson Correlations: porosity index [1] (UTE-MRI), a novel signal-intensity (SI)-based MRI surrogate for BMD [2] (UTE-MRI), and cortical porosity (%), pore volume, and BMD (HR-pQCT). Both % porosity and pore volume significantly and positively correlated with porosity index (Fig1D-E). For BMD, two HR-pQCT scans are pending analysis. Still, the abbreviated dataset showed SI BMD has a moderate, albeit insignificant, positive relationship with BMD (Fig1F). SI MRI BMD significantly and negatively correlated to porosity index indicating the more porous the bone, the lower the SI MRI BMD (Fig1G). Finally, SI BMD, but not porosity index, significantly and negatively correlated with specimen age (Fig1H).UTE-MRI correlated with HR-pQCT for cortical porosity measures and captured changes in BMD due to age and increasing porosity. Work is underway to extract bone water content and organic matrix organization from the UTE-MRI, where the sum of these efforts will describe a comprehensive set of bone imaging biomarkers to characterize bone health using a single innocuous clinical imaging modality.

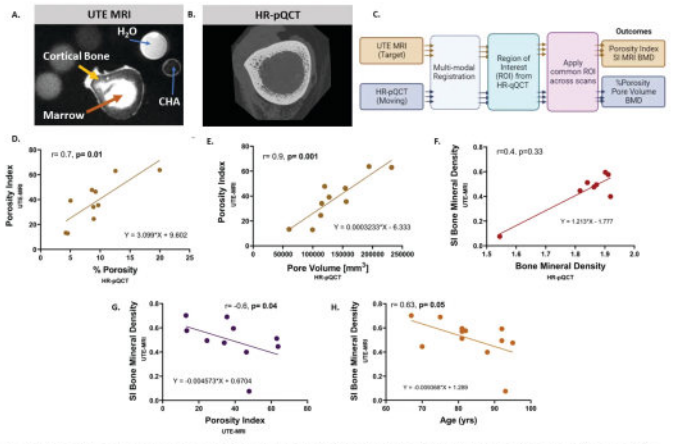

Figure 1. Ten 5cm long cadaveric femoral bone specimens from the proximal femoral shaft underwent (A) UTE-MRI with the bone fully submerged in a fluoroinert solution to reduce susceptibility and maintain hydration (flip angle: 12°, FOV: 160 mm3, 2 averages, 50K radial spokes, readout BW: 250 kHz, 0.45 mm isotropic resolution, TA: 20min 2s). (B) HR-pQCT imaging was acquired with the specimen wrapped in phosphate buffered saline-soaked gauze. (C) Images were registered, and a 4.5 mm proximal region of interest (ROI) was delineated using a structure-based mask in HR-pQCT images and applied to the UTE-MRI creating a common ROI for analysis. Porosity index and a signal intensity (SI) MRI based BMD was calculated from UTE-MRI and %porosity, pore volume, and BMD from HR-pQCT. Pearson correlation coefficients revealed that porosity index significantly and positively correlated with HR-pQCT measures of %porosity (D) and pore volume (E). SI MRI BMD was not significantly correlated to BMD perhaps due to ongoing troubleshooting with several HR-pQCT scans which could not be included in analysis. (G) SI MRI based BMD significantly and negatively correlated with porosity index; the more porous the bone the lower the BMD. While porosity did not correlate with specimen age, we observed a significant negative relationship between specimen age and SI MRI base BMD (H). The older the specimen, the lower the BMD.

Utilization, Diagnoses, Medications, and Laboratory values in the Electronic Health Record can Predict Fractures Independently of FRAX *Rajesh Jain[1], Eric Polley[1], Mark Weiner[2], Amy Iwamaye[3], Elbert Huang[1], Tamara Vokes[1]. [1]University of Chicago, United States. [2]Weill Cornell Medicine, United States. [3]Lewis Katz School of Medicine at Temple University, United States

Introduction: FRAX is the fracture prediction tool most commonly used in the United States. We recently demonstrated that FRAX probabilities derived using information from electronic health records (EHRs) were generally as accurate as studies where patients were directly asked. FRAX includes 11 risk factors; however, it is not known if variables available in the EHR would add predictive value independently of FRAX. Thus, our study sought to assess the ability of routinely available EHR variables to predict fracture.Methods: We used data from the EHR in years 2010-2019 obtained at an academic medical center in Philadelphia, PA. All patients over 50 years of age who had received routine care were included. FRAX 10-year major osteoporotic fracture (MOF) predictions were based on at least 1 year of data in the EHR, and subsequent incident MOFs were captured by diagnosis codes. Additional variables besides those in FRAX were examined based on their known or suspected association with fracture, or because of high frequency in the data. These included categories such as utilization, vital signs, diagnoses, medications, and laboratory values. Missing values in vital signs or labs were imputed using a random forest imputation algorithm in RStudio 02.03. All other analyses were done in Stata 17.Analyses were done using Cox regression. First, each variable was analyzed while controlling for FRAX 10-year probability and the risk factors within FRAX. Then, we created a model that included all the statistically significant variables (p<0.05), as well as FRAX variables, and removed variables using a backwards stepwise approach. We allowed variables to remain in the model if p-value <0.2. We compared Harrell's C-statistic of our final model versus that of FRAX 10-year estimates. Results: There were 24,189 patients included with mean age 62.8 +/- 9.7 and 3.8 +/- 1.8 years of follow up. Overall, the MOF rates were 4.3 and 6.0 MOFs per 1,000 person-years in men and women, respectively. There were 26 risk factors significantly associated with MOF independently of FRAX, of which 14 met criteria for the final model. Table 1 shows the risk factors in the final model. The final model demonstrated a C-statistic of 0.69 versus FRAX alone of 0.63 (p<0.001).Conclusion: Information from the EHR can predict fractures independently of FRAX and may allow for automated fracture prediction at the point of care, reducing the clinician burden of ascertaining risk factors verbally.

Table 1: Risk factors in an Electronic Health Record-derived Final Model (in addition to FRAX variables) to predict major osteoporotic fracture

Risk Factor	Individual Model HR[1]	95% CI, p-value	Final Model HR[2]	95% CI, p-value
Pulse SD (per 5 BPM)	1.18	1.07-1.18, p=0.002	1.11	1.00-1.24, p=0.06
Visits with PCP (per 1 visit)	1.03	1.02-1.04, p<0.001	1.05	1.01-1.08, p=0.02
GABA use	1.60	1.20-2.14, p=0.001	1.27	0.94-1.71, p=0.12
PPI use	1.39	1.14-1.69, p=0.001	1.23	1.01-1.51, p=0.04
Anticonvulsant use	2.14	1.47-3.11, p<0.001	1.73	1.18-2.53, p=0.005
TZD use	1.87	1.19-2.95, p=0.007	1.80	1.14-2.84, p=0.01
Loop diuretic use	1.81	1.38-2.39, p<0.001	1.39	1.05-1.85, p=0.02
Sodium level (per 1 mmol/L)	0.94	0.90-0.98, p=0.001	0.97	0.93-1.01, p=0.11
CKD Stage 3b or worse	1.91	1.37-2.67, p<0.001	1.48	1.05-2.09, p=0.02
Alkaline phosphatase (per 25 U/L)	1.09	1.05-1.14, p<0.001	1.07	1.02-1.12, p=0.003
Albumin (per 1 g/dL)	0.56	0.46-0.69, p<0.001	0.72	0.58-0.91, p=0.006
RDW (per 1%)	1.09	1.03-1.15, p=0.001	1.04	0.98-1.11, p=0.17
Psychoses	3.07	1.72-5.50, p<0.001	2.65	1.48-4.75, p=0.001
Musculoskeletal Pain	1.35	1.10-1.65, p=0.003	1.24	1.01-1.52, p=0.04

Subject-Specific Fall Probability Improves Hip Fracture Prediction Beyond Bone Mineral Density: AGES-Reykjavik Study *Fjola Johannesdottir[1], Thor Aspelund[2], Sigurdur Sigurdsson[3], Vilmundur Gudnason[2], Mary Bouxsein[4]. [1]Beth Israel Deaconess Medical Center & Harvard Medical School , , [2]Icelandic Heart Association Research Institute and University of Iceland, Iceland, [3]Icelandic Heart Association Research Institute, Iceland, [4]Beth Israel Deaconess Medical Center, Harvard Medical School, United States

Current assessment of fracture risk does not directly include the probability of falling despite the fact that nearly all hip fractures are due to a fall. It remains unknown whether incorporation of subject-specific probability of falling improves assessment of hip fracture risk. Thus, we aimed to develop a subject-specific fall risk tool to evaluate probability of falling and test whether combining probability of falling and hip BMD would improve hip fracture risk assessment beyond BMD alone among older men and women from the AGES-Reykjavik study.We used baseline data from 3242 individuals (58% women) to predict repeated falling >=2 in the past 12 mos at follow-up (~5yrs later) by finding the best predictive logistic regression model using stepwise variable selection procedure (data were partitioned into training set 65% and test set 35%) considering age, sex, fall history, neuromuscular function, dynamic balance and medications as predictors. Further, in a prospective case-cohort study design of 698 hip fracture cases and 1348 controls from AGES cohort with median follow-up of 10yrs (6.1-13.9), we used Cox proportional hazards models to predict hip fracture. We tested whether fall probability combined with CT-derived femoral neck (FN) aBMD predicts hip fracture better than FN aBMD alone by comparing the time-dependent area under the receiving operating characteristic curve (AUC).295 individuals had >= 2 falls in the past 12 mos prior to follow-up visit. The best model to predict future falls at follow-up included fall history, timed up-and-go test and grip strength (AUC for predicting falls in test set = 0.67 (0.61-0.72)). The probability of falling predicted incident hip fracture independently of FN aBMD in both sexes. Individuals in the highest two quantiles of fall risk were 2.03-2.56 fold more likely to sustain a hip fracture than the ones in the lowest quantile, after adjusting for age, sex height, weight and FN aBMD. (Table). AUC for the model predicting 5 and 10 yrs hip fracture risk was greater when fall probability was combined with FNaBMD compared to FNaBMD alone (p<=0.001), as it was 76% (72-79, 95%CI) vs 73% (70-77, 95%CI) for 5-yrs and 80% (77-82, 95%CI) vs 78% (76-81, 95%CI) for 10yrs. In a population-based study of older adults, the probability of falling predicted incident hip fracture and improved hip fracture prediction beyond FNaBMD. Thus, subject-specific fall risk may provide added value in clinical assessment of hip fracture risk.

Table: Hazard ratios for incident hip fracture (95%, CIs) according to fall probability (Model 1: Fall probability, Model 2: Fall probability adjusted for FNaBMD)

Outcome predictor	Model 1#	Model 2#
Fall probability		
Q2vsQ1	1.60 (1.16-2.20)	1.40 (1.01-1.95)
Q3vsQ1	1.71 (1.24-2.35)	1.59 (1.14-2.21)
Q4vsQ1	2.33 (1.69-3.23)	2.03 (1.45-2.83)
Q5vsQ1	2.93 (2.08-4.13)	2.56 (1.80-3.66)
Femoral neck aBMD*	-	1.78 (1.58-2.00)

Discordance in secular trends of bone mineral density measurements in different ages of postmenopausal women *Kwang Yoon Kim[1], Bom Taeck Kim[2]. [1]Myungju hospital / Ajou university hospital, Republic of Korea, [2]Ajou university hospital / School of medicine of Ajou university, Republic of Korea

Background: Age-adjusted bone mineral density (BMD) in postmenopausal women decreases in developed countries whereas incidence of osteoporotic fracture decreases or remains stable. We investigated secular trends of bone density from 2008 to 2017 among different age groups of postmenopausal women.Methods: We analyzed BMD data obtained from health check-up of 4905 postmenopausal women during three survey cycles from 2008 to 2017. We divided them into 3 groups by age (50-59 years, 60-69 years, and 70 years or more) and observed the transition of lumbar and femoral BMD in each group, before and after adjusting for variables that may affect BMD.Results: Age-adjusted BMD, bone mineral content (BMC), and T-score demonstrated a declining trend over the survey period at lumbar spine (-2.8%), femur neck (-3.5%) and total femur (-4.3%), respectively. In the analysis for the age groups, the BMD, BMC, and T-score presented linear declining trend (-6.1%) in younger postmenopausal women while women aged over 70 or more showed linear increasing trends (+6.3%) at lumbar spine during the survey period. Femoral neck and total femur BMD demonstrated a declining linear trend only in the 50-59 and 60-69 years groups (-5.5%, -5.2%, respectively), but not in the above 70 group.Conclusion: BMD in younger postmenopausal women has decreased considerably but has increased or plateaued in elderly women. This discordance of BMD trends among different age groups may contribute to decreased incidence of osteoporotic fracture despite a recent declining BMD trend in postmenopausal women.

Automated Deep Learning-based Bone Mineral Density Assessment of Vertebral Bodies in CT Scans *Nicolai Krekiehn[1], Eric Orwoll[2], Eren Bora Yilmaz[3], Claus-C Glueer[4]. [1]Christian-Albrechts-Universität zu Kiel, Germany, [2]Oregon Health & Science University, United States, [3]Christian-Albrechts-Universität Kiel , , [4]Christian Albrechts Universitaet zu Kiel, Germany

Automated measurement of volumetric vertebral trabecular bone mineral density (vBMDvt) on computed tomography (CT) scans using artificial intelligence (AI) methods may be useful for both diagnosis of osteoporosis and opportunistic fracture risk prediction (no added radiation dose).Aim: To develop and test an AI tool for automated assessment of vBMDvt on lumbar CT scans.Methods: A convolutional neural network (U-Net) architecture for segmenting individual vertebrae was trained on Verse data (236 CT scans, 1793 vertebrae). Subsequently the individual vertebral masks (VM) are automatically reduced to the trabecular region of the vertebral body (VB), where vBMDvt value is measured. This pipeline has already been tested on an external dataset, a subset of Diagnostik Bilanz study. We tested the method on the MrOS CT sub cohort. vBMDvt results (central 70% of the VB) previously generated by classical quantitative CT (QCT) image processing were used as reference. Since QCT segmentation masks were not available the segmentation step had to be tested without re-training of the AI model. For selection of the vBMDvt region a fully automated multistep peeling procedure was applied: we first reduce the VM of the cortex to the center core region of the VB. Subsequently, the VM is enlarged again to cover as much trabecular volume as possible. Third, 0 to 4 peeling steps are applied to shrink the VM to its final shape. If two VBs were available per subject, the vBMDvt results were averaged, cases with missing data were excluded. In order to test whether AI-based BMD results are likely to be good predictors for future fracture risk we ran logistic regression to test whether they discriminated between men with and without prevalent vertebral fractures.Results: The pipeline produced segmentation masks in 1300 of 1331 men (97.7%) included. QCT

based and AI based vBMDvt results were highly correlated (r=0.94). In 1151 of 1300 cases (88.5%) the subsequent peeling process could be finished fully automatically. vBMDvt significantly discriminated between men with and without vertebral fracture (Genant SQ grade >=2). AI based age adjusted standardized odds ratios (sOR) ranged up to sOR=4.1(2.8-6.1), AUC 0.76 after 3 or 4 peeling steps (see figure) versus sOR=3.2(2.2-4.6), AUC 0.74 for QCT.Conclusions: Compared to QCT on same data our AI based vBMD assessment method performed at least as well in discriminating vertebral fracture and will next be tested as predictor of future fracture.

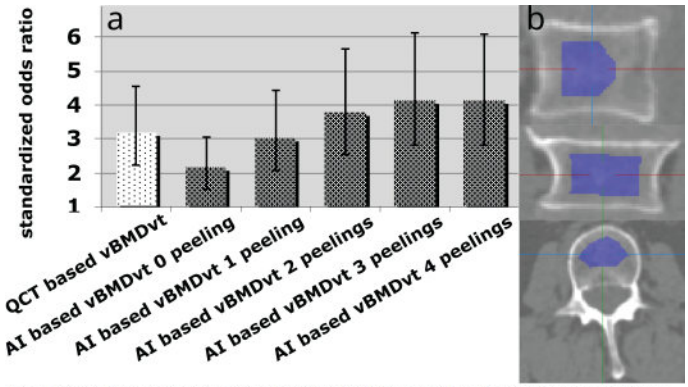

Figure: **a)** Age-adjusted standardized odds ratio for discrimination of men with and without prevalent vertebral fractures based on QCT based vBMDvt versus AI based vBMDvt with different amounts of peelings. **b)** AI based mask after four peeling steps

SAT-392

FRAX® Adjustment Using Renormalized Trabecular Bone Score (TBS) from L1 Alone is Optimal for Fracture Prediction: The Manitoba BMD Registry *William Leslie[1], Heenam Goel[2], Neil Binkley[3], Eugene McCloskey[4], Didier Hans[5]. [1]University of Manitoba, Canada. [2]CentraCare, St. Cloud, United States. [3]University of Wisconsin, Madison, United States. [4]University of Sheffield, United Kingdom. [5]Lausanne University Hospital & University of Lausanne, Switzerland

Lumbar spine trabecular bone score (TBS) used in conjunction with FRAX® improves 10-year fracture prediction. The derived FRAX adjustment is based upon TBS measured from L1-L4, designated TBSL1-L4-FRAX. Previous studies show that TBS measurements that include L1 and exclude L4 give better fracture stratification than L1-L4. However, TBS limited to upper lumbar vertebral levels is lower than L1-L4 and direct entry into the FRAX adjustment will overestimate fracture risk.AIM: To compare fracture risk stratification from TBS-adjusted FRAX using TBS derived from different combinations of upper lumbar vertebral levels renormalized for level-specific differences.METHODS: We included individuals from the Manitoba Bone Density Program aged >40 years with baseline assessment of TBS and FRAX. TBS measurements for L1-L3, L1-L2 and L1 alone were calculated after renormalization for mean level-specific differences. Corresponding TBS-adjusted FRAX scores designated TBSL1-L3-FRAX, TBSL1-L2-FRAX and TBSL1-FRAX were compared with TBSL1-L4-FRAX for fracture risk stratification. Incident major osteoporotic fractures (MOF) and hip fractures were assessed through linkage to population-based data sources. The primary outcome was incremental change in area under the curve (?AUC) compared using the Hanley-MacNeil method.RESULTS: The study population included 71,209 individuals (mean age 64 years, 89.8% female). Mean TBS for L1-3, L1-L2 and L1 was significantly lower and TBS-adjusted FRAX significantly higher than from using TBSL1-L4. These differences were largely eliminated when TBS was renormalized for level-specific differences. During mean follow-up of 8.7 years 6745 individuals sustained incident MOF and 2039 sustained incident hip fractures. Compared with TBSL1-L4-FRAX, use of FRAX without TBS was associated with lower stratification (?AUC = -0.009, p<0.001). There was progressive improvement in MOF stratification using TBSL1-L3-FRAX (?AUC = +0.001, p<0.001), TBSL1-L2-FRAX (?AUC = +0.004, p<0.001) and TBSL1-FRAX (?AUC = +0.005, p<0.001). TBSL1-FRAX was significantly better than all other combinations for MOF prediction (p<0.001). Incremental improvement in AUC for hip fracture prediction showed a similar but smaller trend.CONCLUSION: This single large cohort study found that TBS-adjusted FRAX performance for fracture prediction was improved when limited to the upper lumbar vertebral levels, and was greatest for L1 alone. Validation is required in other cohorts.

SAT-393

Establishing error bounds for internal calibration on quantitative computed tomography (QCT) *Bryn Matheson[2], Nathan Neeteson[2], Steven Boyd[2]. [2]University of Calgary, . [2]University of Calgary, Canada

The current gold standard for osteoporosis screening uses dual X-ray absorptiometry (DXA) to calculate bone mineral density (BMD) at the hip and spine. However, DXA has limitations, such as low population screening rates and the lack of 3D bone geometry. To address this, computed tomography (CT) scans that include the osteoporotic bones of interest can be repurposed to assess fracture risk. However, most clinical CT scans do not contain calibration phantoms within the field of view (FOV), and it remains a challenge to perform accurate and precise phantomless, or internal, calibration of CT images. The current study aims to develop error bounds for the measurement of BMD using internally calibrated CT. Clinical CT scans containing the lumbar vertebrae and proximal femur were obtained at the University of Calgary's Centre for Mobility and Joint Heath. These scans follow the standard CT imaging protocol for the kidneys, urinary tract, and bladder and included a Mindways Model 3 CT calibration phantom in the FOV. Five tissue regions of interest (for internal calibration) and the bones of interest were extracted by segmentation from the scans. The error bounds of our previously established internal calibration1 method were estimated using Monte Carlo simulation and standard error propagation. For gold-standard phantom calibration, the calibration rods were extracted and a linear relationship was used to convert the scan to its equivalent K2HPO4 values. Integral BMD was calculated using both density calibration techniques. The agreement between internal and gold-standard phantom calibration results was evaluated by determining whether the internal calibration error bounds contained the reference mean BMD, calculated using phantom-calibrated densities, for the fourth lumbar vertebra (L4) and both femurs. With a dataset of 25 scans, we found the 95% confidence interval for the internal calibration estimations of BMD consistently captured the reference phantom BMD for both femurs and L4 vertebrae (Figure 1). The mean difference is 8.2 mg/cc [~2.5% error bound]. The estimated error bounds for internally calibrated CT measurements of BMD account for error sources related to variation across scanners and imaging artifacts. With our new method for estimating the accuracy of internal calibration, future work using this tool can focus on modifying the calibration procedure to narrow the error bounds.1. Michalski A, et al. SAT-394

Establishing Japanese Osteoporosis Equivalent Femoral Strength Using Biomechanical CT (E-JOS Femoral Study) *Taro Mawatari[1], Shoji Baba[1], David Lee[2], Satoshi Hagio[1], Koichiro Kawano[1], Reima Sueda[1], Satoru Harada[1], Junta Mawatari[1], Yasuharu Nakashima[3], Tony Keaveny[2]. [1]KKR Hamanomachi Hospital, Japan. [2]O.N. Diagnostics, LLC, United States. [3]Kyushu University, Japan

Purpose: This study aimed to establish population-specific reference values for osteoporosis equivalent femoral strength using nonlinear finite element analysis (biomechanical CT) in a Japanese cohort, while taking into account the substantial difference in physique between Japanese and Americans. This would allow for more accurate assessment and treatment of osteoporosis in Japanese individuals. Methods: This study included a total of 717 patients (327 male and 390 female) aged 45-90 years who visited a general hospital for a CT scan including the hip joint and had a bone density test within 3 months before and after the scan. Up to 63 patients in each 5-year age group who met certain inclusion criteria were randomly selected. Femoral strength was calculated by phantom-less calibration from existing CT data. Osteoporosis and osteopenia equivalent femoral strength values were calculated based on femoral neck bone mineral density by DXA in Japanese subjects. Results and Discussion: The results showed that the osteoporosis equivalent femoral strength and osteopenia equivalent femoral strength in Japanese men were 3,000N and 4,000N, respectively, while those in Japanese women were 2,500N and 3,500N, respectively. These values were approximately 500N lower than the reported values for Americans. However, external factors, such as height, weight, BMI, and skeletal structure, also differ between the two populations. Conclusions: The study highlights the importance of using population-specific reference values for accurate assessment and treatment of osteoporosis. The estimated Japanese male and female osteoporosis equivalent femoral strength were found to be lower than reported values for Americans, emphasizing the need for region-specific reference values. Incorporating these population-specific reference values in the assessment of osteoporosis could help improve the accuracy of diagnosis and treatment.

Differences in Cortical Bound and Pore Water Concentrations between Osteoporotic and Non-Fracture Cases *Jeffry Nyman[1], Thammathida Ketsiri[2], Elizabeth Louie[1], Kevin Harkins[1], Mary Kate Manhard[3], Donald Lee[1], Bobo Tanner[1], Mark Does[2]. [1]Vanderbilt University Medical Center, United States. [2]Vanderbilt University, United States. [3]Cincinatti Children's, United States

Many fragility fractures occur in adults with T-scores of the hip and spine above -2.5. Moreover, the current clinical assessment of fracture risk lacks diagnostic information about the inherent quality of a person's bone tissue. Using MRI to quantify both tissue hydration and porosity in cortical bone, we hypothesized that concentrations of bound water (Cbw) and pore water (Cpw) are lower and higher, respectively, in adults with a fragility fracture (Fx) than in sex-matched adults without osteoporosis (Non-Fx). We enrolled patients who experienced a fragility fracture of the distal radius and matched them to volunteers with no history of Fx. Adiabatic inversion recovery (AIR) and dual adiabatic full-passage (DAFP) sequences were used to acquire pore and bound water maps (Fig. A) of the distal-third radius (non-fracture side). For quantification of Cbw and Cpw, we assumed fixed relaxation rates of bound water (T1=290 ms and T*2=0.35 ms) and pore water (T1 =450 ms and T*2=2.6 ms) and used signal from a phantom (20%H2O/80%D2O/20-24 mM CuSO4) to convert intensity signals into moles of 1H per liter of bone. After acquiring DXA scans, 3 patients (F 59 yo, M 28 yo, and M 58 yo) in the Fx group were not eligible for MRI, leaving an age disparity between Fx and non-Fx groups for MRI measurements (Fx subjects were on average 21% older; Welch's p=0.030). Among the remaining 20 Fx and 20 Non-Fx subjects, there were no significant differences in BMI (Mann-Whitney, M-W, p=0.794) and in 10-year probability of major osteoporotic fracture (FRAX) between the 2 groups (M-W p=0.794). The 10-year probability of hip fracture (FRAX) was significantly higher (M-W p=0.027) in Fx [0.75% (0.10%, 2.45%)] than in Non-Fx group [0.20% (0.00%, 0.70%)]. Cbw was significantly lower (t-test p=0.003) in Fx (22.3+/-8.7 mol 1H/L) than in Non-Fx (30.8+/-7.9 mol 1H/L), while Cpw was higher (Welch's p=0.001) in Fx (26.7+/-7.8 mol1H/L) than in Non-Fx (19.2+/-4.1 mol 1H/L). The 2 groups tend to cluster in Cbw vs. Cpw plots (Fig. B). In logistic regressions of all imaging measurements, age, and BMI, the combination of Cpw, Cbw, and hip BMD best predicted the 2 cases (Fig C). Without MRI, hip BMD had the highest area under the receiver operating characteristic curve (AUC=0.73). Without DXA, the Cpw plus Cbw (AUC=0.88) was best (adding age didn't improve prediction). MRI offers new quantitative markers of fracture risk that are specific to the hydration state of collagen and pore space within cortical bone.

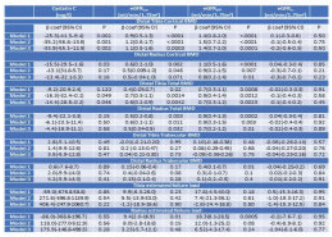
SAT-397

Cystatin C-derived renal function parameters and Volumetric Bone Density and estimated Failure Load Among Older Men for the Osteoporotic Fractures in Men Study (MrOS) Research Group *Eugenie Koumakis[1], Alison Potok[2], Kristine Ensrud[3], Andrew Burghardt[4], Nancy Lane[5], Kerri Freeland[1], Charles Ginsberg[6], Jane A. Cauley[7]. [1]University of Pittsburgh, United States. [2]Division of Nephrology-Hypertension, University of California San Diego, San Diego, CA., United States. [3]University of Minnesota and Minneapolis VA Health Care System, United States. [4]University of California, San Francisco, United States. [5]University of California, Davis Medical Center, United States. [6]UCSD, . [7]UNIVERSITY OF PITTSBURGH, United States

Serum cystatin (Cys) C has been proposed to be superior to creatinine(Cr)-based measures of kidney function in detecting mild to moderate decreases in kidney function in older adults, in part because it is less dependent on muscle mass. Higher Cys C is associated with an increased risk of hip fracture independent of traditional risk factors including hip bone mineral density (BMD). Recently, eGFRdiff, the difference between eGFRCys and eGFRCr has been found to be associated with frailty in older adults. To date, the association between Cys C, eGFRCys and eGFRdiff, and bone microarchitecture assessed by High-resolution peripheral quantitative computed (HR-pQCT) has not been investigated.We used data from 555 community-dwelling men in MrOS with measurements of Cys C, creatinine and HR-pQCT parameters at the Year 14 exam. eGFRdiff (eGFRCys-eGFRCr) was calculated using 2021 CKD-EPI equations. We used linear regression to examine the association of Cys C, eGFRCys, and eGFRdiff with estimated failure load, total volumetric BMD (Tt.BMD), trabecular and cortical BMD (Tb.BMD, Ct.BMD) at the distal radius and tibia.Among the 555 men assessed, mean age was 84 years (SD 4); 181(32.6%) had an eGFRCr<=60 ml/min/1.73m2. Median eGFRCys was 51 ml/min/1.73m2, and median eGFRdiff was -16mL/min/1.73m2. In the unadjusted model, higher Cys C, lower eGFRCys and lower eGFRdiff were each associated with lower Ct.BMD at the tibia and radius, whereas eGFRCr was not related to Ct.BMD. These associations remained at the tibia after accounting for age, race, BMI, clinical center, CKD category by eGFRCr, smoking status, diabetes, hypertension, cal-

culated D3Cr muscle mass, serum albumin, self-reported physical activity, and femoral neck aBMD. Lower eGFRCys and lower eGFRdiff were also each associated with lower total tibia and radius BMD in unadjusted and multivariate models. Although lower eGFRdiff was associated with lower estimated failure load and Tb.BMD at the radius in the unadjusted model, these associations did not remain after adjustment.Older community-dwelling men with higher Cys C, and lower eGFRCys and eGFRdiff have lower total and cortical BMD which may contribute to the higher risk of fracture in this population. Creatinine-based eGFR was not associated with these HR-pQCT indices. Future studies should evaluate whether addition of Cys C-based eGFR measurements to traditional models improves identification of people at the highest risk of fracture.

Table. Linear regression model of Association of Cystatin C, $eGFR_{Cys}$, $eGFR_{diff}$, and $eGFR_{Cr}$ with Distal Tibia and Radius volumetric BMD and failure Load.



β coefficient represents the change in volumetric BMD for every 1-unit increase in Cystatin C, $eGFR_{Cys}$, $eGFR_{diff}$, and $eGFR_{Cr}$.
Model 1: unadjusted model.
Model 2: adjusted for age, race, body mass index (BMI), clinical center, chronic kidney disease (CKD) category by $eGFR_{Cr}$ (≥ 60 or < 60 ml/min/1.73m²), smoking status, diabetes, hypertension, muscle mass, and serum albumin.
Model 3: further adjusted for self-reported physical activity, and femoral neck aBMD.
$eGFR_{Cr}$ not adjusted for CKD in model 2 and 3.

SAT-398

Quiescent bone surface is not so "quiescent": An important but overlooked index for the estimation of bone remodeling *Shijing Qiu[1], Sudhaker Rao[2]. [1]Henry Ford Health, United States. [2]Henry Ford Hospital, United States

Bone surface (BS) is composed of: 1) quiescent surface (QS), where the bone remodeling begins; 2) eroded surface (ES) caused by osteoclastic bone resorption and 3) osteoid surface (OS) produced by osteoblastic bone formation (Fig 1). Currently, bone remodeling is assessed by tetracycline-based histomorphometry of bone tissue. In this study, we tested the hypothesis that QS decreases with increasing bone remodeling.Trans-iliac bone biopsies were obtained after double tetracycline labeling in 144 bone healthy women (43 blacks aged 24-70y and 109 whites aged 20-74y). Histomorphometric measurements were performed in cancellous, intracortical and endocortical bone envelopes. The relationship of static quiescent bone surface (QS/BS) with tetracycline-based bone remodeling variables, including mineralizing bone surface (MS/BS), surface-based bone formation rate (BFR/BS), and activation frequency (Ac.f) were analyzed in each bone envelop for black, white and all women using Spearman method.The results showed that QS/BS was strongly negatively correlated with bone remodeling related variables in all 3 bone envelops in black, white, and all women. R values ranged from 0.53 to 0.87 (all p values <0.0001; Table). However, there were no significant differences in QS/BS and other bone remodeling variables in all bone envelops between black and white women (data not shown).QS/BS is a static variable that does not contain tetracycline-based variables. Therefore, it is appropriate to perform correlation analyses between QS/BS and bone remodeling variables. Based on the strong correlations between QS/BS and the tetracycline-based bone remodeling variables in all bone envelops, we propose that QS/BS as a valid indicator to estimate bone remodeling in the absence of tetracycline labeling. Since bone remodeling always takes place on quiescent bone surface, QS/BS would decrease with increasing bone remodeling. Accordingly, the change in QS/BS can be used to estimate bone remodeling status in bone samples without tetracycline labeling such as from surgery, biopsy, or autopsy. Understanding of bone remodeling in these often discarded but readily available bone samples may provide valuable information in the research of osteoporosis, metabolic bone diseases and efficacy of pharmaceutical agents.

Fig 1. Types of bone surface

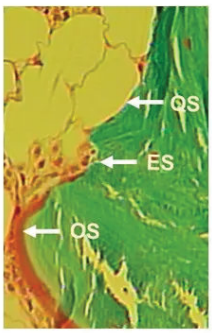

Table 1.Correlation of QS/BS with bone remodeling variables

	MS/BS	BFR/BS	Ac.f

Communicating Fracture Risk: Results from the RICO Study *Mitali Sharma[1], Charlotte Beaudart[2], Mickael Hiligsmann[2], Stuart Silverman[3]. [1]The OMC Research Center, United States. [2]Department of Health Sciences Research, Maastricht University, Netherlands. [3]Cedars-Sinai/UCLA, United States

Objective: The Improving Risk Communication in Osteoporosis (RICO) study aims to identify and improve the apparent communication gap between patients and physicians when discussing fracture risk. RICO was a global initiative to understand patient preferences for fracture risk communication as well as the impact of age, fracture history, and education on the patient's willingness to initiate osteoporosis medication.Materials & Methods: Across eleven sites in nine different countries, 332 women with osteoporosis or at high risk of fracture were given a structured survey, in which they voiced their preferences for fracture risk communication as well as their attitudes towards initiating a prescription osteoporosis medication. Willingness to start a medication was measured in terms of fracture risk decision point (FRDP) or the lowest hypothetical fracture risk-in terms of FRAX score-at which the participant would initiate an osteoporosis medication with minimal, transient side effects. Results: 85.7% of participants indicated that it was important to receive information about their fracture risk with a mean rating of 6.22+/-1.40 on a Likert scale from 1-7. However, only 55.7% reported that they had been told about their fracture risk by a healthcare provider, and only 47% of patients could remember whether their risk was low, moderate, or high. Additionally, participants across all age groups indicated a significant preference for visual presentation of FRAX score-rather than numeric- ($p<0.001$) and reported interest in a two-year FRAX presentation in addition to the existing ten-year timeframe ($p=0.022$). In terms of willingness to initiate medication, participants with higher education expressed a significantly higher FRDP of 10% fracture risk when compared to those with high school education or less-who had a FRDP of 5% fracture risk ($p<0.001$). However, FRDP did not vary significantly based on participants' age ($p=0.082$) or fracture history ($p=0.175$).Discussion: These results confirm a communication gap with regards to how osteoporosis patients receive information regarding fracture risk. Furthermore, understanding the impact of demographic and clinical risk factors on attitudes toward medication initiation may assist both patient and physician in shared clinical decision-making.

Assessing osteoporosis in postmenopausal women: Preliminary results using a novel lumbar spine phantom-based MRI scoring method *Rahman Ud Din[1], Haisheng Yang[1]. [1]Beijing University of Technology, China

PurposeDual-energy X-ray absorptiometry (DXA) may have limitations in distinguishing between patients with osteoporosis and associated fractures. Hence, a new method for detecting osteoporosis has been proposed, which is based on novel magnetic resonance imaging (MRI) lumbar phantom scoring and utilizes fundamental MRI principles.MethodsA study was conducted after obtaining approval from the ethical board, which included testing of four different oils with varying T1 relaxation times, as well as 62 consenting females aged 55 years and above. Participants with bone issues were excluded. Both MRI (with novel phantom) and DXA scans were performed on the participants (November 2022 and March 2023). Two experienced readers evaluated the signal intensities (SI) on T1- and T2-weighted parametric images of 146 vertebrae. Median L1-L5 SI divided by T1 and T2 control SI was used to calculate F- and W-scores, respectively. The diagnostic performance of the new scores in detecting osteoporosis and vertebral fractures was assessed using ROC analysis. Nonparametric Mann-Whitney, regression analysis, box-whisker plots, and descriptive statistics were also used for the analysis.ResultsThirty eligible participants (mean age, 62.56 years +/-6.15; BMI, 28.78+/-6.15) were enrolled out of 62. Coconut oil and deionized water were used as reference controls in the MRI phantom. Higher mean F- and W-scores were reported in individuals with osteoporosis (3.81 and 2.28, respectively) compared to those without (3.05 and 1.78, respectively), with correlation coefficient (ICC) of 0.92 for F-score and 1.00 for W-score. Similar findings were observed in individuals with osteoporotic (3.82 and 2.47, respectively) and non-osteoporotic groups (3.13 and 1.69). The F- and W-scores achieved higher AUC values in individuals with osteoporosis (0.86 and 0.75, respectively) compared to vertebral bone quality (VBQ) (0.71) and signal-to-noise ratio (0.68) with p-values <.05 and p=.093, respectively. The new scores AUC (F-score, 0.80 and W-score, 0.86) better-differentiated participants with osteoporotic vertebral fractures (13/30 or 43.3%) compared to DXA (aBMD, 0.27) with p<.01 and p=.03, respectively.ConclusionA novel MRI lumbar spine phantom was developed and real-time safely tested. The newly defined F- and W-scores exhibited a capability to distinguish osteoporosis from non-osteoporosis, and further demonstrated improved detection ability of osteoporotic vertebral fractures when compared to DXA.

Osteoporosis and Its Role in Periprosthetic Fractures of Total Hip Arthroplasty Patients *Mark Wishman[1], Katherine Haseltine[3], Joseph Lane[3]. [1]Weill Cornell Medical College, United States. [3]Hospital for Special Surgery, . [3]Hospital for Special Surgery, United States

Purpose:Patient undergoing total hip arthroplasty (THA) are routinely under screened for metabolic bone disease at the time of surgery leaving these patients at risk for poor outcomes including periprosthetic fractures (PPFx). As the number of THA procedures increases over the next few decades, the number of patients at risk will also increase. Therefore, there is a need to identify patients at highest risk for PPFx following THA so they can undergo appropriate screening and treatment for osteoporosis if necessary.Methods:We identified fifty-four periprosthetic fracture patients following primary THA. These patients were matched 2:1 to unfractured control THA patients by age and sex. Retrospective chart review was used to collecte demographic variables and past medical history. We then compared Fracture RIsk Assessment Tool (FRAX) scores and associated risk factors as well as treatment with vitamin D/calcium and osteoporosis medications. All data was gathered at the time of fracture PPFx group. In the control patients, an office visit that occurred at the same age as their fracture counterpart's hospitalization occurred was used for data collection. Statistical analysis was done using student t-tests for continuous variables and chi-square analysis for categorical variables. An alpha value of .05 was used to determine significance. Results:When comoparing PPFx patients to unfractured controls there was no difference in age (78.5 +/- 10.87 years vs 78.19 +/- 10.02, p=.79) or sex (?2(1) = 0, p=1). PPFx patients had increased 10-year risk of major osteoporotic fracture (21.86 +/- 10.7 vs 15.86 +/- 9.85, p=.0005) and hip fracture (10.81 +/- 8.48 vs 7.09 +/- 6.59, p.002) by FRAX analysis. PPFx patients had lower BMI (24.85 +/- 5.16 vs 27.92 +/- 6.03, p=.0023) and were more likely to have a history of fragility fracture (?2(1) = 30.65, p=<.00001), be current smokers (?2=(1) = 6.57, p=.0103), and have secondary risk factors for osteoporosis (cirrhosis, diabetes mellitus, etc.)(?2(1) = 16.73, p=.0004) compared to control patients. There was no difference in Vit D/Ca (?2(1) = 1.63, p=.201) or osteoporosis medication usage (?2(1) = 0.12, p=.729) in these groups.Conclusion:These findings suggest that despite PPFx patients having identifiabile risk factors for osteoporosis including increased FRAX scores, lower BMI, and history of fragility fractures, tobacco use, and secondary osteoporosis there is no difference in osteoporosis treatment in these groups.

Retrospective study on the effectiveness and the clinical usefulness of bone turnover marker in patients with osteoporosis: A multicenter study in Korea *Jun-Il Yoo[1], Deog-Yoon Kim[2], Yong-Chan Ha[3], Seong Hee Ahn[4]. [1]Inha University Hospital, Republic of Korea. [2]Kyung Hee University Hospital, Republic of Korea. [3]Seoul Bumin Hospital, Republic of Korea. [4]Inha University Hospital, Inha University School of Medicine, Republic of Korea

Background: The purpose of this study is to investigate real-world data of CTX, P1NP, and Osteocalcin through present multicenter clinical study, and retrospectively analyze the usefulness of bone turnover markers (BTM) in Koreans. The observed data values would provide information that can be used as reference values for the diagnosis and treatment of osteoporosis in patients.Methods: The study focused on pre- and post-menopausal patients diagnosed with osteoporosis and excluded patients without certain test results or with test intervals of more than 1 year. The collected data included age, gender, menopause, fracture history, drug history, osteoporosis treatment history, and three bone turnover markers (CTX, P1NP, and Osteocalcin). The patients were classified by demographic characteristics and the concentrations of the bone turnover markers were analyzed by group.Results: In women who had no history of fractures, the levels of P1NP (n = 2100) were 43.544 +/- 36.902, CTX (n = 1855) were 0.373 +/- 0.927, and osteocalcin (n = 219) were 10.81 +/- 20.631. For men who had no history of fractures, the levels of P1NP (n = 221) were 48.498 +/- 52.892, CTX (n = 201) were 0.370 +/- 0.351, and osteocalcin (n = 15) were 7.868 +/- 10.674. Treatment with teriparatide led to an increase in P1NP levels after three months in both men and women, with a 50% increase observed in women. Similarly, treatment with Denosumab led to a decrease in CTX levels after three months in both men and women, with a reduction of 60% observed in women.Conclusions: The results of this study can contribute to appropriately evaluating the bone replacement status in Koreans. We also provide the PINP level in the Korean population for future comparative studies with other populations.

Skeletal Muscle Energetics and HR-pQCT Bone Parameters: The Study of Muscle, Mobility and Aging (SOMMA) *Jane A. Cauley[1], Tong Yu[4], Lauren S. Roe[3], Nina Heilmann[4], Kerri Freeland[4], Nicole Sekel[4], Kristen Koltun[4], Katelyn I. Guerriere[5], Julie Hughes[5], Bradley Nindl[4], Ashley Weaver[6], Nancy Glynn[4], Philip Kramer[6], Peggy Cawthon[7], Theresa Mau[8], Anne Newman[4], Paul Coen[9], Elsa Strotmeyer[4]. [1]UNIVERSITY OF PITTSBURGH, United States. [4]University of Pittsburgh, . [3], . [4]University of Pittsburgh, United States. [5]US Army Research Institute of Environmental Medicine, United States. [6]Wake Forest University, United States. [7]California Pacific Medical Center, United States. [8]University of California, San Francisco , United States. [9]Adventhealth, Translational Research Institute, United States

Mitochondria are important in aging muscle as they generate the energy needed for contraction. The SOMMA Bone study was designed to improve our understanding of the bone-muscle crosstalk. Here, we examined associations between muscle mitochondrial energetics and high resolution peripheral quantitative tomography (HR-pQCT) parameters. Bone microarchitecture, volumetric bone mineral density (BMD) and bone strength (failure load) were assessed by HR-pQCT. Muscle oxidative capacity was determined by 31 P-Magnetic Resonance Spectroscopy (ATPmax) and state-3 respiration (Max OXPHOS) was assessed in muscle biopsies. A total of 117 community dwelling older men and 178 women participated; mean age, 76.1+/-4.5 years; 86% White. HR-pQCT scans were obtained at the distal radius (DR) and tibia (DT). Failure load, total (Tt) BMD, and cortical (Ct) and trabecular (Tb) BMD, bone area (Ar), thickness (Th) and number (N) were measured. Linear regression models were used to examine the association between ATPmax and Max OXPHOS with sex-specific standardized HR-pQCT parameters. In minimally adjusted models (age, race, limb length), higher DR failure load, Tb.BMD and Ct.Ar were associated with higher ATPmax in men while there was no association in women, Table 1. At the DT, Tt.Ar was associated with higher ATPmax in women and Tb.N in men. There was no association with Max OXPHOS in women or men at the DR. At the DT, Max OXPHOS was positively related to the Tb.N in men and Tb.Ar in women. In the fully adjusted models (age, race, limb length, smoking, alcohol and comorbidities), the association between ATPmax and failure load at the DR (?=0.269*), and Tb.N at the DT (?=0.264*) in men retained significance. The association between ATP max and Tb.BMD at the DT in men became significant (?=0.228*). The fully adjusted association between Max OXPHOS and Tb.N at the DT in men also became significant (?=0.238*). There were no associations between muscle energetics and Ct.Th or Ct.Po at either the DR or DT. In conclusion, these preliminary results suggest that there may be an association between skeletal muscle energetics, specifically ATP max and failure load, Tb.BMD and Ct.Ar in men at the DR. The associations were generally not significant in women and may suggest gender differences in bone-muscle crosstalk. There was little association with Max OXPHOS. Further analyses will explore other markers of skeletal muscle energetics with bone.

Table 1: Associations of skeletal muscle energetics with HR-pQCT parameters at the distal radius and distal tibia in SOMMA older men and women. Standardized β are shown from linear regression models.

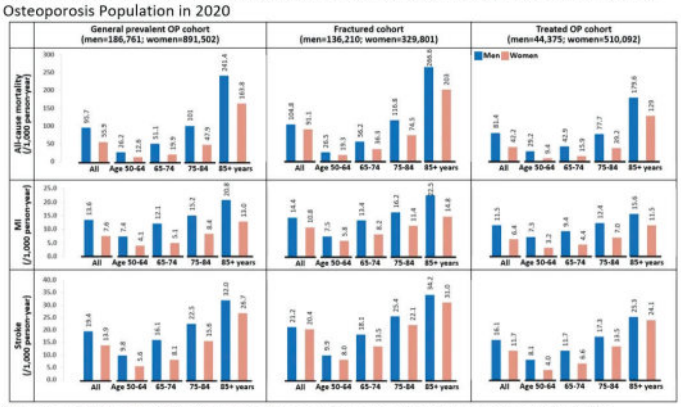
SAT-409

Background incidence rates for 1-year all-cause mortality, myocardial infarction, and stroke in U.S. male and female osteoporosis population in the year 2020 *Hsu-Chih Chien[1], Mary Oates[1], MICHELE MCDERMOTT[1], Tzu-Chieh Lin[1]. [1]Amgen, United States

BackgroundPublished literature on all-cause mortality and incidence of myocardial infarction (MI) and stroke has been limited in osteoporosis (OP) to women receiving OP medication or is based on older data. For OP-treated women, the literature reports 1-year MI incidence and stroke of 3 to 13, and 16-38 per 1,000 person-years respectively. In this epidemiology study, we aimed to update clinical knowledge with more recent data that includes both men and women with OP in the U.S.MethodsMen and women with OP >=50 years of age defined by either having a diagnosis of OP, fracture, or a prescription for OP medication among all available history prior to 1 January 2020 were included from Optum's de-identified Clinformatics® Data Mart Databases (Optum CDM). Individuals with a history of Paget's disease and metastatic cancer were excluded. Eligible patients were followed from 1 January 2020 for 1 year to identify study outcomes including all-cause mortality, MI, and stroke (ischemic, hemorrhagic, and uncertain type) using validated claims-based ICD algorithms. Kaplan-Meier (KM) method was applied to estimate the incidence rate and 95% CI for each study outcome. Event rates within each age subgroups (50-64, 65-74, 75-84, and 85 years and older) were also reported.Results1,078,263 OP patients met inclusion criteria in Optum data in 2020. Of these, 17.3% (186,761) of patients were men and 82.7% (891,502) were women; 79.6% of men and 89.4% of women were >=65 years of age. Fracture was experienced in 72.9% (136,210) of male OP patients and 37.0% (329,801) of female OP patients. Treatment was received by 23.8% (44,375) of male patients and 57.2% (510,092) of female patients.Overall, event rates per 1,000 patient-years were higher than women across all study outcomes (all-cause mortality, men: 95.7 [95% CI: 94.3, 97.1]; women: 55.9 [95% CI: 55.4, 56.4]; MI, men: 13.6 [95% CI: 13.1, 14.2]; women: 7.6 [95% CI:7.5, 7.8] ; stroke, men: 19.6 [95% CI: 19.0, 20.3]; women: 13.9 [95% CI: 13.7, 14.2]). The event rates increased with age and individuals >= 85 years old had the highest rates. Higher rates were also observed in men and women who experienced fracture across all age groups. (Figure 1)ConclusionWe updated the background rates of all-cause mortality, MI and stroke in men and women with OP in U.S. in 2020. The overall rates were within the range from published literature, and we observed a higher rate in men (vs women), older age and those with fracture history.

Figure 1. 1-year Incidence Rates of Myocardial Infarction, Stroke and All-cause Mortality in US Osteoporosis Population in 2020



MI: myocardial infarction, OP: osteoporosis. Osteoporosis treatment included anabolic agents (including romosozumab and PTH analogues [teriparatide and abaloparatide]), denosumab, oral bisphosphonates (alendronate, risedronate and ibandronate) and intravenous zoledronic acid

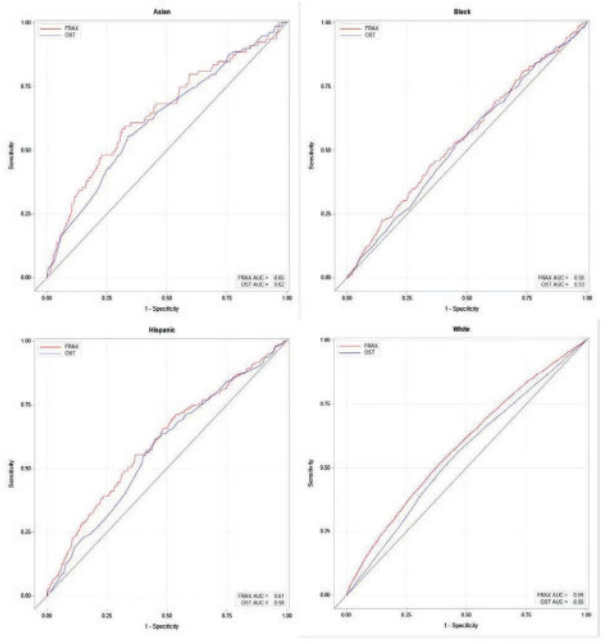
Race/ethnicity and Fracture Prediction in Younger Postmenopausal Women: Results from the Women's Health Initiative Study *Carolyn Crandall[1], Joseph Larson[2], John Schousboe[3], JoAnn Manson[4], Nelson Watts[5], John Robbins[6], Peter Schnatz[7], Rami Nassir[8], Aladdin Shadyab[9], Karen Johnson[10], Jane A. Cauley[11], Kristine Ensrud[12]. [1]University of California, Los Angeles, United States. [2]Fred Hutchinson Research Center, United States. [3]Park Nicollet Clinic HealthPartners Institute University of Minnesota, . [4]Harvard Medical School, United States. [5]Mercy Health Osteoporosis and Bone Health Services, . [6]University of California Davis Medical Center, United States. [7]Reading Hospital/Tower Health and Drexel University, United States. [8]University of California, Davis, United States. [9]University of California, San Diego, United States. [10]University of Tennessee Health Science Center, United States. [11]UNIVERSITY OF PITTSBURGH, United States. [12]University of Minnesota and Minneapolis VA Health Care System, United States

Importance: The best approach to identify younger postmenopausal women for osteoporosis screening in uncertain. The Fracture Risk Axsessment Tool (FRAX), which includes self-identified race/ethnicity information, and the Osteoporosis Self-Assessment Tool (OST), which does not, are risk assessment tools recommended by United States Preventive Services Task Force Guidelines to identify candidates for bone mineral density (BMD) testing in this age group.Objective: To compare the ability of FRAX vs. OST to discriminate between younger older postmenopausal women who do and do not experience incident fracture during 10-year follow-up in the four racial/ethnic groups specified by FRAX.Design: This observational study of Women's Health Initiative Study participants included 67,169 women aged 50-64 years at baseline with 10 years of follow-up for major osteoporotic fracture (MOF). at 40 U.S. clinical centers. Incident MOF and BMD (in a subset of 4,606 women) were assessed. The area under the receiver operating characteristic curve (AUC) for FRAX (without BMD information) and OST were calculated within each racial/ethnic category. Results: Mean (SD) participant age at baseline was 57.8 (4.1 years); 1,486 self-identified as Asian, 5,927 as Black, 2,545 as Hispanic, and 57,211 as White. During follow-up, 5,594 women experienced MOF. For discimination of MOF, AUC values (95% confidence interval) for FRAX were 0.65 (0.51-0.78) for Asian, 0.55 (0.49-0.61) for Black, 0.60 (0.52-0.68) for Hispanic, and 0.55 (0.53-0.57) for White women. AUC Values for OST were 0.67 (0.54-0.79) for Asian, 0.55 (0.48-0.61) for Black, 0.50 (0.52-0.68) for Hispanic, and 0.56 (0.54-0.58) for White women. See Figure 1. For discrimination of femoral neck osteoporosis, AUC values were excellent for OST (range 0.79-0.85), higher for OST than FRAX (FRAX AUC range 0.72-0.74), and similar in each of the four racial/ethnic groups. Conclusions: Within each racial/ethnic category, the U.S. FRAX tool and OST have suboptimal performance in discimination of MOF in younger postmenopausal women. In contrast, for identifying osteoporosis, OST was excellent. The U.S. version of FRAX should not be routinely used to make screening decisions in younger postmenopausal women.

Figure 2. Receiver Operating Characteristic (ROC) Curves by Race/Ethnicity for Major Osteoporotic Fracture during 10 years of Follow-up among Women aged Between 50 and 64 years at Baseline, by Race/Ethnicity[1]



[1] FRAX vs. OST: All Participants, p<0.001; Asian, p=0.59; Black, p=0.50; Hispanic, p=0.35; White, p<0.001; p-values from a Chi-square statistic on 1 degree of freedom testing the difference between each paired group

Vitamin D Status in Patients with Non-Vertebral Fragility Fractures *Satoshi Hagio[1], Taro Mawatari[2], Reima Sueda[3], Satoru Harada[3], Koichiro Kawano[3], Shoji Baba[3]. [1]HAMANOMACHI HOSPITAL, Japan. [2]Hamanomachi Hospital, Japan. [3]KKR Hamanomachi Hospital, Japan

Introduction:Vitamin D insufficiency or deficiency is a global health issue, and studies have reported that half of osteoporosis patients in Japan have vitamin D deficiency. This study aimed to investigate the vitamin D status in patients with non-vertebral fragility fractures, including distal radius (DRF), proximal humerus (PHF), femoral neck (FNF), and femoral trochanteric (FTF) fractures, who visited a hospital in Japan.Patients and Methods:A retrospective analysis was conducted on the serum 25(OH)D levels of 436 patients (107 males, 329 females, mean age 73 years) who visited a regional public general hospital in Japan for surgical treatment of non-vertebral fractures. Available information on other blood chemistry data and bone mineral density measured by dual-energy X-ray absorptiometry was also collected. The institutional review board approved this study.Results:Serum 25(OH)D levels were measured in patients with non-vertebral fragility fractures, including DRF (n=99), PHF (n=54), FNF (n=164), and FTF (n=119). The mean serum 25(OH)D levels were 15.7 ng/ml for DRF (mean age 65.3 years), 13.7 ng/ml for PHF (mean age 69.8 years), 11.9 ng/ml for FNF (mean age 77.9 years), and 11.3 ng/ml for FTF (mean age 83.6 years). Significant differences in serum 25(OH)D concentrations were observed between patients with DRF and those with FNF, as well as between those with DRF and FTF ($p<0.05$).No correlation was found between age and serum 25(OH)D ($R=0.03$), but significant differences were found in all groups except for PHF and DRF ($p<0.05$). The incidence of vitamin D deficiency, defined as serum 25(OH)D levels <20 ng/ml, was 76% for DRF, 81% for PHF, 89% for FNF, and 94% for FTF. The rates of severe deficiency, defined as serum 25(OH)D levels <10 ng/ml, were 18%, 31%, 48%, and 51%, respectively.Discussion and Conclusion:This study found that vitamin D insufficiency or deficiency is prevalent in patients with non-vertebral fragility fractures, especially in older patients with FNF and FTF. The incidence of vitamin D deficiency in this patient population is higher than the general population in Japan, highlighting the importance of monitoring and addressing vitamin D status in these patients. Fracture site differences in serum 25(OH)D levels suggest a potential relationship between the degree of vitamin D deficiency or insufficiency and the location of the fracture.

SAT-415

Self-reported physical function is associated with increased fracture and mortality risk *Dana Bliuc[1], Thach Tran[1], Dunia Alarkawi[1], Weiwen Chen[2], Robert Blank[3], Jacqueline Center[1]. [1]Garvan Institute of Medical Research, Australia. [2]Garvan Institute, Australia. [3]Medical College of Wisconsin, Division of Endocrinology,

Poor muscle strength and physical performance, as measured by common tests, increase the risk of falling and fracture, particularly for men. However, those unable to perform these tests have the highest fracture risk, suggesting that simpler qualitative measures might be useful. This study investigated the association between self-reported physical function (PF) and fracture risk in women and men.45 and Up is a prospective population-based cohort of 116,001 (from 267,357) people with complete baseline questionnaire data linked to hospital, emergency, and mortality datasets. Four self-reported measures of PF (walking, lifting, climbing stairs and bending) were analysed. Fractures were identified from hospital admission and emergency care administrative data, and mortality from vital statistics data over the first 5 years of follow-up.The association of PF measures and fracture and mortality risk were determined using cause-specific Cox models, a competing risk approach which produces simultaneous estimates of fracture and mortality risk. The models were further adjusted for age, weight, prior fracture and falls. Given a significant interaction with self-reported PF, Cox models were stratified by age (< 75, >= 75).Approximately 20% of participants reported limitation in at least one PF domain. Interestingly, most participants reported limitation in all PF domains (Figure). During the first 5 years of follow-up, there were 7190 fractures and 4958 deaths in women and 4267 fractures and 7845 deaths in men. All PF domains were associated with an increased risk of fracture and mortality in both age groups and genders. Those who reported a limitation in all 4 PFs had the highest risk. In those < 75, the hazard ratio was 1.73 (95% CI, 1.58 - 1.89) for fracture and 1.21 (95% CI, 1.12 - 1.32) for death in women and 1.64 (1.45 - 1.86) and 1.28 (1.19 - 1.37) in men. In those >= 75, the respective hazard ratios for fracture and death were 2.16 (95% CI, 1.88 - 2.47) and 1.46 (95% CI, 1.34 - 1.60) in women and 2.44 (2.09 - 2.84) and 1.50 (1.40 - 1.58) in men. Approximately 8% of fractures and 5% of deaths were attributable to PF impairment in those aged 75.PF limitation is common and is associated with increased fracture and mortality risk. Our findings suggest that simple self-assessment may be a useful clinical tool for selecting candidates for further investigation and intervention.

SAT-416

The Relationship between Sarcopenia and Bone Mineral Density in Community-Dwelling Subjects Aged 50 Years or Older in Men and Postmenopausal Women in Korea *Dong Jin Chung[1], Bitz-Na Kim[2], Jin Ook Chung[1], Dong Hyeok Cho[2], Jeong-Ran Cho[3]. [1]Chonnam National University Medical School, Republic of Korea. [2]Chonnam National University Hospital, Republic of Korea. [3]Kwangju Women's University, Republic of Korea

Sarcopenia is a progressive and generalized skeletal muscle disorder associated with poor health outcomes such as falls, fractures, cardiovascular, metabolic disease, lower quality of life, disability, and mortality. In this study, we used nation-wide data from 2008 to 2011 Korea National Health and Nutrition Examination Survey (KNHANES) to analyze the association between bone mineral density (BMD) and sarcopenia in community-dwelling men and women. Subjects with history of medication for osteoporosis or with illness or malignancy affecting bone metabolism were excluded. Data of anthropometric measurements and demographic characteristics were collected by trained examiner. Serum was separated from peripheral venous blood samples obtained after 8 hours of fasting. BMD was measured at the lumbar spine, femur neck and total femur using dual-energy X-ray absorptiometry (DXA). Sarcopenia was defined using the revised Asian Working Group for Sarcopenia (AWGS) classification with SMI (skeletal muscle index; <7.0 kg/m2 for men and <5.4 kg/m2 for women). We included 2,133 subjects aged 50 years or older in men (N=1,246, 887 without sarcopenia, 359 with sarcopenia) and postmenopausal women (N=887, 692 without sarcopenia, 195 with sarcopenia). All data analyses were performed using a weighted complex sample design. Prevalence of sarcopenia was significantly higher in men (28.8%) than women (22.0%). Compared with subjects without sarcopenia, men with sarcopenia had lower BMD at the lumbar spine, femur neck and total femur, whereas, women with sarcopenia had lower BMD at the femur neck and total femur. In multiple regression analysis, sarcopenia was significantly associated with low bone mass at the lumbar spine, femur neck and total femur BMD after adjusting age, obesity, hyperlipidemia, hypertension, smoking

status, alcohol consumption, monthly house income, physical activity, daily calcium intake and vitamin D concentration in men. However, there was no association between sarcopenia and bone mass in women in same analysis. In conclusion, sarcopenia is significantly related to low bone mass, especially in men aged >=50 years in Korea.

Association of Sex Steroid Hormone Changes and Femoral Neck Area and Bone Mineral Content Across the Menopausal Transition: Findings from the Michigan Bone Health and Metabolism Study *Carrie Karvonen-Gutierrez[1], Irena Chen[2], Aleda Leis[3], Kerry Richards-McCullough[1], Tom Richards[1], ERIN BIGELOW[4], Robert Goulet[5], Karl Jepsen[3]. [1]Department of Epidemiology, University of Michigan, United States. [2]Department of Biostatistics, University of Michigan, United States. [3]University of Michigan, United States. [4]UNIVERSITY OF MICHIGAN, United States. [5]Michigan Medicine, University of Michigan, United States

Bone mineral density (BMD) declines rapidly during the menopausal transition (MT); nearly 50% of lifetime BMD loss in women occurs during the MT. It also a period of rapid endocrinologic change, with accelerated rises in follicle-stimulating hormone (FSH), beginning five years before the final menstrual period (FMP) and accelerated declines in estradiol (E2), beginning 2 years before the FMP. Given the co-occurrence of these two processes - endocrinologic and bone changes - sex hormones are hypothesized to have a major role in the regulation of bone metabolism, but the evidence is mixed. The majority of research has focused solely on BMD, a summary measure of bone change, which can obscure unique impacts on bone area and bone mineral content (BMC). In this analysis, we evaluate the relationship between E2 and FSH levels across the MT and patterns of change in bone area and BMC. Data are from 211 women (1929 observations) in the Michigan Bone Health and Metabolism Study, initiated in 1988 with 15 follow-ups through 2009. At each visit, participants received a DXA scan of the femoral neck and a blood sample was obtained in days 3-5 of the follicular phase of the menstrual cycle. E2 and FSH were assayed in duplicate and log-transformed for analysis. Models were adjusted for baseline BMC and area and included random intercepts to account for within-woman correlation. Time to FMP was fit with a linear spline, with knots at -2 and +2 years for E2 models and -2 and +1 years for FSH models. Analyses were conducted in R Studio. Latent class analysis was used to estimate trajectory groups representing patterns of change in BMC and area across the MT. In models relating BMC trajectory group to sex hormones, there were no statistically significant associations with E2 or FSH. However, a one unit higher baseline BMC was associated with an 11% lower FSH. In models relating area trajectory groups to sex hormones, women in the group with the highest but slightly declining area had 22% lower FSH as compared to women in the group with low but slightly increasing area. Further, a one unit higher baseline bone area was associated with a 19% higher FSH value. There were no statistically significant associations between bone area and E2. These findings suggest that increases in bone area are associated with higher FSH values. More research is needed to elucidate the relationship between sex hormone changes and changes in bone morphology across the MT.

Epidemiology of fractures in different ethnic groups across the lifespan in New Zealand *Brya Matthews[1], Subhajit Konar[1], Zhenqiang Wu[1], David Musson[1], Sarah-Jane Paine[1], Roger Harris[2]. [1]University of Auckland, New Zealand. [2]Australia and New Zealand Fragility Fracture Registry, New Zealand

Fractures lead to increased morbidity and mortality in the elderly, but they are a musculoskeletal issue that occurs at all ages. Fracture rates are often estimated based on hospitalisation data, which only gives a complete picture for certain fracture types. In New Zealand, injuries are covered by a no-fault national insurance system known as ACC. Most fractures that require clinical attention are recorded as ACC claims. The aim of this study was to determine the frequency of fractures in New Zealand overall and at key sites in different genders and ethnic groups across the lifespan.Individualised fracture claim data were obtained from ACC for 2010-2018. 851,544 fracture claims were included in the analysis. Prioritised ethnicity was reported (order of priority is Maori, Pacific peoples, Asian, Other, European) for 98% of claims. Census data was used to calculate fracture incidence. A setting where the injury occurred was reported in 91% of claims.Males accounted for 52.8% of fractures in the entire dataset, however over the age of 50, fracture incidence is 67% higher in women (Table). All ethnicities showed peaks in fracture incidence in adolescence and the elderly. We noted aging-related increases in fracture incidence at all anatomical sites except hands and feet, including sites like lower leg, ribs and skull and face that are not typically considered sites of fragility fracture. Europeans had the highest fracture incidence overall, and Maori and Pacific people have lower incidence of fractures than Europeans in all age groups in women and all but 20-39 years of age in men. Asians had the lowest fracture incidence overall, particularly in males. Hip fractures mainly occur in the elderly and show higher incidence in Europeans than other ethnicities (Table). Almost half of all fractures occurred at home, rising to over 80% in the elderly. 30% of fractures in people aged 10-39 occurred in a place of recreation or sports. Males consistently had more fractures outside the home than females.Age, gender and ethnicity all affect fracture incidence, with peaks in adolescents, young men, and the elderly. Non-Europeans in New Zealand generally have lower fracture rates than Europeans. Our data suggest that most types of fractures in older people could be indicators of skeletal fragility.

Table: Total fracture incidence in New Zealand 2010-2018 (per 10,000 people/year)

	Female					Male

Osteoporosis Risk Prediction by Machine Learning Approach Using Clinical and Metabolomic Data *Chuan Qiu[2], XIAO ZHANG[2], Anqi Liu[2], Luo Zhe[2], Qing Tian[2], Hui Shen[2], Hong-Wen Deng[2], Kuan-Jui Su[3], YUN GONG[2]. [2]Tulane University, United States. [2]Tulane University, , [3]Tulane.edu, United States

Osteoporosis, characterized by low bone mineral density (BMD), is an increasingly serious public health issue. So far, several traditional machine learning (ML) algorithms have been proposed for predicting osteoporosis risk. However, these models have shown relatively low accuracy in clinical implementation. Recently proposed deep learning (DL) approaches, such as deep neural network (DNN), which can discover knowledge from complex hidden interactions, offer a new opportunity to improve predictive performance. In addition, recent multi-omics studies showed that metabolomics has a great potential to identify predictive biomarkers for complex human diseases. Therefore, DL-based disease prediction methods, integrating multi-omics data such as metabolites, as well as conventional clinical factors, could be a promising approach for disease prediction and prevention. In this study, we aimed to assess whether DNN can achieve a better performance in osteoporosis risk prediction, especially by adding metabolomics data into the prediction model. By utilizing hip BMD and extensive demographic and routine clinical data of 2,376 subjects from the Louisiana Osteoporosis Study (LOS), we constructed a DNN framework for predicting osteoporosis risk and compared its performance in osteoporosis risk prediction with four conventional ML models, namely random forest (RF), artificial neural network (ANN), k-nearest neighbor (KNN), and support vector machine (SVM), as well as a traditional regression model termed osteoporosis self-assessment tool (OST). Model performance was assessed by area under the 'receiver operating curve' (AUC) and accuracy. By using 16 discriminative variables, we observed that the DNN approach achieved the best predictive performance (AUC = 0.793) in classifying potential osteoporosis (hip BMD T-score <= -1.0) and non-osteoporosis risk (hip BMD T-score > -1.0) subjects, compared to the other approaches. Feature importance analysis showed that the top 5 most important variables identified by the DNN model were weight, height, age, gender, and grip strength. Furthermore, we assessed the effects of metabolomics data on the predictive performance of these tested models. Notably, the predictive performance was further improved (AUC = 0.815) by integrating the metabolomics data into the DNN model. In conclusion, DNN was an effective algorithm for the early diagnosis and intervention of osteoporosis.

Higher Muscle Power and Strength are Associated with HR-pQCT Volumetric Bone Density, Microarchitecture and Strength: the Study of Muscle, Mobility and Aging *Elsa Strotmeyer[2], Nina Heilmann[2], Kerri Freeland[2], Tong Yu[2], Lauren S. Roe[3], Nicole Sekel[2], Kristen Koltun[2], Katelyn Guerriere[4], Julie Hughes[5], Bradley Nindl[2], Ashley Weaver[6], Paolo Caserotti[7], Peggy Cawthon[8], Anne Newman[2], Jane A. Cauley[9]. [2]University of Pittsburgh, United States. [2]University of Pittsburgh, , [3], , [4]Military Performance Division, United States Army Research Institute of Environmental Medicine, United States. [5]US Army Research Institute of Environmental Medicine, United States. [6]Wake Forest University, United States. [7]University of Southern Denmark, Denmark. [8]San Francisco Coordinating Center, United States. [9]UNIVERSITY OF PITTSBURGH, United States

Muscle and bone may be connected via mechanostat loading or by muscle-bone signaling. We hypothesized that higher muscle function in the Study of Muscle, Mobility and Aging (SOMMA) was associated with better high-resolution peripheral quantitative computed tomography (HR-pQCT) distal tibia (DT) and radius (DR) bone density (BMD), microarchitecture and strength, in the SOMMA Bone Study at year 1 (Pittsburgh, PA site, N=297; 59.0% women; 87.9% White; 77.2+/-4.6 years). Muscle function tests included best stair climb ascend power (Watts=W) of 3 stair climb laps, single leg press peak power (W; 40-70% 1-RM) and strength (1-RM, kg), and grip strength (kg). Muscle function was higher in men vs. women (all p<0.001). Partial correlations of muscle function and DT and DR outcomes adjusted for sex, age, race, limb length, height and weight were weak (all r<=0.2); though positive and significant for DT (failure load: all but grip strength, Ct.BMD: leg power and strength, Tt.Ar: leg power and strength, Ct.Ar: all, Tb.Ar: leg strength, and Ct.Th: leg power), and DR (failure load: all, Tt.Ar: leg/grip strength, Ct.Ar: stair climb power, Tb.Th: leg power, and Tb.Ar: leg/grip strength), which were mostly consistent for men and women. In multivariable linear regression, muscle function was associated with sex-specific z-score outcomes (except total BMD), and results varied by sex, tests, and DT/DR site (Table 1). For DT, more findings in women (N=152) were for leg power and leg/grip strength and only leg strength with Tt.Ar in men (N=109). For DR, more findings in women (N=137) were for stair climb power and in men (N=103) for grip strength. Higher muscle function was associated with higher DT Tt.Ar (women: grip strength; women and men: leg strength), DR Tt.Ar (men: leg power and strength) and DR failure load (women: stair climb power; men: grip strength). In women, higher muscle function was associated with higher Ct. outcomes (DT Ct.BMD: leg power and strength; DT Ct.Ar: all; DT Ct.Th: leg power, grip strength; DR Ct.BMD, Ct.Ar and Ct.Th: stair climb; DR Ct.Ar: grip strength), but higher DR Tb outcomes in men (Tb.Ar: leg strength; DR Tb.BMD and Tb.Th: grip strength). Higher muscle function in older women (power and strength) and men (mostly strength) was associated with varied tests and DT/DR outcomes, notably DR failure load which predicts fracture. Muscle-bone differences by sex for Ct vs. Tb bone and upper vs. lower extremity sites may also impact fracture risk.

Table 1. Multivariable linear regression of muscle function predictors (standardized β of stair climb power, leg power, leg strength and grip strength) and HR-pQCT sex-specific z-score outcomes in women and men

Comparison of Risk Factors for Initial Fragility Fractures vs. Recurrent Fractures *Lucas Steele[2], Amina Anwar[2], Aamir Kadri[2], Madhumathi Rao[2]. [2]University of Kentucky, United States. [2]University of Kentucky,

Fragility fractures refer to low trauma fractures and are often the first indication of underlying osteoporosis. The occurrence of a fracture sharply increases the risk of a second fracture by 2- to 3-fold, but other risk factors may also contribute to the occurrence of recurrent fractures. In this study, we aimed to characterize the differences between patients presenting with an initial fragility fracture and those presenting with a recurrent fracture, as this has yet to be performed in such a population.A retrospective chart review was performed to collect data pertaining to variables such as age, sex, race, BMI, comorbidity, osteoporosis risk factors, and types of fractures. Admission lab values were obtained for all patients, including metabolic, hematologic, inflammatory, and bone turnover markers. Categorical data were analyzed with Chi-squared analysis; means were compared using independent sample T-tests and sex, age, and BMI-adjusted means were compared using regression analysis with significance set at p=0.05.In total, we had 196 patients, mean age 78.1 +/- 9.6 years, 76.5% female; 92 patients presented with an initial fracture and 104 with a recurrent fracture. There were no significant differences in sex, BMI, or race, prior osteoporosis treatment history or osteoporosis risk factors such as cancer, steroid history, and tobacco exposure. Notably there was no difference in age (78.6 +/- 9.3 vs 77.7 +/- 10.0) between patients who presented with an index fracture compared to those with recurrent fractures. Patients presenting with an index fracture had higher baseline serum creatinine (1.12 vs 1.01, SE = 0.095, p = 0.001 after adjusting for sex and BMI). Patients with a prior fracture history also had a significantly higher prevalence of microvascular comorbidities (92.3% vs 81.5%, p = 0.024). Lastly, 63.3% of index fractures were femur fractures, compared to 53.8% in the recurrent group (p = 0.05).Our results suggest that patients presenting with recurrent fractures may be those who begin fracturing at a younger age and have more microvascular disease (hypertension and diabetes). Patients that presented with an index fracture appeared to have a higher overall baseline creatinine and were more likely to present with a femur fracture. Improved characterization of these differences would help with better risk stratification for preventive strategies.

Clinical outcomes of COVID-19 infection in patients with osteoporosis: A nationwide cohort study in Korea *Seong Hee Ahn[1], Sung-Hyo Seo[2], Chai Young Jung[3], Dong Han Yu[4], Youngjoon Kim[1], Yongin Cho[1], Da Hea Seo[1], So Hun Kim[1], Jun-Il Yoo[5], Seongbin Hong[1]. [1]Department of Endocrinology and Metabolism, Inha University Hospital, Inha University School of Medicine, Republic of Korea. [2]Department of Research Planning, Gyeongsang National University Hospital, Republic of Korea. [3]Biomedical Research Institute, Inha University Hospital, Republic of Korea. [4]Big Data Department, Health Insurance Review and Assessment Service, Republic of Korea. [5]5Department of Orthopedic Surgery, Inha University Hospital, Inha University School of Medicine, Republic of Korea

Background: The association between comorbidities and severe COVID-19 outcomes has been extensively researched, but little is known about the clinical outcomes of COVID-19 patients with osteoporosis. To address this gap, we conducted a nationwide cohort study in Korea to investigate the clinical outcomes of COVID-19 patients with a history of osteoporosis before their infection.Methods: We conducted a retrospective cohort study using data from Health Insurance Review and Assessment Services encoded in the Observational Medical Outcomes Partnership Common Data Model. We included patients >=50 years old diagnosed with COVID-19 infection between 1 January 2020 and 30 April 2022 and stratified them into two groups according to a history of osteoporosis before COVID-19 infection. Clinical outcomes within 30 days after COVID-19 infection were analyzed using propensity score stratification and logistic regression analysis.Results: Of the 597,011 COVID-19 patients included in the study, 105,172 had a history of osteoporosis. COVID-19 patients with osteoporosis had a lower risk of mortality than those without osteoporosis (OR 0.82, P <0.002). However, among COVID-19 patients with osteoporosis, those who also had a history of fracture had a higher risk of mortality, pneumonia, hospitalization, major adverse cardiovascular events (MACE), and venous thromboembolism than COVID-19 patients without osteoporosis (OR 1.32-1.58, P<0.001 to P=0.001). In male COVID-19 patients, those with osteoporosis had an increased risk of pneumonia, hospitalization, and MACE compared to those without osteoporosis (OR 1.11-1.18, P<0.001 to P=0.026), and the risk of mortality was not significantly different between the two groups. In female COVID-19 patients, the risk of mortality was lower in those with osteoporosis than those without osteoporosis (OR 0.84, P<0.001).Conclusion: Our study suggests that patients with severe osteoporosis who have experienced fractures have an elevated risk of mortality and other severe complications with COVID-19. However, patients with osteoporosis who have not experienced fractures and have sought medical attention have demonstrated a lower risk of

mortality. Effective management of osteoporosis may result in better clinical outcomes in the context of COVID-19, despite the potential impact of deteriorating bone health itself on the severity of COVID-19 complications.*This study used OMOP-CDM data made by Health Insurance Review & Assessment Service.

SAT-426

PPI use is not associated with bone microarchitecture and bone strength in a 3-year follow-up study of FLS patients *MERLE SCHENE[1], MELISSA BEVERS[2], Wim Van Der Vijgh[3], Johanna Driessen[4], Lisanne Vranken[5], Robert van der Velde[6], HANNA C. WILLEMS[7], Joop Van Den Bergh[8], Caroline Wyers[9]. [1]Viecuri Medisch Centrum , , [2]VieCuri Medical Center, , [3]VU University Medical Center, , [4], Netherlands. [5]Department of Internal Medicine, VieCuri Medical Center; 2 NUTRIM School of Nutrition and Translational Research in Metabolism, Maastricht University, Netherlands. [6]Department of Internal Medicine, VieCuri Medical Center, Netherlands. [7]Amsterdam UMC, Netherlands. [8]VieCuri MC Noord-Limburg and Maastricht UMC, , [9]VieCuri Medical Centre, Netherlands

The use of proton pump inhibitors (PPI) has been associated with an increased fracture risk in observational studies. Proposed biological mechanisms include a decreased calcium absorption, hypergastrinemia and increased bone resorption. However, the association between PPI use and bone mineral density (BMD), bone microarchitecture and strength is inconsistent. The aim of this study was to assess the association between PPI use and bone microarchitecture and strength using high resolution peripheral quantitative CT (HR-pQCT). This three-year prospective cohort study included 323 patients aged >=50 years with a recent fracture (median age 62 [IQR 56-69], 68.7% women) who attended the Fracture Liaison Service (FLS) and had no treatment indication with anti-osteoporosis medication. At the FLS visit (T0), 63 (19.5%) patients used PPI. At baseline, female PPI users had a significantly higher BMI and more often probable sarcopenia (EWGSOP2) compared to non-users. Male PPI users had more often a hip/major fracture than non-users. In both men and women, PPI users had more cardiovascular co-morbidities than non-users. HR-pQCT scans of the distal radius and tibia were acquired at T0 and at three-year follow-up (T3). Scans of sufficient quality at T0 and T3 were available for assessment of bone microarchitecture and strength in 166 women at the distal radius (33 PPI-users and 133 in non-users) and 190 at the distal tibia (34 and 156, respectively) and for 76 men at the distal radius (14 and 62) and 90 men at the distal tibia (19 and 71). Sex-stratified linear regression analyses were used to investigate the association between PPI use and bone microarchitecture and strength parameters at T3. Covariates included age, HR-pQCT parameter at T0, vitamin-D deficiency (<30 nmol/L), prednisone use, and cardiovascular co-morbidity in the models for men and women. In men, fracture type (major/hip vs. all others) and in women probable sarcopenia were additional covariates. In both men and women, when compared to non-use, PPI use was not associated with bone microarchitecture and strength at T3 at the distal radius and tibia, except for a marginally decreased trabecular thickness at the distal radius in men (B= -0.003, p=0.048). To conclude, PPI-use was not associated with bone microarchitecture and strength in FLS patients at 3 years of follow-up. This indicates that bone quality might not be related to fracture risk of PPI users found in observational studies.

SAT-427

Cardiovascular events and bone fragility in a large population: a study based on the CARTaGENE cohort *Clément Vachey[1], Aurélie Dufour[2], Laetitia Michou[2], Claudia Gagnon[1], Mohsen Agharazii[1], Fabrice Mac-Way[3]. [1]CHU de Quebec, Universite Laval, Canada. [2]Universite Laval, Canada. [3]L Hotel-Dieu de Quebec, Canada

Purpose: An association between bone fragility and cardiovascular health has been previously reported. Our study aimed to evaluate the impact of osteoporosis on cardiovascular events (CVE) risk in the Quebec (Canada) population.Methods: From the large population-based cohort CARTaGENE, which represents 1% of the Quebec population aged from 40 to 70 years old, recruited between 2009 and 2010, we studied the impact of osteoporosis on CVE risk in subjects without any prior CVE. We then evaluated the impact of fragility fractures, occurring after 40, on CVE risk. A semi-parametric Cox model was used with adjustment for age, cardiovascular risk factors and medications. We also investigated whether sex was an effect modifier.Results: We included 18 644 subjects (mean age 54.2+/-7.9, women 52.9%, osteoporosis 4.4%, prior fragility fracture 7.8%). We observed a total of 342 CVE after a median follow-up time of 5.8 years. In multivariable analyses adjusted for cardiovascular risk factors, a diagnosis of osteoporosis was associated with a significant increased risk of CVE (Hazard Ratio (HR) =1.60, 95% confidence interval (95%CI): 1.02-2.50). We did not observe any effect modification by sex on this association. The occurrence of a fragility fracture after 40 was not marginally associated with a significant increased risk of CVE (HR=1.14, 95%CI: 0.78-1.66). However, there was a substantial increased risk in women (HR=1.89, 95%CI: 1.08-3.30) versus men (HR=0.82, 95%CI: 0.49-1.39). After adjustment for potential confounding medications, osteoporosis was still associated with CVE risk (HR=1.55, 95%CI: 0.99-2.44) while fragility fractures was associated with CVE risk only in women (HR=1.85, 95%CI: 1.06-3.24).Conclusion: In a relatively young and low cardiovascular risk population, osteoporosis is associated with CVE while the occurrence of a fragility fracture after 40 is associated with cardiovascular morbidity only in women.

SAT-428

Force Plate Leg Power and Velocity Was Associated With the Risk of Major Osteoporotic Fractures (MOF): the Osteoporotic Fractures in Men Study (MrOS) *Tong Yu[1], Elsa Strotmeyer[1], Nina Heilmann[1], Deborah Kado[2], Kristine Ensrud[3], Mary Winger[4], Paolo Caserotti[5], Peggy Cawthon[6], Jane Cauley[1]. [1]University of Pittsburgh, United States. [2]Stanford University, United States. [3]University of Minnesota, Minneapolis VA Health care system, United States. [4]UPMC Insurance Services Division, United States. [5]University of Southern Denmark, United States. [6]University of California San Francisco, California Pacific Medical Center, Research Institute, United States

MOFs are clinical fractures at the vertebrae, hip, wrist and humerus, which may negatively impact physical function and quality of life. Previous studies found that lower extremity muscle function is associated with risk of falls and fractures, however, most studies have examined strength (force), but not power (force*velocity). A novel jump test on a force plate measures weight-bearing leg power and allows the dissection of peak power into its components, force and velocity. We investigated the association between jump test leg power measures and MOF risk in men from the MrOS study.The study included 1841 older men (median age 84 years, range 77-101 years) who completed the Year 14 visit (2017). Peak jump power (Watt/kg body weight), force (Newton/kg body weight) at peak power, and velocity (m/s) at peak power were measured by jump tests on a force plate at Year 14 visit. Follow-up times were truncated at 5 years to avoid extrapolating the effect of leg power on fractures. Fractures were identified by triannual questionnaires, with all self-reported fractures confirmed by medical record. Cox proportional hazards models were used to estimate hazard ratios (HR) and 95% Confidence Intervals (CIs) of MOFs by continuous (per one SD increment) and quartiles of jump test measurements. Participants that did not do jump tests mainly due to low physical function were classified into the "lowest" power group (referent).Incident clinical fractures occurred in 265/1841 (14%) within 5 years, of which 136 (51%) were MOFs. In the fully adjusted model, one SD increment of peak power/kg body weight was associated with 29% lower risk of MOF (HR 0.71, 95% CI 0.54-0.92). Similarly, one SD increment of velocity at peak power was associated with 24% lower risk of MOF (HR 0.76, 95%CI:0.59-0.98). Further adjustment of femoral neck (FN) bone mineral density (BMD) and fall history did not attenuate the association. Compared to the referent group, the fourth (highest) quartile of power and velocity were also significantly associated with decreased risk of MOF, P=0.003 and P=0.025 for trend, respectively. For force at peak power, only the highest quartile was significantly associated with lower risk of MOF, but not after adjusting for FN BMD.Peak leg power and velocity, but not force, during a force plate jump test predicted MOF risk independent of FN BMD. Power, which incorporates velocity, may play a more important role than force in reducing the risk of a fracture.

Table 1. Hazard ratio estimates from Cox regression models for associations between jump test measures and major osteoporotic fracture risk.

OsteoboostTM Is Effective in Preserving Bone Strength and Density of the Spine in Women with Low Bone Mass *Laura Bilek[2], LAURA FLORES[2], Nancy Waltman[3], Lynn Mack[3], Derek Hillstrom[4], Laura Yecies[4], Kara Smith[5], Meghan Griffin[4], Michael Jaasma[4]. [2]UNIVERSITY OF NEBRASKA MEDICAL CENTER, United States. [2]UNIVERSITY OF NEBRASKA MEDICAL CENTER, , [3]University of Nebraska Medical Center, United States. [4]Bone Health Technologies, United States. [5]Universithy of Nebraska Medical Center, United States

Introduction: Fragility fractures result in significant morbidity and mortality, which is of particular concern in postmenopausal women who are at high risk of fractures due to loss of estrogen. Pharmaceutical interventions are effective but have low uptake and adherence and are generally not indicated for patients with osteopenia. Vibration has the potential to prevent bone loss and holds promise as an effective, yet minimal risk, treatment. The OsteoboostTM, a novel wearable device delivering targeted vibration to the lumbar spine and hips, is designed to improve bone strength and bone density. Thus, this study aims to evaluate the efficacy of a 12-month intervention with the Osteoboost on preserving strength of the first lumbar vertebrae in postmenopausal women with low bone mass.Methods: This double-blinded, randomized controlled trial enrolled postmenopausal women with low bone mass who were not taking bone-active medications. Women had a bone density DXA and assessment of thyroid function to screen for eligibility Those who qualified were randomized to receive Osteoboost treatment 5x/week for 12 months with the belt in either the active or sham setting. The sham device created a sound but did not deliver vibration. Compressive strength (N) and volumetric density of the 1st lumbar vertebra (L1) was analyzed using Finite Element Analysis (FEA) of computed tomography (CT) scans of lumbar spine by ON Diagnostics.Results: 126 women (64 Active, 62 Sham) with low bone mass participated in the study, with an average age of 62.1 years (SD +/- 5.8) and 60.6 years (+/- 5.3) in the Active and Sham groups, respectively. Most participants were of White race (98%) and non-Hispanic (96%). There were no significant differences in baseline demographics between the sham and active groups.Intent to treat analysis revealed no significant difference in percent change in vertebral bone strength between the Active and Sham groups over time (baseline to 12 months). When stratified by age category, significant differences in percent change in vertebral bone strength were present in the 50-60 year old category; the Sham group lost 3.4% of their vertebral bone strength compared to a 0.5% loss in the Active group (p=0.018). While bone was preserved in the active group relative to the sham in the women over 60, it was not significant (p=0.20). With analysis of those who met the compliance criterion of 3x/week, the Sham group lost 2.84% compared to 0.48% in the Active group (p=0.014); representing a 5 times greater loss in the Sham group. Additionally, the Osteoboost treatment preserved volumetric bone density of L1, with the Active treatment group losing 0.29% BMD relative to a 1.97% loss in the Sham group; representing a 6.8 times greater loss in the Sham group (p=0.008).Conclusion: Osteoboost holds promise as a therapeutic intervention for women with low bone mass to prevent decline to osteoporosis and reduce fracture risk.

Does femoral bowing expedite bisphosphonate-related atypical femoral fracture? *Dong Won Byun[1], Young-Kyun Lee[2], Hyoung-Moo Park[3], Deog-Yoon Kim[4], Yong-Chan Ha[5]. [1]Soonchunhyang University Hospital, Republic of Korea. [2]Seoul National University Bundang Hospital, Republic of Korea. [3]Grace Women Hospital, , Republic of Korea. [4]Kyung Hee University Medical Center, Republic of Korea. [5]BUMIN Hospital, Republic of Korea

Background ; Long-term use of bisphosphonate is a risk factor for atypical femoral fractures (AFFs). Femoral bowing is known to be associated with diaphyseal AFFs. However, whether the femoral bowing quickens the occurrence of AFF is unknown. We hypothesized severe anterolateral femoral bowing expedites the occurrence of AFF.Purpose ; The purpose of this study was to determine whether AFF occurs earlier in patients with severe femoral bowing than in those without severe bowing.Methods; One hundred and sixty-six AFF patients (179 AFFs), who were diagnosed from January 2006 to December 2018, were eligible for this study. Among them, we excluded 41 patients (42 AFFs), who had bony metastasis or metabolic bone disease, in whom the duration of bisphosphonate use was uncertain, or in whom the femoral bowing could not be measured. The remaining 125 patients (137 AFFs) were subjects of this study. According to severity of the femoral bowing, patients were divided into two groups; (1) severe bowing group (the line between the tip of the greater trochanter and the center of the intercondylar notch passes medial to the medial cortex of the femoral shaft, 20 patients) and (2) non-severe bowing group (105 patients). We compared the time of AFF occurrence after bisphosphonate therapy using cumulative percentage between the two groups.Results; Age and gender were similar between the two groups, while body mass index was lower in the severe bowing group. The duration of bisphosphonate use was shorter in the severe bowing group (3.2+/-3.6 years) than in the non-severe bowing group (4.7+/-4.2 years). However, the difference was not statistically significant (p=0.114). Cumulative percentage plot of AFFs in the severe bowing group was left-shifted compared to the non-severe bowing group.Conclusion; Severe femoral bowing expedites AFF development. In osteoporosis patients with severe femoral bowing, the duration of bisphosphonate use should be shortened.

Drug utilization patterns of anabolic agents - romosozumab and parathyroid hormone analogues - among postmenopausal women in the U.S., 2019-2021 *Hsu-Chih Chien[1], Ye Liu[2], Tzu-Chieh Lin[1], Tarun Arora[3], Mary Oates[1], MICHELE MCDERMOTT[1], Jeffrey Curtis[2]. [1]Amgen, United States. [2]University of Alabama at Birmingham, United States. [3]Foundation for Advancing Science Technology Education and Research, United States

BackgroundRomosozumab (Romo) and parathyroid hormone analogues (PTHA) are anabolic agents for postmenopausal women with osteoporosis (OP) at high risk of fracture. This study aims to describe the real-world utilization patterns of Romo and PTHA in the early period following Romo's U.S. approval.MethodsWomen >=66 years old who newly initiated Romo or PTHA (teriparatide or abaloparatide) were identified in Medicare Fee-For-Service Claims data (Medicare FFS) during April 1, 2019-October 1, 2021. The 12-month adherence (the proportion of days covered [PDC] by medication) and interruption (defined as a patient who did not refill a medication within 30 days after exhaustion of the days' supply of the previous dispensing, or usual dosing interval) were calculated for both Romo and PTHA groups. Kaplan-Meier method was applied to estimate the interruption rate and 95% confidence interval [CI], with censoring points of completing 12 doses, death, disenrollment, and the end of the follow up or the end of data (September 30, 2021). In a subgroup of Romo users with >=15 months available follow-up time, completion rates of 12-doses and follow-up treatment sequences (where individuals were required to have at least 1 additional month of coverage) were described.ResultsWe identified 8,408 new Romo and 7,428 PTHA users in Medicare FFS data. Romo users were slightly older (76.1+/-6.8 vs 75.5+/-6.8 years) and with less recent fracture history (33.4% vs. 38.3%) and higher previous OP treatment history (59.4% vs. 45.7%). Higher 12-month adherence was found among Romo users (PDC, Romo: 73.8+/-28.3%; PTHA: 57.3+/-33.8%. p<0.01). Lower 12-month interruption rate was observed among Romo users (Romo: 52.8%, 95% confidence interval [CI]: 50.6-54.9%; PTHA: 62.7%, 95% CI: 60.6-64.9%). Among individuals with >=15 months data available, 57.9% Romo users completed 12 doses. 21.8% of completers did not receive any OP treatment following the completion. Among those switching to another OP therapy following Romo treatment completion, denosumab was the most often used (83.2%) OP medication (Table 1).ConclusionWe observed higher adherence and fewer interruptions among Romo users versus PTHA users in the Medicare population. While more than half of Romo users completed the 12-doses within 15 months, a meaningful fraction (>20%) did not receive subsequent treatment, despite treatment guideline recommendations advising following Romo with antiresorptive therapy to prevent bone density decline.

Table 1: Selected baseline characteristics and utilization patterns in new romosozumab and PTH analogue users in Medicare FFS

	Romosozumab*,[a] users (N= 8,408)	PTHA users* (N= 7,428)
Age (mean [SD])	76.1 (6.8)	75.5 (6.8)

Daily Administration of An Oral Robotic Pill (RT-102) Safely and Reliably Delivers Teriparatide with High Bioavailability in Women Volunteers: A Phase I Study *Joshua Myers, MS[1], Anvesh Dasari, PhD[1], Archana Battiwala, MS[1], Nidhi Patel, MS[1], April Toledo Vo, MS[1], Alyson Yamaguchi, DVM[1], Kyle Horlen, DVM[1], Leonard Fung, MS[1], Baber Syed, MS[1], Son Nguyen, PhD[1], Jacques Van Dam, MD, PhD[1], Mir Imran, BS[1], Mir Hashim, PhD[1], Arvinder Dhalla, PhD[1]
[1]Rani Therapeutics, United States

Purpose: Teriparatide, an effective osteoanabolic agent, requires chronic daily subcutaneous (SC) injections which can impact patient compliance and quality of life. We have developed an oral robotic pill (RP) designed to deliver biotherapeutic agents with bioavailability rivaling that of parenteral injections. Here we present data from a Phase I study on the safety and tolerability of repeat administrations of an oral RP containing teriparatide (RT-102), 20µg, in healthy and post-menopausal women volunteers. Methods: Every day for 7 consecutive days, overnight-fasted participants (N=17) orally ingested a single RT-102 capsule followed by a meal 3 hours later. Fluoroscopic images were taken daily to track the transit and deployment status of the RP in the GI tract. During Days 1-6, drug delivery success was determined by the detection of drug in at least one of 3 blood samples taken at 3-hour intervals every day following the oral dose. On Day 7, a full PK profile of RT-102 was generated from serially collected serum samples in which teriparatide was quantified using an ELISA. Results: Safety: A total of 104 RT-102 capsules were swallowed by study participants with no observed serious adverse events (SAEs). Seven participants were excluded per protocol with 10 completing the full study. Mild and transient adverse events (AEs) observed in 4 participants were attributed to either the drug (2) or the device (3). No participants were excluded due to any RT-102-related AEs. In all participants, capsule remnants were excreted without sequelae within 1.9 +/- 0.9 days. Reliability: Based on detectable drug levels in the 10 participants who completed the study, the overall success rate of drug delivery was 91% (63/69 capsules). Bioavailability: With a Cmax of 296 +/-243 pg/mL and a Tmax of 57 +/- 35 minutes, RT-102 delivered teriparatide with higher estimated bioavailability compared to that of historical Forteo® SC data. Effect of Food: During Days 1-6, similar rates of successful deployments of RT-102 occurred before (35) and after food was consumed (37), suggesting that the presence of food did not impact RP performance. Conclusions: This study provides the first clinical evidence of safe and successful repeat delivery of oral teriparatide administered daily to human participants via the RP with high reliability and bioavailability. These data suggest that RT-102 can potentially offer an oral osteoanabolic treatment option to osteoporosis patients.

SAT-436

Safety and Immunogenicity of Proposed Denosumab Biosimilar GP2411 Compared with Reference Denosumab in Postmenopausal Women with Osteoporosis at 78 Weeks: The Randomized, Double-Blind, ROSALIA Study *S?awomir Jeka[1], Eva Dokoupilová[2], Alan Kivitz[3], Susmit Sekhar[4], Samik Banerjee[4], Natalia Krivtsova[4], Johann Poetzl[4], Arnd Schwebig[4], Jean-Jacques Body[5], Richard Eastell[6]. [1]Clinic and Department of Rheumatology and Connective Tissue Disease, University Hospital No.2. Bydgoszcz, Collegium Medicum in Bydgoszcz, UMK, Poland. [2]Masaryk University, Faculty of Pharmacy, Department of Pharmaceutical Technology, Czech Republic. [3]Altoona Center for Clinical Research, United States. [4]Hexal AG, Germany. [5]Department of Medicine, University Hospital Brugmann, Belgium. [6]Department of Oncology and Metabolism, University of Sheffield, United Kingdom

BackgroundDenosumab is a human monoclonal antibody to RANK ligand for osteoporosis in postmenopausal women with high fracture risk. Similarity of GP2411, a proposed denosumab biosimilar, with reference denosumab (ref deno) has been demonstrated at 52 weeks; here we report cumulative 78-week data, including a treatment switch.MethodsROSALIA (NCT03974100) was an international, double-blind, parallel group, Phase III study postmenopausal women with osteoporosis aged 55-80 years, with a bone mineral density (BMD) T-score <=-2.5 and >=-4.0 at the lumbar spine (LS-BMD). Patients were randomized (1:1) to 60 mg s.c. of GP2411 or EU-authorized ref deno on Day 1 and Week 26. Prior to the third dose at Week 52, patients in the ref deno group were re-randomized (1:1) to ref deno or GP2411 (switch period). Safety and immunogenicity (binding anti-drug antibodies [ADAs] and neutralizing antibodies [NAbs]) were assessed in the switch period. Efficacy was analyzed descriptively with percentage change from baseline (%CfB) in LS-BMD, femoral neck BMD (FN-BMD), and total hip BMD (TH-BMD). Outcomes were evaluated up to Week 78.ResultsIn subjects who reached Week 52 and received a third dose (502 of 527 randomized), the cumulative (78 week) incidence rate of all-grade treatment-emergent adverse events (TEAEs) was similar between groups. Most TEAEs were Grade 1 or 2 and not treatment related (Table 1); none led to study or treatment discontinuation. The most common TEAEs were hypocalcemia, COVID-19 infection, and nasopharyngitis; there were no fatal or serious treatment-related TEAEs. The vast majority of observed ADAs had very low, non-reportable titers (<20 ng/mL), were non-neutralizing, and transient (Table 2). There were no clinically meaningful differences between groups in the rate of new vertebral fractures (GP2411/GP2411: 9.9%; ref deno/ref deno: 13.6%; ref deno/GP2411: 13.7%) or in %CfB of LS-BMD, FN-BMD, or TH-BMD. Switching from ref deno to GP2411 did not affect the incidence and severity of TEAEs, and immunogenicity profiles were similar between groups. ADAs were not associated with hypersensitivity reactions.ConclusionsROSALIA demonstrated comparable safety, immunogenicity, and efficacy up to 78 Weeks between proposed denosumab biosimilar GP2411 and ref deno in postmenopausal women with osteoporosis, with switching to GP2411 having no impact.

Table 1. Summary of 78 weeks cumulative safety data in patients who received a third treatment dose at Week 52.

Category	GP2411/GP2411 N=253 n (%)		Ref deno/ref deno N=125 n (%)		Ref deno/GP2411 N=124 n (%)

SAT-438

12 months experience with romosozumab: A real-life descriptive study *Mariana Gonzalez Pernas[1], Jesica Pingel[1], Natalia Lopacsek[1], Vanesa Longobardi[1], Paula Garibaldi[1], Lorena Conejos[1], Patricia Slavinsky[1], Soledad Sosa[1], Marcelo Sarli[1], Mariela Sesta[1], Maria Belen Zanchetta[1]. [1]IDIM, Argentina

Introduction: Recent guidelines recommend romosozumab (ROMO) as initial therapy for women with a very high risk of fracture, including those with a very low T-score (< -3.0), high fracture probability by FRAX, or multiple vertebral fractures. ROMO can also be used to reduce vertebral, hip, and nonvertebral fractures in cases of previous osteoporosis therapy failure. ROMO became available in Argentina in August 2021. This study aims to describe the baseline characteristics and 12-month outcomes of the first 10 postmenopausal women who completed ROMO treatment.Methods: A prospective study to assess clinical and densitometric features (spine, hip, and radius), muscle health (performance, hand grip (HG), IMME by DXA), spine RX, fatigue (FACIT), bone microarchitecture by HR-pQCT and bone biomarkers. This partial cross-sectional analysis includes clinical, BMD, muscle quality, vertebral fracture assessment of the first 10 postmenopausal women who completed 12 months of ROMO treatment until April 2023.Results: The study population had a median age of 76 (54-82) yo and all had a history of fractures: wrist (1), hip (1), and vertebral (9 (17 VTFx)). Half of them had two or more vertebral fractures, and all of them with imminent fracture risk. 30% of the patients were treatment-naïve, while the rest had received one or more drugs: 70% bisphosphonates, 20% sequential treatment (teriparatide-denosumab); mean treatment duration was 11.2 years. Baseline densitometric values (T-Score) reflected osteoporosis: LS -3, FN -2.2, and TH -2.3. After 12 months of ROMO treatment, there were significant increases in BMD at all measured sites: 12.9% LS, 3.6% FN, and 3.4% TH. Mean final T-score was -2.3 in LS, -2.1 FN, and -2 TH (p=0.03, p=0.02). No new fractures were reported in these patients. Mean baseline HG, sit-stand, and IMME values were: 14+/-2kg, 12+/-2s, and 6.1+/-0.9kg/m2. A significant improvement in muscle strength tests was observed with 12 months of treatment: HG 16,6+/-3kg (+18,5%), SS 9.8+/-3s (-18%) (p=0.04). Discussion: Beyond the limitations of the use of new osteoactive treatment in real life, in this study we show that the results are similar to those reported in pivotal studies. Treatment with ROMO can effectively improve BMD in postmenopausal women with very high-risk osteoporosis. It also seems to have a positive effect on muscle mass, however more studies are needed to confirm these data.

SAT-439

Effects of denosumab or zoledronic acid on bone density and muscle mass in drug-naive patients with postmenopausal osteoporosis : multicenter 3-year observational study *Jeonghoon Ha[1], Jinyoung Kim[1], Chaiho Jeong[1], Jeongmin Lee[1], Yejee Lim[2], Ki-Hyun Baek[1]. [1]The Catholic University of Korea, Republic of Korea. [2]Seoul National University Bundang Hospital, Republic of Korea

Objectives: Denosumab and zoledronic acid are potent anti-resorptive agents used to treat osteoporosis in postmenopausal women. However, limited research exists on their direct comparison in drug-naïve patients. This study aimed to compare the effects of denosumab and zoledronic acid in drug-naïve Korean postmenopausal women with osteoporosis. Methods: This prospective, observational, nonrandomized study included 120 patients, with 60 receiving denosumab and another 60 receiving zoledronic acid. Throughout the 3-year treatment period, patients were monitored for bone density and biochemical parameters, and changes in skeletal mass were evaluated using bioelectric impedance analysis.Results: Baseline characteristics, including age, BMI, and prevalent fracture, were similar between the two groups. Serum 25(OH), Ca, and P levels, as well as baseline bone mineral density (BMD), were also comparable between the groups before treatment. After the 3-year treatment period, both groups demonstrated significant increases in BMD from baseline. The denosumab group exhibited a BMD increase of 9.7% at the lumbar spine and 5.1% at the total hip, while the zoledronic acid group showed a BMD increase of 7.1% at the lumbar spine and 4.4% at the total hip. However, only the denosumab group displayed a significant increase in skeletal muscle mass at 1 year, with a notable increase in those with a baseline T score of -3.0 or lower.Conclusions: In conclusion, both denosumab and zoledronic acid are effective anti-resorptive agents with significant increases in BMD observed over the 3-year treatment period in drug-naïve patients. Nonetheless, denosumab may be a more suitable initial treatment option for patients with combined osteosarcopenia due to its significant increase in skeletal muscle mass.

SAT-441

Zoledronic acid dosing frequency among older adults in the community *Kaleen Hayes[1], Natalia Konstantelos[2], Angela Cheung[3], Suzanne Cadarette[2]. [1]Brown University, . [2]University of Toronto, Canada. [3]University Health Network-University of Toronto, Canada

Background: Zoledronic acid (ZOL, 5mg/100mL) is typically administered annually in outpatient infusion clinics to treat osteoporosis. A post-hoc analysis identified similar fracture protection when ZOL was dosed every 18 months compared to annual dosing. Evidence on ZOL dosing frequency in real-world practice is limited.Objectives: To describe ZOL dosing frequency overall and by prior osteoporosis medication history among older community-dwelling adults.Methods: We identified community-dwelling residents aged >=66 years initiating ZOL between 01/2006-10/2021 using Ontario healthcare administrative data. We excluded those who had a malignant cancer diagnosis captured through the Ontario Cancer Registry, a history of bone-related health conditions (e.g., Paget's disease), or a second dose administered within 31 to 334 days after the initial dose (to identify potential off-label dosing for cancer). We looked forward until October 31, 2022 to identify subsequent dispensings of ZOL after initiation. We described each patient's history of other osteoporosis medication use (oral bisphosphonates [alendronate/risedronate], denosumab, other [calcitonin, etidronate, raloxifene, teriparatide]) within 5 years prior to ZOL initiation. For patients with more than one administration of ZOL, we described the median length of time between each dose and described the number and timing of ZOL doses by other osteoporosis medication history.Results: We identified 4,337 eligible patients starting ZOL (average age 76 [SD 6.9] years, 82% female). Fifty-eight percent had a history of osteoporosis pharmacotherapy: 45% alendronate or risedronate, 10% denosumab, and 3% another osteoporosis medication (primarily raloxifene or etidronate). Among all ZOL initiators, 64% received only 1 dose during follow-up, 18% received 2 doses, and 18% received 3 or more doses. Among those with at least two administrations of ZOL, the median time between the first and second dose of therapy was 391 (IQR 366-456) days. For those with >=3 ZOL administrations, the median time between the second and third dose was 379 (IQR 364-422) days. Time between doses did not meaningfully differ by osteoporosis medication history.Conclusions: Among ZOL initiators, around two-thirds received a single dose. Many have a history of oral bisphosphonate use. Among those with more than one dose of ZOL, dosing largely aligns with labeling recommendations (annually).

Under-treatment of Osteoporosis in "Very Elderly" Elective Orthopedic Surgical Patients *Aamir Kadri[1], Amina Anwar[2], Lucas Steele[2], Madhumathi Rao[1]. [1]University of Kentucky, . [2]University of Kentucky College of Medicine, United States

Introduction: Osteoporosis is associated with adverse orthopedic surgical outcomes. Post-operative use of anabolic or anti-resorptive therapies minimize osteoporosis related complications. However, the benefits of these medications are not well studied in the "very elderly" patient age >=80. We hypothesized that "very elderly" fracture patients received post-operative anti-osteoporosis medications less often than patients aged 50-79 (elderly) after surgical fixation of low energy fractures despite meeting clinical indications for treatment.Methods: Between June 2021-December 2022, 98 patients age >=80 were compared with 97 patients aged 50-79 who were referred to a single institution's bone health clinic after surgical fixation. Fracture Risk Assessment (FRAX) scores without BMD were calculated. Osteoporosis was defined by a history of hip or spine fracture, FRAX MOF risk >=20% or hip risk >=3%, or T-score < -2.5.Results: In the "very elderly" compared to the elderly, mean age was 87.6 vs 71.1 (p=0.001), BMI 26.1 vs 29.5 (p=0.002), and 72% vs 75% were female. The fracture requiring surgical fixation occurred at the hip/spine in 43% of "very elderly" vs 39% of elderly patients. Prior fracture after age 50 was present in 25% vs 54% (p=0.002). Current tobacco use was present in 36% vs 52% (p=0.01). Indications for treatment were met in 100% of "very elderly" and 92% of elderly patients. In the "very elderly," excluding non-ambulatory patients, those with active co-morbidities precluding therapy, and those who died prior to initiating therapy, 82% were candidates for treatment, which was prescribed in 2% of "very elderly" vs 12% of elderly patients (p=0.002).Conclusion: "Very elderly" patients received anti-osteoporosis therapies less often than the elderly despite most meeting indications for treatment. This finding suggests that, despite sustaining fractures diagnostic for osteoporosis, "very elderly" patients may be undertreated due to limited data on the efficacy of osteoporosis therapies in this age group. Further research evaluating the safety and efficacy of pharmacologic treatment in this age group is warranted. Recognizing simple risk factors, such as prior fracture or current tobacco use, may help identify patients at risk for surgical complications related to bone disease who may benefit from pharmacologic treatment, representing an opportunity to improve secondary fracture care and reduce mortality risk associated with fracture in this age group.

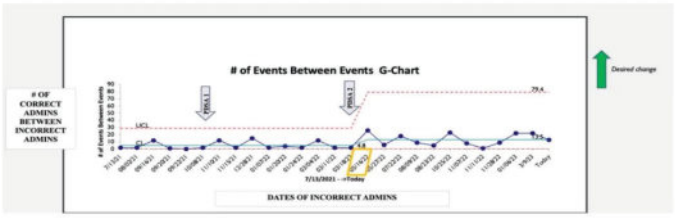
Reduction in the Non-adherence Rate to Denosumab Therapy with Clinical Pharmacy Collaboration: A Quality Improvement Project in an Osteoporosis Clinic *Amna Khan[1], Jaliyah Johnson, RN[2], Alexandria Tsikouras PharmD[3], Anna Zuschnitt, PharmD[3]. [1]University of Pennsylvania and Philadelphia VA medical center, United States. [2]Division of Endocrinology, Diabetes and Metabolism, University of Pennsylvania , United States. [3]University of Pennsylvania , United States

BACKGROUNDInterrupting or delaying Denosumab (DMab) beyond 7 months (210 days) from the last injection leads to transient increase in bone turnover known as rebound phenomenon, resulting in rapid loss of bone density and increased vertebral fracture. Risk of missing or delaying DMab therapy increased especially during the COVID-19 national emergency.Numerous studies suggest that clinical pharmacist participation in chronic disease state management leads to positive clinical outcomes and increase in medication adherence. Very few studies have evaluated pharmacist-physician collaboration for osteoporosis management and reduction in care gap and no study has evaluated the impact of this collaboration on preventing interruptions or delays in DMab therapy.METHODSThe Plan Do Study Act (PDSA) method of quality improvement was used for this project. Baseline review of charts revealed a non-adherence rate of about 21% amongst patients receiving this therapy for osteoporosis. Root cause analysis was performed.The aim of this study was to reduce the non-adherence rate to less than 5% by April 2023.INTERVENTIONSIn July 2021, 2 clinical pharmacists joined the Osteoporosis Clinic and hence the pharmacist-physician collabora-

tion was initiated.The first intervention began in October 2021. The pharmacists provided education to all patients starting DMab.The second intervention was implemented in March 2022. The pharmacists created an active reminder list of all patients receiving DMab in the electronic medical record system. They reviewed the list weekly. Lab reminders were sent to patients 1 month prior to their injection due date electronically and/or telephonically. Physician was alerted to review the labs for injection scheduling. Reminder closed 2 weeks post injection administration.RESULTSResults were analyzed using Statistical Process Control (SPC) G chart method (see attached). With these interventions, number of correct administrations between incorrect ones (delayed beyond 210 days) improved from an average of 4.8 to 13.5. These effects became visible about 10 weeks post intervention resulting in a reduction of non-adherence rate from 21% to 6.8% by April 2023.CONCLUSIONS-Pharmacist-Physician collaboration can reduce the non-adherence rate for drugs such as Denosumab, interruption of which can result in serious consequences. This can also relieve the overburdened nurses and physicians resulting in reduced burnout of healthcare teams.



Statistical Process Control (SPC) G chart method

Bone mineral density change over three years before, during and after switching to Romosozumab followed by Denosumab *Yoichi Kishikawa[1.] [1]Kishikawa Orthopedics, Japan

BackgroundThese days, in considering life time management of severe osteoporosis, when and how to switch anabolic agents to anti-resorptive agents, and vice versa, is the key in keeping strong healthy bones. When switching from Denosumab (DSMb) to Romosozumab (RZMb), bone formation is activated, but bone resorption is activated as well. This change of bone metabolism is quite different from naïve or switching from Bisphosphonates (BPs) case, and the difference make a great influence on bone mineral density (BMD). The follower after RZMb is also important because the bone metabolism change still continues at the 12th administration of RZMb. I usually chose DSMb for severe osteoporosis patients as a follower to follow RZMb.PreviouslyI reported at the ASBMR annual meeting 2020 and 2021 as follows. Bone metabolism markers OC, ucOC, ucOC/ OC increased significantly in both groups after 4 months after switching from Bisphosphonate (BPs) or Denosumab (DSMb) to Romosozumab (RZMb), and TRACP5b increased when switching from DSMb however it decreased when switching from BPs. I reported neither Femoral total nor neck BMD change significantly in either group, however Lumbar spine BMD significantly increased in BPs group after 1year from switching.Subjects and methodThis time I followed 20 cases in the DSMb group and 19 cases in the BPs group of RZMb followed by DSMb in both groups. Subjects were retrospectively observed and statistically demonstrated from the point of BMD (Lumbar, Femoral neck and total) before switching from Bisphosphonate or Denosumab to RZMb, during RZMb for one year, and after switching from RZMb to Denosumab one year later.ResultsBone metabolism markers change were just the same results I reported before. TRACP5b increased when switching from DSMb however it decreased when switching from BPs.1.DSMB groupBone mineral density (BMD) change in DSMb group, BMD increased in lumbar and decreased in femoral total and neck during RZMb, then BMD increased in each site after Denosumab following RZMb. The changing rate of each BMD significantly increased in each site when comparing before and after RZMb for one year.2. BPs groupBMD in BPs group increased in each site administrating RZMb, then BMD increased in each site after Denosumab following RZMb. The changing rate of each BMD significantly increased in lumbar and femoral total while not significantly increased in femoral neck when comparing before and after RZMb for one year.

A Phase I, Randomized, Double-blind, Single-dose Study to Evaluate the Biosimilarity of SB16 (Proposed Denosumab Biosimilar) with Reference Denosumab in Healthy Male Subjects *Hyuna Lee[1.] Sujung Kim[1.] Hyoryeong Seo[1.] Soyeon Kim[1.] [1]Samsung Bioepis, Republic of Korea

Background: SB16 has been developed as a biosimilar of the reference denosumab (DEN). Denosumab is a human monoclonal antibody, which inhibits the osteoclast formation and osteoclast-mediated bone resorption. It is currently indicated for postmenopausal osteoporosis, osteoporosis in men, breast cancer treatment-induced bone loss, prostate cancer treatment-induced bone loss, and glucocorticoid-induced osteoporosis. Objective: The primary objective of this phase I study was to demonstrate the pharmacokinetic (PK) equivalence between SB16, EU sourced DEN (EU-DEN), and US sourced DEN (US-DEN). Pharmacodynamic (PD), safety, tolerability, and immunogenicity were also evaluated as secondary objectives.Methods: In this double-blind, three-arm, multi-center, parallel group and single-dose study, healthy male subjects between 28-55 years of age were randomized in a ratio of 1:1:1 to receive a single 60 mg dose of either SB16, EU-DEN, or US-DEN subcutaneously. PK, PD, safety, tolerability, and immunogenicity were evaluated for 197 days. The primary PK endpoints were area under the concentration-time curve (AUC) from time zero to infinity, AUC from time zero to the last quantifiable concentration, and maximum serum concentration. Equivalence was determined if 90% confidence intervals (CIs) for the ratio of geometric least squares means (LSMeans) of the treatment groups compared were within the equivalence margin of 0.80 to 1.25. Results: A total of 168 subjects (56 per groups) were randomized. All of the corresponding 90% CI of geometric LSMean ratio of primary PK parameters for comparison of SB16 and EU-DEN, SB16 and US-DEN, and EU-DEN and US-DEN were within the pre-defined equivalence margin. The mean area under the effect curve from time zero to Day 197 for C-telopeptide of type I collagen (CTX) percent inhibition was comparable for SB16, EU-DEN, and US-DEN. The incidence of treatment-emergent adverse events (TEAEs) was comparable between the treatment groups. The majority of TEAEs were mild to moderate in severity. Three serious adverse events (SAEs) were reported in SB16 only but all the events were considered not related to investigational product. The overall incidence of subjects with post-dose anti-drug antibodies positive to denosumab was also comparable.Conclusion: This study demonstrated PK bioequivalence between SB16, EU-DEN, and US-DEN in healthy male subjects. PD, safety, and immunogenicity profiles were comparable.

Short-Term Effects of Sclerostin Inhibition on Calcium Homeostasis *Savannah Ryan[1.] Mackenzie Jordan[1.] Sabashini Ramchand[1.] Joy Tsai[1.] Benjamin Leder[1.] Sherri-Ann Burnett-Bowie[1.] [1]Massachusetts General Hospital, United States

Background: Romosozumab is a monoclonal antibody that inhibits osteocyte-derived sclerostin and thus stimulates bone formation and inhibits resorption. While the effects of romosozumab on bone mineral density (BMD), serum markers of bone remodeling, and blood calcium are known, romosozumab's effects on other measures of mineral metabolism and their potential consequences are less well defined. Thus, we explored the effects of romosozumab on mineral metabolism in postmenopausal women receiving adequate calcium and vitamin D intake.Methods: As part of a clinical trial, 31 postmenopausal women at high fracture risk (mean age 69) received monthly romosozumab 210-mg SC for 3 months. Subjects consumed approximately 1200-mg elemental calcium and a minimum of 400IU vitamin D daily from diet/supplements. Fasting serum calcium, albumin, 25hydroxyvitamin D (25OHD), parathyroid hormone (PTH), phosphate (PO4), and alkaline phosphatase (ALP) were compared at baseline and 3 months (paired t-test).Results: As shown in the Table, after 3-months of romosozumab, albumin-corrected calcium decreased by 3.1% (P<0.0001), PTH

increased by 57% (P<0.0001) and ALP increased by 20% (P<0.0001). There was no significant change in PO4 (P=0.9) or 25OHD (P=0.06). At month 3, of the 31 patients treated with romosozumab, three subjects (10%) developed asymptomatic hypocalcemia (calcium 77 pg/mL). While changes in serum PTH and ALP were not correlated, there was a significant negative correlation between the changes in serum PTH and calcium (R= -0.38, P=0.03). Conclusions: In postmenopausal osteoporotic women receiving calcium and vitamin D supplementation, 3 months of romosozumab treatment decreased serum calcium, resulting in significant increases in PTH and secondary hyperparathyroidism that impacted 1/3 of subjects. Despite the increase in PTH, serum PO4 was unchanged, which raises the question of possible compensatory changes in other mineral metabolism factors (such as FGF-23). Providers should be aware that secondary hyperparathyroidism may occur and persist in patients treated with romosozumab despite optimal 25OHD levels and calcium intake. Further larger studies are needed to determine whether these metabolic changes influence the clinical response to romosozumab and limit or mediate the observed gains in BMD.

	Week 0	Week 12	Delta	P value
Calcium (8.6-10.4 mg/dL)	9.2 (0.3); 8.6-9.9	8.9 (0.3); 8.4-9.6	-0.3 (0.3); -3.1 (3.4)	< 0.0001

HIgh Frequency of Acute-Phase Response After Zoledronate: Who Has More Risk? *VANESA LONGOBARDI[1], Fernando Jerkovich[1], María Fernanda Carballo[1], Marcela Esparza Ramirez[1], MARIANA GONZALEZ PERNAS[1], ruben abdala[2], Rodolfo Gorris[1], Walter Sandoval[1], Nancy Sire[1], MARIA ZANCHETTA[3]. [1]IDIM, Argentina. [2]Instituto de Diagnóstico e Investigaciones Metabólicas, Argentina. [3]idim, universidad del salvador, Argentina

Introduction: Zoledronate (ZOL) is an effective treatment for several metabolic bone diseases. The reported frequency of acute-phase reactions (APRs) is widely variable.Aim: To describe the frequency of APRs after ZOL infusion and to identify associated factors. Methods: A prospective and observational study was designed. Patients who received 5 mg infusion of ZOL at our institution were invited to participate. After consent, they received 2 electronic questionnaires at 3 and 7days after infusion. APRs were divided into fever, musculoskeletal (ME) (myalgia, arthralgia, bone pain), general (malaise, fatigue, headache, dizziness, chills), gastrointestinal (GI) (abdominal pain, nausea, vomiting), and ocular (pain, red eye) symptoms (outcomes). Intensity for each symptom was classified on a scale of 1 to 10. Intensity >= 8, interference with daily activities, body T >= 37.8° or if the patient responded that would not receive ZOL again was considered a "severe symptom". The following variables were assessed: age >= 66 yo., sex, number of infusions, smoking, prior use of oral bisphosphonates (BP) and preventive NSAIDs. A uni- and multivariate analysis was performed.Results: Out of 653 patients invited to participate, 252 signed informed consent and completed at least one questionnaire. The mean age was 66.3 +/- 9 yo., 95% women. ZOL was administered for the first time in 138 (55%) patients, 58 of whom had received previous treatment (30 denosumab, 23 oral BP, 5 anabolic therapy). The frequency of APRs were: at least one symptom 207 (82%), general 173 (69%), ME 156 (62%), GI 70 (46%), fever 66 (43%), oculars 30 (20%), and severe 101 (40%). Significant associations between factors and APR symptoms were detailed in Table 1. First infusion of ZOL was significantly associated with a higher chance of having general, ME, GI, ocular and severe symptoms. It was also associated with higher frequency of fever although non-significant (p=0.063). Older age (>=66 yo.) was associated with a less chance of developing severe symptoms. 229 (91%) responded that if needed they will receive ZOL again.Conclusion: We observed a high frequency of APRs probably due to immediate and exhaustive. First ZOL infusion was the most important factor associated with practically all APRs symptoms and severity. Precise knowledge about the potential APRs after ZOL and effectively communicating this information with patients, will surely improve our clinical practice.

Table. Significant associations between variables and APRs after ZOL infusion
Only positive results are shown

Effect of gender on the evolution of pain and quality of life after treatment of symptomatic vertebral fragility fracture. *Pilar Peris Bernal[1], Jordi Blasco[2], Ana Monegal[1], Helena Florez[1], Nuria Guañabens[1], Josep Lluis Carrasco[3]. [1]Rheumatology Departament, Hospital Clinic, Spain. [2]Neurointerventional Departament, Spain. [3]Basic Clinical Practice, University of Barcelona , Spain

In a previous randomized clinical study comparing the effect of vertebroplasty (VP) vs. conservative therapy (CT) on pain evolution and quality of life (QoL) of patients with symptomatic vertebral fractures (VF), we observed the development of chronic back pain in 23% of subjects, independently of the therapy received. This study analyses the effect of gender on the evolution of pain and QoL in these subjects.Methods: 118/125 randomized patients (27 males/91 females) with recent symptomatic VF were evaluated. All received standardized analgesic and antiosteoporotic treatment. Pain and QoL were evaluated by VAS and Qualeffo-41, respectively, at baseline, at 2 weeks and 2 and 6 months. We compared pain evolution and QoL after treatment (CT vs. VP) according to gender, and analysed factors including age, time of evolution, treatment received, baseline VAS, previous VF (total and recent), incidental VF, lumbar and femoral T-scores, analgesic and antiosteoporotic treatment.Results: At baseline, there were no differences in age (males 74.8+/-11.2 vs. females:73.2+/-8.7 years), time of pain evolution, number of VF (males:3.8+/-2.4 vs. females: 3.1+/-2.4), treatment received (VP, males: 59%, females: 45%), lumbar or femoral T-scores, baseline VAS (males:6.8+/-2.1 vs. females: 6.8+/-2.2) or Qualeffo score (males:52.2+/-24.4 vs. females:59.7+/-20.6). Pain and QoL evolution differed according to gender, being better in males (figure 1). These differences were significant after two months and were independent of the treatment and the development of incidental VF during follow-up (males: 18.5 vs. females 12.1%).Conclusion: Pain and QoL evolution after a symptomatic VF differs according to gender, with a worse evolution in women independently of the treatment received.

SAT-453

Coronary artery calcification is associated with smaller increases in femoral neck bone mineral density in patients on anti-resorptive therapy *Rachael Hii[1], Nitesh Nerlekar[1], Peter Ebeling[2], Alexander Rodriguez[3]. [1]Monash Heart, Australia. [2]School of Clinical Sciences, Monash University, Australia. [3]Monash University, Australia

IntroductionAnti-resorptive medications are first-line treatments for osteoporosis. Additionally, patients with osteoporosis are at high cardiovascular risk, partly due to vascular calcification, such as in the coronary vessels. It is uncertain if the presence of coronary artery calcification (CAC) effects bone mineral density (BMD) response to anti-resorptive treatment. We therefore assessed changes in BMD following initiation of anti-resorptive treatment for osteoporosis in patients with and without evidence of CAC.MethodsIndividuals dispensed at least one prescription for an anti-resorptive medication (bisphosphonates or denosumab) at Monash Health between 2009-2022 were identified. Unique record numbers for these individuals were then cross-matched against the cardiac CT imaging service at Monash Heart (HREC#73603). CAC was detected by CT coronary angiogram (CTCA) using a Aquilion Vision (Canon Medical Systems Corporation, Otawara, Japan). We included only those patients having a baseline BMD measurement within two years of CTCA. The annualised percentage change in femoral neck BMD was calculated and adjusted for age, sex, height, weight, and number of years on anti-resorptive treatment.Results106 individuals were identified of which 85 (women=70 [85%], median age=73 years [interquartile range 64-79 years]) had a follow-up BMD measurement including 19 with, and 66 without, evidence of CAC. Those with CAC were older (76 years versus 64 years, p<0.001). There were 70 bisphosphonate users and 15 denosumab users. Individuals with evidence of CAC experienced, on average, a 1.2% lower increase [(0.345% (0.343 to 0.348) versus -0.881% (-0.883 to -0.879), mean difference -1.226% (-1.493 to -0.959; p<0.05)] in annualized femoral neck BMD with anti-resorptive therapy after adjusting for important clinical risk factors. InterpretationThese preliminary data suggest that CTCA-determined CAC may negatively impact femoral neck BMD increases with anti-resorptive therapy. Analysis of the full cohort is presently underway.

Coronary calcification	n	Annualised change in femoral neck BMD (%)^
Absent	19	0.345 (0.343 to 0.348)
Present	66	-0.881 (-0.883 to -0.879)
Mean difference		-1.226 (-1.493 to -0.959)

^Adjusted for age, sex, height, weight, number of years on anti-resorptive

KER-012, A Modified ActRIIB Ligand Trap, Increased Bone Density in Healthy, Post-menopausal Women *Harveen Natarajan[1], Sylvain Bedard[1], Richard Friend[2], Ying Jiang[1], Jennifer Lachey[1], Jasbir Seehra[1], Simon Cooper[1]. [1]Keros Therapeutics, United States. [2]Nucleus Network, Australia

Background: TGF-? superfamily ligands are known to play a fundamental role in bone homeostasis. More specifically, activins A and B negatively regulate bone remodeling and suppress bone growth1. KER-012 is an investigational modified ActRIIB ligand trap designed to bind and inhibit activins to increase bone mass. A research form of KER-012 (RKER-012) not only prevented but reversed bone loss in multiple preclinical models of bone loss2. Further, in healthy post-menopausal women, KER-012 elicited rapid and robust increases in bone formation biomarkers3. The data presented here further support the potential effects of KER-012 on bone remodeling.Methods: A two-part Phase 1 study has been conducted with KER-012 in healthy post-menopausal women. Participants received either placebo or a single dose of KER-012 ranging between 0.75 and 5.0 mg/kg in Part 1 or multiple doses between 0.75 and 4.5 mg/kg in Part 2, subcutaneously once every 4 weeks over a 12-week period. Safety, PK, and biomarkers of activin target engagement were assessed. Additionally, bone mineral density was assessed temporally by DXA in Part 2 of the study. Informed consent was obtained from all subjects prior to enrollment in the study.Results: KER-012 was generally well tolerated at dose levels up to 5 mg/kg as a single dose and at dose levels up to 4.5 mg/kg administered Q4W for a total of 3 doses3. As previously reported at ASBMR 20223, biomarkers of bone formation were elevated post-KER-012 administration in both Part 1 and Part 2. Trends towards increases in whole-body bone mineral density were observed at all dose levels in Part 2 with a mean increase of 1.48% (median 2.8%, range -1.8 to 3.6%) at day 113 after three doses of KER-012 in the highest dose group vs an increase of 0.02% (median -0.40, range -1.9 to 2.7%) in the placebo group.Conclusions: KER-012 was generally well tolerated in this Phase 1 study in healthy post-menopausal women and elicited rapid and robust increases in bone formation biomarkers along with trends towards increasing whole-body bone mineral density. The observed safety profile along with the observed change in bone mineral density is supportive of further development of KER-012 in patients with disorders with diminished bone mass.References:1. Pharmacokinetic (PK) Profile of EBP05/EB613 Oral Teriparatide Tablets in Women of Post Menopausal Age Versus Young Adult Men *Arthur C. Santora[2], Gregory Burshtein[2], Constantin Itin[2], Hillel Galitzer[2], Anke Hoppe[2], Miranda Toledano[2], Chana Sternberg[3], Auryan Szalat[4], Yoseph Caraco[4]. [2]Entera Bio, United States. [2]Entera Bio, Israel. [3]CSC Ltd, Israel. [4]Hadassah Medical Center, Israel

Background: EBP05/EB613 is an oral, daily tablet formulation of teriparatide [hPTH(1-34)] being developed by Entera Bio for the treatment of osteoporosis. A 161 patient, placebo-controlled, six-month Phase 2, dose-ranging study of EBP05/EB613 in postmenopausal women met biomarker and Bone Mineral Density endpoints (NCT04003467; ASBMR 2021: LB-1116). The 2.5 mg daily dose was selected for evaluation in a registrational Phase 3 study. An earlier Phase 1 study in young male volunteers (NCT02202603) and a Phase 2 study in female and male patients with hypoparathyroidism (NCT03516773; ASBMR 2019: LB SUN-972) evaluated the PK profile of EBP05/EB613 at a top dose of 2.25 mg. The current retrospective analysis compares PK data of EBP05/EB613 in the two different populations (young adult men vs. women of menopausal age), obtained from these studies. Methods: Evaluable PK profiles were obtained from nine young men (mean age of 23, range 21-26), and six women of menopausal age (mean age of 60, range 49-63) after administration of 2.25 mg EBP05/EB613 tablets in the morning, following an overnight fast. Subjects received up to 3 administrations of the treatment. For the current analysis, each administration is regarded as an independent event, resulting in a total number of 11 evaluable PK profiles obtained from this group.Results: Following the administration of a 2.25 mg dose of EBP05/EB613, the PK profiles obtained in young men and in women of menopausal age were found to be similar (Fig 1). Median Cmax was 425 (range 131-1772) vs 521 (172-2610) pg/mL and median AUClast was 157 (range 45.6-547) vs 158 (33.1-1078) pg*hour/mL in young men and women of menopausal age, respectively.Discussion: This retrospective comparison evaluating a 2.25mg dose of EBP05/EB613 in healthy males versus the target postmenopausal female population showed a consistent PK profile and bioavailability. A phase 3 study in postmenopausal women with osteoporosis is being planned.

Cost-Effectiveness of Sequential Abaloparatide/Alendronate for US Women and Men at Very High Risk of Fracture: an Economic Evaluation Based on Network Meta-Analysis *Mickael Hiligsmann[1], Stuart Silverman[2], Andrea Singer[3], LENY PEARMAN[6], Yamei Wang[5], John Caminis[6], Jean-Yves Reginster[7]. [1]Maastricht University, Netherlands. [2]Cedars-Sinai/UCLA, United States. [3]MedStar Georgetown University Hospital, United States. [6]Radius Health, . [5]Radius Health, Inc., United States. [6]Radius Health, United States. [7]University of Liège, Belgium

Current clinical evidence supports the use of a sequential treatment with an anabolic agent first followed by an antiresorptive in patients at very high fracture risk. In addition to clinical evidence, cost-effectiveness analyses are needed to assess the economic value of this strategy due to the higher cost of anabolic agents. Few economic analyses have been conducted so far, and to our knowledge, none have used efficacy data derived from network meta-analyses. In this study, a network meta-analysis-based economic evaluation was conducted to assess the cost-effectiveness of sequential treatment with abaloparatide (ABL) followed by alendronate (ALN) compared to alternative treatments in US men and women at very high risk of fracture. A previously validated economic model assessed lifetime healthcare costs (expressed in 2022 dollars) and outcomes (measured in quality-adjusted life years [QALYs]) of sequential ABL/ALN compared to a similar sequence with unbranded teriparatide (TPTD/ALN), to monotherapy with ALN and to no treatment. Efficacy data were derived from a recent network meta-analysis (Willems et al. Clin Ther 2022;44[1]:81-97). Populations included men and women aged 50-90 years with a recent fracture and densitometric osteoporosis (bone mineral density T-score <=?2.5). The results of the analyses were expressed in incremental cost-effectiveness ratios (ICERs) defined as the difference in costs between sequential ABL/ALN and alternative strategy, divided by their differences in QALYs. In all simulations, sequential ABL/ALN was associated with more QALYs for lower costs compared to sequential unbranded TPTD/ALN, being therefore dominant. In men, sequential ABL/ALN was also shown to be cost-effective at the US cost-effectiveness threshold (ie, $150,000 per QALY gained) compared to no treatment and to monotherapy with ALN over the full age range. In women, sequential ABL/ALN was cost-effective compared to no treatment in those aged >=60 years and compared to monotherapy with ALN in those aged >=65 years. In conclusion, this network meta-analysis-based cost-effectiveness analysis suggests that sequential ABL/ALN incurs less costs for more QALYs than sequential unbranded TPTD/ALN in both men and women aged 50-90 years, and is also cost-effective compared to monotherapy with ALN in men aged >=50 years and women >=65 years.

SAT-458

The Preference of the Treatment of Glucocorticoid-induced Osteoporosis in Korean Patients with Autoimmune Diseases *Chang-Hee Suh[1], Ji-Won Kim[1]. [1]Ajou University School of Medicine, Republic of Korea

PurposeGlucocorticoid-induced osteoporosis (GIOP) is common in patients with autoimmune disease who were prescribed with long-term glucocorticoids. The most commonly used drugs for GIOP is bisphosphonate. Zoledronate is a convenient treatment option that allows compliance to be advantageous over other bisphosphonates. Our aim is to evaluate the efficacy compared to other bisphosphonates as well as the preference and patient satisfaction of zoledronate.MethodsFifty patients with autoimmune diseases were recruited with new fractures or osteoporosis found in follow-up bone densitometry after taking oral bisphosphonates for at least 1 year for the treatment of GIOP. After 1 year of treatment with zoledronate, patients completed the survey to rate their preference and satisfaction. The treatment efficacy was analyzed by comparing the changes in bone density and fractures with patients maintaining oral bisphosphonates as controls.ResultsMean age of zoledronate group and oral bisphosphonates group was 64.1 vs 63.1 years, 96% vs 98% were female, and the mean duration of GIOP was 5.5 vs 4.2 years, respectively. There was no difference in the cumulative glucocorticoid doses of the two groups. Thirty-nine patients (78%) preferred and were more satisfied with intravenous zoledronate over oral bisphosphonates, and satisfaction was strongly affected by the administration interval and convenient regimen. The infusion-related adverse events of zoledronate were only 2 patients (4%). In addition, there were no significant differences in annualized percentage change in bone density in the lumbar spine (1.9 +/- 3.91 g/cm2 vs. 1 +/- 5.3 g/cm2, p = 0.355), femur neck (-0.91 +/- 6.31 g/cm2 vs. 0.41 +/- 5.07 g/cm2, p = 0.264), and hip (0.29 +/- 2.91 g/cm2 vs. 0.41 +/- 5.07 g/cm2, p = 0.888) between patients who received zoledronate and those who took oral bisphosphonates. The occurrence of new fractures was two in each of the two groups, showing no difference. ConclusionsZoledronate was preferred and more satisfactory by patients with autoimmune disease, and the treatment efficacy for osteoporosis was similar to oral bisphosphonates. Therefore, zoledronate is recommended as an appropriate treatment for GIOP.

SAT-459

Bisphosphonates preserve bone mineral density and suppress bone turnover markers in early menopausal women: A systematic review and meta-analysis of randomized trials *Aria Ahadzadeh Ardebili[4], Fariba Aghajafari[2], Timothy Fu[2], Nicole Dunnewold[3], Emma Billington[4]. [4]University of Calgary, . [2]Cumming School of Medicine, Canada. [3]Health Sciences Library, Canada. [4]University of Calgary, Canada

Women can lose up to 30% of their bone mass within the first 5 years following menopause. As such, 50% of postmenopausal women will experience a fracture within their lifetime. However, most women are ineligible for pharmacologic osteoporosis treatment until they have irreversible bone loss or have sustained a fracture. These outcomes may be preventable by short or intermittent bisphosphonate therapy courses initiated around the time of menopause. As such, the goal of this systematic review and meta-analysis was to determine the effects of nitrogen-containing bisphosphonate therapy on fracture incidence, bone mineral density (BMD) and bone turnover markers in early menopausal women.MEDLINE, EMBASE, CENTRAL, and CINAHL were systematically searched from their inception to July 2022. Randomized controlled trials (RCTs) over >=12 months examining the effects of nitrogen-containing bisphosphonates on fracture incidence, BMD, and bone turnover markers in early menopausal women (perimenopausal or <5 years postmenopausal) were included. Risk of bias was evaluated using the Cochrane Risk of Bias 2 tool and random effect meta-analysis was undertaken using RevMan v5.3.Fourteen articles (12 trials) were included (N = 1722 women). Four studies were assessed as having low risk of bias and 8 studies raised some concerns. Three studies reported on the incidence of fracture, all being infrequent. Bisphosphonate therapy improved BMD over 12 months versus placebo (mean percentage difference [95% CI]) at the lumbar spine (4.32[3.10-5.54]%, P<0.0001, N=8 studies), femoral neck (2.56[1.85-3.27]%, P=0.001, N=6 studies), and total hip (1.22[0.16-2.28]%, P=0.002, N=4 studies). Long-term (24-72 months) bisphosphonate therapy improved BMD at the lumbar spine (5.81[4.71-6.91]%, P<0.0001, N=8 studies), femoral neck (3.89[2.73-5.05]%, P=0.0001, N=5 studies) and total hip (4.09[2.81-5.37]% P<0.0001, N=4 studies). Bisphosphonate therapy reduced urinary N-telopeptide (-52.2[-60.3,-44.2]%, P<0.00001, N=3 studies) and bone-specific alkaline phosphatase (-34.2[-42.6,-25.8]%, P<0.00001, N=4 studies) over 12 months of treatment versus placebo.We conclude that nitrogen-containing bisphosphonate therapy improves BMD in early menopause. These BMD improvements are comparable to those in high fracture risk women following bisphosphonate therapy. These results warrant further investigations on bisphosphonate therapy for osteoporosis prevention in early menopausal women.

SAT-460

Assessing the robustness of evidence for the efficacy of anti-fracture medications *Nick Tran[1], Thach Tran[2], Tuan Nguyen[3]. [1]Macquarie University, Australia. [2]Garvan Institute of Medical Research, Australia. [3]University of Technology Sydney , Australia

Background: The evidence of the efficacy of anti-fracture medications is conventionally derived from randomized controlled clinical trials (RCTs) with P-values < 0.05 being the gold standard. However, the robustness of the evidence at this P-value threshold has never been examined. This study sought to quantify the fragility of the RCT evidence for ant-fracture medications.Methods: We searched for RCTs published in high-impact medical journals that reported a statistically significant result (P< 0.05) for at least one fracture site as either a dichotomous or time-to-event outcome. We included parallel trials that allocated participants in a 1:1 ratio to treatment and control groups. The fragility of the evidence was assessed by the 'Fragility Index' (FI) which is defined as the minimum number of patients whose condition would need to change from non-fracture to fracture to invalidate a statistically significant outcome.Results: This analysis included 22 RCTs which generated 110 positive results (P < 0.05); of these 37 (~34%) used fracture as the primary endpoint. The median FI of these analyses was 9 (interquartile range [IQR]: 3, 11), indicating that adding as few as 9 fracture patients (~0.4% of the study size) to the intervention group would eliminate the previously documented evidence of fracture prevention efficacy. Notably, in 65% of these analyses, the number of participants lost to follow-up exceeded the corresponding FI. Among the 34 results with P < 0.001, the median FI was 25 (IQR: 17 to 47) which was lower than the number of participants lost to follow-up in 25 results. Specifically, the anti-fracture efficacy of denosumab and calcium/vitamin D supplementation would be statistically lost if only an additional 4 (IQR: 3 to 17) and 6 (IQR: 2 to 16) patients respectively, sustained a fracture during the follow-up period (see Figure). Even when fracture was the primary outcome measure, the evidence for anti-fracture efficacy remained fragile, with a median FI being 15 (IQR: 8 to 25). In 86% of the positive results (P<0.05), the number of participants lost to follow-up was higher than that required to render the results statistically non-significant.Conclusions: These data indicate that the existing RCT evidence of anti-fracture efficacy is relatively fragile. In order to increase the robustness of the anti-fracture evidence, the P-value threshold should be lower than 0.001.

SAT-461

One versus 2 years of Alendronate Following Denosumab: The CARD Extension *Joy Tsai[1], Mackenzie Jordan[2], Savannah Ryan[2], Sabashini Ramchand[3], Hang Lee[4], Benjamin Leder[5]. [1]MASSACHUSETTS GENERAL HOSPITAL, United States. [2]Massachusetts General Hospital, United States. [3]Melbourne University, . [4]Biostatistics Center, Massachusetts General Hospital, United States. [5]Massachusetts General Hospital Harvard Medical School, United States

Background: When denosumab (DMAB) is discontinued, antiresorptive therapy is critical to attenuate high-turnover bone loss. The ideal choice and duration of antiresorptive therapy is not yet defined, however. In the CARD study, we demonstrated that 12-months of alendronate (ALN) was better able to maintain the BMD gains achieved with 12-months of DMAB versus 12-months of raloxifene (RAL). In this extension, we wished to determine if 12-months of ALN would be sufficient in maintaining these DMAB-induced BMD gains. Methods: In the CARD study, postmenopausal osteoporotic women aged 60-79 at high fracture risk received 12 months of DMAB 60-mg SC every 6 months followed by 12 months of either ALN 70-mg weekly (N=26) or RAL (N=25). All subjects in the ALN arm were then offered participation in a 1-year extension in which they were randomized to continue ALN for an additional 12 months (N=10) or to receive calcium and vitamin D (Ca/Vit D) alone (N=8). The primary outcome was change in PA spine BMD between months 24 and 36. Exploratory endpoints included changes in aBMD at other anatomic sites as well as changes in serum bone turnover markers.Results: The results of the CARD study, which demonstrated the effectiveness of 12-months ALN in preserving DMAB-induced BMD gains were presented previously and are currently in press. As shown in the Figure, in the extension, aBMD was maintained at the PA spine, TH and FN in both those randomized to an additional year of ALN and those randomized to Ca/Vit D alone. We did, however, observe a transient comparative decrease between months 24-30 in the Ca/Vit D group at the TH (P=0.008) and FN (P=0.040). At the end of 24 months of the CARD study, CTX and PINP were suppressed in both groups and then increased more between months 24-36 in the Ca/Vit D group than the ALN group (P=0.051 for CTX, P=0.030 for P1NP). Both CTX and PINP remained below the month 0 baseline in both groups (P<0.05 for all comparisons).Conclusions: With the limitations of our small sample size, these data suggest that both 1 and 2 years of ALN effectively maintain BMD gains achieved with one year of DMAB and prevented any rebound in bone turnover marker levels above pre-DMAB baseline. This is the first randomized trial to assess minimum duration of bisphosphonate after short term DMAB and may be helpful to guide clinical care. Similar studies performed after longer durations of DMAB would be helpful to further define optimal management.

Targeted coaching to improve osteoporosis therapy adherence: a single arm variation of the C-STOP study *Carrie Ye[1], Finlay McAlister[1], Debbie Bellerose[1], Meng Lin[2]. [1]University of Alberta, Canada. [2]Alberta Health Services, Canada

Despite having medications that are efficacious at preventing bone loss and fractures, suboptimal treatment rates are further attenuated by poor medication adherence and persistence. In our original C-STOP Trial, we found that a Nurse Case Manager (CM) could significantly increase testing for osteoporosis and starting treatment and that 12-month adherence rates were high (79%) in both the active control group and the CM group in the C-STOP Trial.AIM: In this pre-planned variation of the C-STOP Trial, we evaluate if adherence-specific coaching by the case manager (CM) can further improve adherence and persistence rates compared to those seen in the original C-STOP Trial.METHODS: We conducted a prospective observational cohort study of community-dwelling adults 50 years or older who suffered an upper extremity fracture, not previously treated with osteoporosis medications, to assess whether a well-trained CM can partner with patients to improve adherence and persistence to oral bisphosphonates. The primary outcome was adherence (taking >?80% of prescribed doses) to oral bisphosphonate at 12 months after study enrollment. Secondary outcomes included primary adherence and 12-month persistence to oral bisphosphonate, and calcium and vitamin D supplement intake at 12 months.RESULTS: The study cohort consisted of 84 participants, 84.5% women, mean age 64.9 years, with mean total hip BMD T-score of -1.4. 30 were prescribed an oral bisphosphonate (Figure). Twenty-two (73.3%) started treatment within 3 months. The adherence rate at 12-months was 77.3%. The persistence rate at 12-months was 95.5%. 62.8% of those not prescribed oral bisphosphonate were taking supplemental calcium and 93.0% were taking supplemental vitamin D at 12-months. Depression was a significant predictor of 12-month non-adherence (adjusted OR 9.8, 95% CI 1.2-81.5).CONCLUSION: Adherence-specific coaching by a CM did not further improve the medication adherence achieved in the original C-STOP study. Importantly, these negative results can inform future adherence intervention studies.

Figure. Flow and outcomes of study participants

SAT-463

A randomized controlled trial of the effect of raloxifene plus cholecalciferol versus cholecalciferol alone on bone mineral density in postmenopausal women with osteopenia *Sungjae Shin[1], Namki Hong[2], Yumie Rhee[3]. [1]Division of Endocrinology, Department of Internal Medicine, Endocrine Reasearch Institute, National Health Insurance Service Ilsan Hospital, Goyang, Korea, Republic of Korea. [2]Division of Endocrinology, Republic of Korea. [3]Yonsei University College of Medicine, Republic of Korea

Raloxifene increases lumbar spine bone mineral density (BMD) and lowers vertebral fracture risk in patients with osteoporosis. However, few prospective clinical trials have studied its efficacy in postmenopausal women with osteopenia. This study investigated the efficacy of raloxifene in postmenopausal women with osteopenia. A single-center, randomized, prospective controlled trial was performed in 112 postmenopausal women with osteopenia. Participants were randomly assigned to receive raloxifene 60 mg/day plus cholecalciferol 800 IU/day (RalD group) or cholecalciferol 800 IU/day (VitD group) for 48 weeks. Osteopenia was defined based on the lowest BMD T-score in the lumbar spine, femoral neck, or total hip. A favorable response was defined as an improvement of BMD at the lumbar spine above 95% least significant change (>=2.76%). The trial was registered with ClinicalTrials.gov (NCT05386784). Compared with the VitD group, the RalD group had a greater increase in lumbar spine BMD (RalD vs. VitD; 2.6% vs. ?0.6%, p=0.005) and less bone loss in total hip BMD (?0.3% vs. ?2.9%, p=0.003). The differences remained significant after adjustment for age, body mass index, baseline BMD, and other covariates. The proportion of favorable responders was higher in the RalD group than the VitD group (54% vs. 25%, p=0.003). During the study period, one wrist fracture and four adverse events (two leg cramps, one hot flushes, and one dry mouth) occurred in the RalD group. In conclusion, RalD significantly improved lumbar spine BMD and attenuated total hip BMD loss compared with VitD alone in postmenopausal women with osteopenia.

Title: Comparative Study of the Effects of Bisphosphonates and Recombinant Human Parathyroid Hormone on Osteogenic Gene Expression and Mineralization in Human Osteogenic Sarcoma Cells.Takdeer Kaur, Vandana Dhiman, Sanjay Kumar Bhadada, ,Naresh Sachdeva, Ravi Pratap Barnwal, Sudhaker Dhanwada RaoAbstract: Despite more than two decades of clinical experience, molecular mechanisms of anti-fracture drugs, are not completely understood. Recent studies suggest fundamentally different mechanism of action of key anti-fracture drugs, bisphosphonates and recombinant human parathyroid hormone (rhPTH) at the tissue level, however their molecular basis of action has not explored completely. Accordingly, we studied the effects of varying cncentrations of zoledronic acid (ZOL; 1µM and 5µM) and rhPTH (5 µg and 10 µg) on Human Osteogenic sarcoma cells (U2OS cells). Cellular viability, mineralization, and osteogenic gene expressions were assessed to elucidate the effects of these two prototypic drugs with diametrically different mechanisms of action. Cellular viability was not affected either by ZOL or rhPTH alone or in tandem treatments. Osteoblastic activity (alkaline phosphatase activity and mineralization) increased significantly with rhPTH followed by ZOL. Further, alkaline phosphatase activity increased significantly with in tandem treatment of rhPTH followed by ZOL both at the mRNA (p<0.001) and protein levels (p<0.04). Moreover, osteoblastic genes (COL1A1 and osteocalcin) were significantly modulated by sequential treatment with rhPTH followed by ZOL. We conclude that rhPTH (5µg) treatment followed by ZOL (1µM) showed the best anabolic effects. Our results warrant further research in assessing similar combinations of anti-fracture drugs which augment osteogenesis to maximize their anabolic effects in preventing osteoporosis in susceptible individuals.

Lithocholic Acid Induced Bone and Renal 25-hydroxyvitamin D-1alpha hydroxylase (CYP27B1) Expression and Activities in vitro and in vivo *Chung Yan Lam[1], Wen Xuan Yu[3], Yayi Shen[3], Man-Sau Wong[4]. [1]The Hong Kong Polytechnic University , Hong Kong. [3]The Hong Kong Polytechnic University, China. [3]The Hong Kong Polytechnic University, Hong Kong. [4]Hong Kong Polytechnic University, Hong Kong

Lithocholic acid (LCA), a gut-derived bile acid, is believed to play a regulatory role in bone health. We hypothesize that LCA regulates bone metabolism via the activation of renal and extra-renal CYP27B1 expression and activities. The present study aimed to study the effects of LCA on CYP27B1 expression and activities in kidney and bone tissues in vitro and in vivo. CYP27B1 protein expression and activities in vitro were studied in human osteoblastic-like MG-63 cells and renal proximal convoluted tubule HKC-8 cells treated with either different concentrations of LCA (10-12 to 10-6 M), PTH (10-7M), or its vehicle for 4 hours. The in vivo time-dependent effects (1, 3, 5, 8, 12 and 24 hours) of LCA (25mg/kg) on serum 1,25(OH)2D3 levels and renal and extra-renal CYP27B1 and CYP24A1 (25-hydroxyvitamin D 24-hydroxylase) protein expression were studied using mature (4-month-old) male C57BL/6 mice.LCA was shown to significantly induce CYP27B1 protein expression at 10-12 to 10-8M in MG-63 cells (P<0.01) and at 10-12 to 10-6M in HKC-8 cells (P<0.05). In addition, LCA significantly induced CYP27B1 activity in MG-63 cells at 10-10M (P<0.05) and in HKC-8 cells at 10-6M (P<0.01). LCA at 25mg/kg significantly induced circulating 1,25(OH)2D3 levels at 3 hours in male C57BL/6 mice (P<0.05) and the level showed a trend returning back to basal level from 5 hours to 24 hours. Renal CYP27B1 expression was found to be significantly increased in male mice upon treatment with LCA for 1 hour (P<0.01). Renal CYP24A1 expression significantly decreased in male mice in response to treatment with LCA for 3 hours (P<0.05) and increased back to basal level. Extra-renal CYP27B1 expression in iliac crest slightly increased by LCA at 1 hour and decreased significantly at 3 and 12 hours (P<0.01 and P<0.001). CYP24A1 expression in iliac crest significantly increased by LCA at 5 hours (P<0.001). Renal CYP27B1 was more responsive than extra-renal CYP27B1 in mice to the treatment of LCA. Renal CYP27B1 and CYP24A1 appeared to exert a negative feedback mechanism to tightly control the level of serum 1,25(OH)2D3 level.In summary, both in vitro and in vivo results showed that LCA is able to regulate renal and extra-renal CYP27B1 expression, which in turn might account for its stimulatory effects on circulating 1,25(OH)2D3 levels. Our study indicated

that LCA might play an important role in bone health via its role in the regulation of vitamin D metabolism.

SAT-469

Protein Kinase A activity modulates osteoclastogenesis *CAROLE LE HENAFF[1], YONGLI QIN[2], Henry Kronenberg[3], Lawrence S Kirschner[4], Baohong Zhao[5], Nicola Partridge[6]. [1]New York University, United States, [2], United States, [3]Massachusetts General Hospital, United States, [4]Departments of Cancer Biology and Genetics and the Division of Endocrinology, Diabetes, and Metabolism, Department of Internal Medicine, The Ohio State University Wexner Medical Center, United States, [5]Hospital for Special Surgery, United States, [6]New York University College of Dentistry, United States

Protein Kinase A action in osteoclasts has not been clearly investigated. Previous studies were mainly done in vitro without clear results yielding controversies in PKA activity in osteoclastogenesis or osteoclast activity. A few studies, such as with calcitonin, associated PKA activation to an inhibition of osteoclastogenesis or osteoclast activity whereas other studies, such as with dopamine showed the opposite. To elucidate the role of PKA activity during osteoclastogenesis and in osteoclast activity, we constitutively modulated this enzyme activity in osteoclastic lineages (from monocytes to mature osteoclasts) using LysM-Cre in mice: first, we deleted the PKA regulatory subunit 1A (Prkar1a) to increase PKA activity (PKAhighOC) and secondly, we hypoactivated PKA using a dominant negative mouse model (PKAlowOC) which results in a mutation in the cAMP binding site of the regulatory subunit and blocks the release of the active catalytic subunit. At 2 months of age, in our mouse models, hyperactive osteoclastic PKA caused a decrease in trabecular bone volume (-23% in males and -33% in female mice), thickness (-12%) and number (-15% to -24%) and an increase in trabecular separation (14%). Conversely, hypoactive osteoclastic PKA increased trabecular bone volume (18%) with increased trabecular thickness (9% to 12%) and separation (23% to 45%). The cortical thickness was decreased in hyperactive mice in the metaphysis (-10% to -14%) but no changes were observed in the diaphysis. Interestingly, the cortical thickness was only reduced in the diaphysis with hypoactive PKA (-7%). The cortical bone phenotype was more pronounced in females compared with males. Primary osteoclastic cell cultures from the hyperactive mouse model showed a doubling in osteoclast numbers confirming the increased osteoclastogenesis in this mouse model. These results collectively suggest that PKA activity positively regulates osteoclastogenesis. These genetic data, for the first time, corroborate that PKA is a key positive regulator in osteoclastogenesis.

Development and Biophysical Characterization of a Humanized FSH-blocking Monoclonal AntibodyTherapeutic Formulated at an Ultra-high Concentration *Satish Rojekar[1], Anusha Rani Pallapati[1], Judit Gimenez-Roig[2], Damini Sant[3], Sakshi Gera[2], Funda Korkmaz[2], Farhath Sultana[4], Orly Barak[4], Ofer Moldavski[4], Uliana Cheliadinova[4], Anisa Azatovna Gumerova[5], Hasni Suhasha Kannangara[5], Tal Frolinger[5], Ronit Witztum[5], Anne Macdonald[5], Pevnev Georgii[6], Steven Sims[6], John N. Caminis[6], Marcia Meseck[6], Vitaly Ryu[6], Se-Min Kim[6], Daria Lizneva[6], Tony Yuen[7], Mone Zaidi[7]. [1]Icahn School of Medicine at Mount Sinai, United States, [2]Icahn School of Medicine at Mount Sinai , United States, [3]Max Planck Institute for Biology of Ageing, Germany, [4]Icahn School of Medicine at Mount Sinai , United States, [5]Icahn School of Medicine at Mount Sinai , United States, [6]Icahn School of Medicine at Mount Sinai , United States, [7]Icahn School of Medicine at Mount Sinai , United States

Highly concentrated antibody formulations are oftentimes required for subcutaneous, self-administered biologics. Here, we report the development of a unique formulation for our first-in-class FSH-blocking humanized antibody, MS-Hu6, which we propose to move to the clinic for osteoporosis,obesity, and Alzheimer's disease. The studies were carried out using our Good Laboratory Practice (GLP) platform, compliant with the Code of Federal Regulations (Title 21, Part 58). We first used protein thermal shift, size exclusion chromatography, and dynamic light scattering to examine MS-Hu6 concentrations between 1 and 100 mg/mL. We found that thermal, monomeric, and colloidal stability of formulated MS-Hu6 was maintained at a concentration of 100 mg/mL. The addition of the antioxidant L-methionine and chelating agent disodium EDTA improved the formulation's long-term colloidal and thermal stability. Thermal stability was further confirmed by Nano differential scanning calorimetry (DSC). Physiochemical properties of formulated MS-Hu6, including viscosity, turbidity, and clarity, conformed with acceptable industry standards. That the structural integrity of MS-Hu6 informulation was maintained was proven through Circular Dichroism (CD) and Fourier TransformInfrared (FTIR) spectroscopy. Three rapid freeze-thaw cycles at -80°C/25°C or -80°C/37°C further revealed excellent thermal and colloidal stability. Furthermore, formulated MS-Hu6, particularly its Fab domain,displayed thermal and monomeric storage stabilityfor more than 90 days at 4°C and 25°C. Finally, the unfolding temperature (Tm) for formulated MS-Hu6 increased by >4.80°C upon binding to recombinant FSH, indicating highly specific ligand binding. Overall,we document the feasibility of developing a stable,manufacturable and transportable MS-Hu6 formulation at a ultra-high concentration at industry standards.The study should become a resource for developing biologic formulations in academic medical centers.

Positive Effects of Cannabidiol on Primary Rat Osteoclasts and Osteoblasts *Krittikan Chanpaisaeng[1], Jirawan Thongbunchoo[2], Narattaphol Charoenphandhu[3]. [1]National Science and Technology Development Agency, , [2]Department of Physiology, Faculty of Science, Mahidol University, Thailand, [3]Center of Calcium and Bone Research (COCAB), Faculty of Science, Mahidol University, Thailand

Cannabidiol (CBD) has received attention because of its potential therapeutic effects including bone health. This study aims to evaluate the effect of CBD on primary osteoclasts (OCs) and osteoblasts (OBs) from Sprague-Dawley rats. At the age of 14 wks old, bone marrow was isolated from femurs and tibiae and cultured in ?-MEM supplemented with 10 ng/mL M-CSF in 96-well plates at 2x104 cells/well to differentiate into OCs. After 24 hrs, the medium was changed to OC differentiation medium containing 10 ng/mL of M-CSF and RANKL. The osteoclast cultures were fixed with 4% paraformaldehyde and stained for tartrate-resistant acid phosphatase (TRAP). OBs were derived from explant cultures of femurs and tibiae in DMEM supplemented with L-ascorbic acid 2-phosphate (AscP). When the cultures reached confluence, cells were passaged and plated in 96-well and 12-well plates at 1x104 and 5x104 cells/well, respectively. Cells in 96-well plates were allowed to settle overnight and CBD at 0, 0.1, 0.5, 1, 5, 10, and 20 ?M was added to the culture. After 48-hr incubation, MTT assay was performed to evaluate cell proliferation. Cells in 12-well plates were cultured to confluence and the medium supplemented with AscP and 2 mM ?-glycerophosphate was added to stimulate osteoblast maturation and mineralization. Aizarin red S staining was used to detect mineralization. Here, we observed that CBD at the concentration of 1, 5, and 10 ?M suppressed osteoclast multinucleation in a dose-dependent manner. Specifically, CBD at 1 ?M significantly reduced the number of multi-nucleated cells (MNCs) when compared to the culture of vehicle control and CBD at 10 ?M almost completely suppressed osteoclast differentiation. For osteoblast culture, CBD at the concentration of 0.1-1 ?M did not impact the growth of pre-OBs whereas higher doses (5, 10 and 20 ?M) increased pre-OB proliferation compared to control. We selected three doses of CBD at 1, 5, and 10 ?M to study osteoblast mineralization. Alrizarin red S staining of cultures in CBD at 1 and 5 ?M showed an increase in mineralization. On the other hand, CBD at 10 ?M seemed to suppress osteoblast mineralization. Our findings demonstrated that CBD at 1 and 5 ?M presented favorable effect towards bone protection whereas CBD at 10 ?M inhibited MNC formation but also reduced OB mineralization. In conclusion, CBD is a potent regulator of osteoclast and osteoblast functions; therefore, could be used to modulate bone turnover towards bone formation.

Bone-targeted far-red probe for the fluorometric detection of extracellular Cathepsin-K *BEN SWANSON[2], Boya Zhang[2], MARGARET DURDAN[3], Megan Weivoda[4], YUJI MISHINA[2], Colin Greineder[2]. [2]University of Michigan, , [2]University of Michigan, United States, [3], , [4]Mayo Clinic, United States

Cathepsin K (CTSK) is a lysosomal cysteine protease secreted by osteoclasts (OC), which plays a crucial role in ECM proteolysis during bone remodeling. CTSK inhibitors have shown promise to treat osteoporosis, but were halted in human trials due to off-target toxicities. To overcome this, new pharmacologic strategies must be developed and novel research tools are needed to detect changes in CTSK activity at the bone surface. Previous attempts to develop CTSK activity probes lack sensitivity and specificity necessary for high-fidelity detection. We aimed to develop a low molecular weight probe that rapidly circulates and localizes to the bone surface, using a fluorophore-quencher pair to detect extracellular CTSK proteolysis in vitro and in vivo. We synthesized a nine-residue peptide based on the consensus sequence of CTSK, modified with a far-red fluorescent residue adjacent to its C-terminus (Cy5) and broad-spectrum quencher (QSY21) at its N-terminus: QSY21-GHP-GGPQ-K(Cy5)-K(N3) (CTSKr). The C-terminal azidolysine was orthogonally conjugated

to a bisphosphonate dibencocyclooctyne (BP-DBCO) to yield BP-CTSKr. We demonstrated the ability of this BP-CTSKr (10 mM) to detect CTSK protease activity in a fluorometric assay, comparable to a commercially available 7-amino-4-trifluoromethylcoumarin inhibitor screening assay (Abcam). Subsequently, when recombinant CTSK was inhibited by FF-FMK (1 mM), fluorescence signal of BP-CTSKr was abolished. BP-CTSKr efficiently localizes to the surface of hydroxyapatite nanoparticles (HA-NP) in solution. When treated with recombinant CTSK, fluorescent signal from the surface of HA-NP at 670 nm is detected by fluorimeter and confocal at a high quantum yield. Primary mouse OC were differentiated and seeded to bovine bone slabs previously incubated with BP-CTSKr. After 24 hours, 3-D confocal laser microscopy demonstrates extracellular BP-CTSKr fluorescence beneath multinuclear TRAP+ OC, correlating to the resorption pit, exacerbated by LPS treatment. BP-CTSKr was injected systemically in 3-month-old C57BL/6 mice (2 mg/kg IP); no systemic or OC toxicity was observed after 24 hours in vivo. BP-CTSKr fluorescence is detected in frozen lumbar spine and femur sections, localized with TRAP+ OC. These results demonstrate a new approach to detecting extracellular CTSK activity with specificity to the bone microenvironment, an important technology requisite for developing new CTSK-targeted therapeutics.

Denosumab Reduces the Number of Circulating Osteoclast Precursor Cells in Postmenopausal Women with Osteoporosis *Jefferson Tsai[2], Kaichi Kaneko[2], Deniece Menez[2], Brian Oh[2], Andrew J. Suh[2], Eugenia Giannopoulou[2], Emily Stein[2], Linda A. Russell[2], Joseph Lane[2], Richard Bockman[3], Kyung-Hyun Park-Min[2]. [2]Hospital for Special Surgery, United States. [2]Hospital for Special Surgery, . [3]Hospital for Special Surgery, Weill Cornell Medical College, United States

Purpose: Osteoporosis is a systemic skeletal disease characterized by low bone mass and increased risk of fracture. Considerable work has been done to improve diagnostic tools to identify low bone mass, but early detection of osteoporosis remains challenging. Therefore, discovering new diagnostic markers that closely correlate with osteoporosis disease activity is imperative.Osteoclasts (OC) are hypothesized to be derived from circulating osteoclast precursor cells (cOCPs) of a myeloid cell origin. We have previously defined a population of cOCPs with high osteoclastogenic potential in postmenopausal women with osteoporosis that shows strong correlations with BMD and CTX, suggesting that the frequency of cOCPs may be indicative of bone quality in these patients. Current strategies for targeting OC in bone diseases such as osteoporosis include denosumab (Dmab), a fully human monoclonal antibody that inhibits RANKL and prevents RANK-mediated OC formation. We hypothesized that Dmab treatment may regulate the frequency of cOCPs. Here, we measured the number of cOCPs in postmenopausal women with osteoporosis on Dmab therapy. Methods: 16 postmenopausal women with osteoporosis on Dmab therapy were recruited for the study. PBMCs were stained with antibodies against different cell surface markers. cOCPs were quantified and analyzed by flow cytometry. CD14+ cells were incubated with macrophage colony stimulating factor and RANKL on a chamber slide and immunocytochemistry staining was performed to analyze RANKL-induced NFATc1 expression. Bone mineral density (BMD) was evaluated using DXA. Results: All 16 participants (mean age+/-SD: 69.3+/-5.3) had osteoporosis prior to beginning Dmab therapy. The duration of therapy was approximately 5 years (mean injection number+/-SD: 10.2+/-5.1). Lumbar spine and total hip T-scores were -1.43+/-1.08 and -2.27+/-0.6, respectively, suggesting that Dmab was effective in increasing BMD. The average number of cOCPs in Dmab patients was diminished (35.9 cOCPs/µL of blood) compared to our cohort of osteoporosis patients without treatment (71.5) and similar to patients with BMD values within normal range (23.1).Conclusions: Dmab treatment lowers the frequency of cOCPs in postmenopausal women with osteoporosis compared to treatment-naïve patients. Our findings indicate that Dmab modulates the frequency of cOCPs and could provide ways in which OC can be therapeutically targeted to prevent pathological bone loss associated with rebound phenomenon.

Resistance exercise but not aerobic exercise in young males leads to increased serum concentration of ?-aminoisobutyric acid, L-BAIBA *Charalampos Lyssikatos[1], Brandon Yates[1], Ziyue Liu[1], Kamal Awad[2], Andrew Coggan[3], Stuart Warden[4], MARCO BROTTO[5], Lynda Bonewald[6]. [1]Indiana Center for Musculoskeletal Health, United States. [2]The University of Texas at Arlington , United States. [3]Department of Kinesiology, School of Health & Human Sciences, United States. [4]Indiana University School of Health & Human Sciences, United States. [5]University of Texas-Arlington (UTA), United States. [6]Indiana University School of Medicine, United States

BAIBA, a non-proteinogenic aminoacid with two enantiomers, L- and D-, is generated through catabolization of two distinct metabolic pathways from valine and thymine respectively. The enantiomers have been reported to have different or similar actions, depending on assay. We have shown the L-BAIBA is more potent than D-BAIBA in maintaining bone through osteocyte viability and is the form made by contracting murine muscle. In this study, we compared aerobic (endurance) and resistance (anaerobic) exercise in humans for circulating levels of L- and D-BAIBA and related butyric acids. We designed a pilot clinical study in asymptomatic, untrained, young (18-35 years old) adult males. To date four healthy volunteers (LDB1 - 4), age range 22 - 32 years old and BMI: 23.4 - 27.1, have been recruited. The study is taking place at the ICMH Musculoskeletal Function, Imaging and Tissue Resource Core. Three of the four participants completed both the endurance and the resistance exercise, each of 30 min duration but only one did not complete the resistance exercise. Blood samples were collected at baseline, during (15 and 30 min) and after (1, 2, 3 and 24 hrs) exercise. Serum levels of aminobutyric acids were quantitated using LC/MS. Plasma from 30 min was used to determine catecholamines level, an indicator of successful exercise stress response. With endurance exercise, L-BAIBA was detectable only at one time point in one participant (LDB2 - L-BAIBA: 0.085 ??) at 1 hr but was detected in all three participants in the resistance exercise. In two of them (LDB2 and LDB4), there was an increase (L-BAIBA: 0.040 -> 0.045 -> 0.046 for LDB2 and 0.039-> 0.049 -> 0.087 for LDB4) at 1, 2 and 24 hrs after the end of the resistance exercise. We also noticed a similar trend for L-AABA at 3 hrs, after a decrease from baseline. D-BAIBA was detectable after both types of exercise and in two participants (LDB2 and LDB4) was increased at 24 hrs. The ratio of L-BAIBA to D-BAIBA and L-AABA showed similar increases at 1 and 24 hrs after the end of the resistance exercise. This is a small observational pilot study to date with only four participants; however, it was striking that L-BAIBA was mainly observed with resistance and not aerobic exercise. This preliminary data supports the need to perform a larger study with greater power. These results may lend insight to how the different forms of exercise can generate distinct signaling factors correlating with beneficial effects on bone.

Changes in Serum Bone Metabolism Markers Can Predict Improved HR-pQCT Measures during Basic Combat Training - The ARMI Study *Jennifer Coulombe[1], Brittany Bozzini[2], Katelyn Guerriere[3], Stephen Foulis[2], Marinaliz Reynoso[4], Leila Walker[2], Jeffery Staab[2], Mary Bouxsein[5], Julie Hughes[6], Kristin Popp[2]. [1]Center for Advanced Orthopedic Studies, Department of Orthopedic Surgery, Beth Israel Deaconess Medical Center, Harvard Medical School, United States. [2]U.S. Army Research Institute of Environmental Medicine, United States. [3]USARIEM, United States. [4]U.S. Army Research Institute of Environmental Medicine, , United States. [5]Beth Israel Deaconess Medical Center, Harvard Medical School, United States. [6]US Army Research Institute of Environmental Medicine, United States

Stress fractures are a significant burden to the U.S. Army, occurring most commonly during Basic Combat Training (BCT). Bone mineral density (BMD) and bone microarchitecture improve during BCT in many, but not all, trainees. We determined changes in bone metabolism markers (BMM) during BCT and whether those changes predict improvements in bone microarchitecture during BCT.We acquired high-resolution peripheral quantitative computed tomography (HR-pQCT, XTremeCTII, Scanco Medical) scans of the distal tibia (4%) during week 1 (pre-BCT) and week 9 (post-BCT). Trainees provided fasted, rested blood samples pre-BCT, at weeks two, four, six, and eight during BCT, and post-BCT. Procollagen type 1 amino-terminal propeptide (P1NP) was measured by chemiluminescent assays (Immunodiagnostic Systems Limited) and cross-linked collagen telopeptide (CTX) was measured by ELISA (Serum CrossLaps). Bone and BMM data are presented as percent change from pre-BCT levels, with significance evaluated by Wilcoxon signed-rank test. We used sex-stratified multivariate regression models to assess the relationship between changes in HR-pQCT measures and P1NP levels at week four of BCT, adjusting for age, race, BMI, and pre-BCT P1NP levels.Participants included 110 men and 124 women (mean+/-SD; age= 20.7+/-4.0 yrs, BMI= 24.2+/-3.6 kg/m2). In women, P1NP levels were higher than pre-BCT values at every timepoint, with peak levels at week four (+45%, Fig 1A). In men, P1NP levels exceeded pre-BCT only during weeks two and four, with peak levels also at week four (+36%, Fig 1A). P1NP at week four of BCT was associated with increased cortical (Ct.) area (R^2=0.46, $p<0.0001$), Ct. thickness (Th) (R^2=0.42, $p<0.0001$), trabecular (Tb.) bone volume (R^2= 0.23, $p=0.0004$), Tb.BMD (R^2= 0.27, $p<0.0001$), and total (Tt.) BMD (R^2=0.28, $p<0.0001$) in women, and Ct. area (R^2= 0.48, $p<0.0001$), Ct.Th (R^2= 0.43, $p<0.0001$), Tb.BMD (R^2= 0.15, $p=0.001$), and Tt.BMD (R^2= 0.29, $p=0.0002$) in men.These

findings indicate that an increase in P1NP from pre-BCT to week four of BCT is associated with improved bone microarchitecture and density after training. Elevated P1NP without corresponding CTX rise may also suggest bone anabolism via uncoupled formation and resorption.Disclaimer: Supported by U.S. Medical Research and Development Command. The views expressed in this abstract are those of the authors and do not reflect the official policy of the Department of Army, Department of Defense, or the U.S. Government.

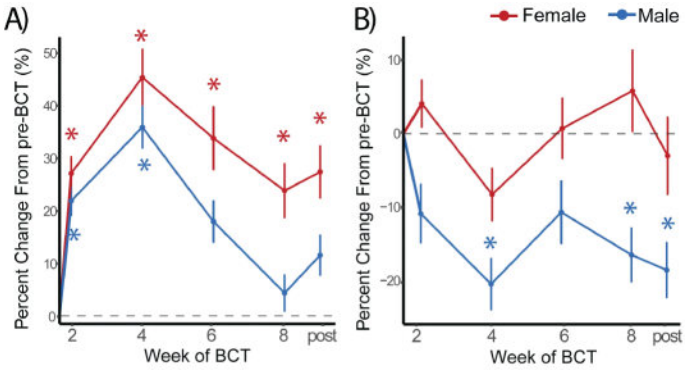

Figure 1: Changes in Serum Bone Turnover Markers during BCT in Men and Women. **A)** P1NP and **B)** CTX. Female and male trainees' P1NP levels peaked at week 4 of BCT (+45.3% and +35.9%, respectively). By contrast, CTX levels in female trainees were never significantly different than pre-BCT levels during BCT but were significantly lower than baseline levels for males during weeks 4 (-20.1%), 8 (-16.1%), and post-BCT follow up (-18.2%). Data are presented as mean and standard error of the mean percent change in P1NP and CTX from pre-BCT levels for female and male trainees. Statistical significance as compared to pre-BCT levels, p-values based on Wilcoxon signed-rank test, * - p<0.01.

Evaluating a New Physical Activity Metric for Predicting Bone Strength During Growth *Christina Alexander[1], Leigh Gabel[1]. [1]University of Calgary, Canada

Accelerometers are often used to examine relationships between free-living physical activity (PA) and bone health. Free-living PA is usually quantified using minutes spent in different activity intensities (e.g., sedentary, light PA, moderate-to-vigorous PA (MVPA), and VPA). However, new metrics to quantify PA have been proposed, including an intensity gradient (IG) approach that bins the full spectrum of accelerometry data. The IG slope indicates how evenly one's PA is spread across intensities, with the hypothesis that a shallower IG slope (greater time in MVPA and VPA) is beneficial for bone. The purpose of this study is to determine whether the IG metric better predicts bone strength during growth compared with traditional metrics (i.e., MVPA and VPA).In the University of British Columbia's Healthy Bones Study, over 300 healthy children and youth (age range 9-21 years) had their distal tibia scanned using high resolution peripheral quantitative computed tomography (XtremeCT, Scanco Medical). Bone strength (failure load, N) was estimated using finite element analysis. Physical activity was assessed using ActiGraph accelerometers worn on the hip for 7-days. MVPA (min/day) and VPA (min/day) were normalized to accelerometer wear time and IGs were calculated for each participant. Linear regression models examined relationships between PA metrics (MVPA, VPA, and IG) and tibia failure load. Models were adjusted for sex, ethnicity, tibia length, and maturity offset.Average minutes per day of MVPA and VPA were 42 minutes and 15 minutes, respectively, while intensity gradient ranged from -2.16 to -1.26. IG was weakly positively correlated with MVPA and VPA (r = 0.20 and r = 0.39, respectively). MVPA and VPA positively predicted bone strength (p = 0.023 and p= 0.050, respectively). A 1-minute increase in MVPA and VPA was associated with 3.6% and 14.6% greater failure load at the tibia, respectively. IG did not predict bone strength.The novel IG metric encompasses the full spectrum of accelerometry data and provides insight into "how" PA is accumulated. However, for predicting bone strength in youth, IG did not outperform traditional threshold-based approaches that rely on "how much" PA is accumulated. Future work should evaluate alternate IG bin sizes along with metrics that combine PA volumes and patterns.

SAT-478

Participating in Sports Applying Multidirectional Loading During Youth Reduces Stress Fracture Risk During U.S. Army Basic Combat Training - The ARMI Study *Katelyn Guerriere[1], Ian Hussian[2], Kathryn Taylor[2], Paul Bartlett[2], Leila Walker[2], Nathaniel Smith[2], Kristin Popp[3], Karl Friedl[2], Mary Bouxsein[4], Stefan Pasiakos[2], Susan Proctor[2], Stephen Foulis[2], Julie Hughes[2]. [1]USARIEM, United States. [2]US Army Research Institute of Environmental Medicine, United States. [3]Massachusetts General Hospital, . [4]Beth Israel Deaconess Medical Center, Harvard Medical School, United States

Stress fractures (SF) risk is high during U.S. Army Basic Combat Training (BCT). However, SF risk may be reduced in Soldiers participating in sports applying multidirectional loading (MDS; e.g., soccer, other ball sports) in the two years before military training. History of MDS in youth is also associated with greater bone size, strength, and microarchitecture compared to those participating in sports applying unidirectional loading (UDS; e.g., running) or non-impact loading (NIS; e.g., swimming). Whether participation in MDS at any point during youth reduces SF risk during BCT is unknown. As part of a prospective observational study, participants completed surveys at the beginning of BCT to describe sport participation from kindergarten through young adulthood. Participants were categorized based on the highest level of osteogenic potential reported (MDS > UDS > NIS) or as having no sports participation (NS). Bone density, area, and microarchitecture were assessed using HR-pQCT at the beginning of BCT. ICD-10 medical diagnoses codes were used to identify stress fractures during BCT. Multivariate generalized linear models and least squared means, adjusted for age, height, weight, sex, race, and tobacco use, were used to analyze the relationship between baseline bone parameters and sport category. Multivariate logistic regression models, further adjusted for fracture history, were used to assess the relationship between sport category and SF risk during BCT. Out of 3090 participants (mean+/-SD; age=20.9+/-3.8, 62% male, 42% non-Hispanic white), 2337 were categorized as MDS (76%), 211 as UDS (7%), 30 as NIS (1%), and 508 as NS (16%). SF % was 4.6% in MDS, 8.5% in UDS, 13.3% in NIS, and 8.7% in NS. MDS had greater total area (Tt. Ar), total and trabecular (Tb.) bone mineral density (BMD), Tb. bone volume fraction, Tb. thickness, and cortical thickness than NS (2.07-5.63%; Table). MDS also had greater Tt.Ar., Tt.BMD, and Tb.BMD than UDS (1.68-3.38%; Table). SF risk was 46% lower for MDS (odds ratios(95%CI), 0.54(0.37, 0.78), p=0.001) than NS. SF risk was not different for the other groups compared to NS. These data demonstrate that participating in MDS, but not UDS, during youth improves bone properties and markedly reduces SF risk during BCT. These findings highlight the importance of participating in MDS to prevent bone fragility and reduce SF risk in adulthood.

Bone Outcome	MDS vs UDS	MDS vs NIS	MDS vs NS
Tt.Ar	**1.68 (0.19, 3.20)**	2.87 (-0.93, 6.73)	**2.51 (1.48, 3.56)**
Tt.BMD	**2.24 (0.05, 4.46)**	1.03 (-4.63, 6.77)	**4.38 (2.95, 5.83)**
Tb.BMD	**3.38 (1.05, 5.75)**	2.80 (-3.13, 8.84)	**5.18 (3.68, 6.70)**
Tb.BV/TV	3.17 (-0.31, 6.72)	2.54 (-3.77, 8.96)	**5.07 (3.45, 6.72)**
Tb.Th	0.41 (-5.35, 6.69)	0.41 (-3.70, 4.60)	**2.07 (0.82, 3.34)**
Ct.Th	0.80 (-4.07, 5.82)	-0.34 (-8.71, 8.26)	**5.62 (0.80, 3.17)**

Data are percent differences (upper and lower control limits). Data in bold font indicate significant differences between sport categories. MDS = multidirectional loading sports; UDS = unidirectional loading sports; NIS = non-impact loading sports; NS = no sports participation; Tt.Ar = total area; Tt.BMD = total bone mineral density; Tb.BMD = trabecular bone mineral density; Tb.BV/TV = trabecular bone volume/total volume; Tb.Th = trabecular thickness; Ct.Th = cortical thickness

Four-year longitudinal assessment of risk factors for bone stress injuries in intercollegiate distance runners *Kenneth Kozloff[1], Melissa Bown[2], Christina Fanning[2], Fiddy Davis[3], Kelly Rogers[4], Ronald Zernicke[1]. [1]University of Michigan, United States. [2]Department of Athletics, University of Michigan, United States. [3]Michigan Performance Research Laboratory, United States. [4]Department of Orthopaedic Surgery, University of Michigan, United States

Bone stress injuries (BSI) are prevalent in sports emphasizing leanness, endurance, and skeletal loading. While individual BSI risk factors have been identified, translating this into actionable models of BSI prevention remains elusive. The Female Athlete Triad Risk Assessment Tool [1] was adapted to identify female [2] and male [3] athletes at high risk for BSI but doesn't account for modifiable factors such as sleep, which has been shown to be associated with BSI in military [4]. Here, we evaluate BSI risk in distance runners using the modified Triad assessment tool and compare risks to those calculated from sleep surveys as an independent predictor of BSI.Male (n=41) and female (n=49) runners from an NCAA D1 Cross Country program were recruited over 4 years. BSI risk scores were evaluated prospectively [2,3] through pre-season surveys and DEXA-derived BMD of the hip and spine. Individual scores on a 0-2 pt scale were summed as follows: Prior BSI (none:0 pt; 1 low risk site:1 pt; >1 high risk site or >2 low risk site:2pt); dietary restriction (none:0pt; some/past DE history:1pt; current DE:2pt); body mass index (BMI>18.5: 0pt; BMI 17.5-18.5: 1pt; BMI-1: 0pt; -1 to -2: 1 pt; <-2: 2 pt). Female surveys included age at menarche (16: 2pt) and cycles over past year (>9 menses: 0pt; 6 to 9:1 pt; <6: 2pt). Sleep was assessed by survey [5] pre-season and after ~8 wks of training. Annual BSI incidence was monitored. Relative risk

(RR) scores for BSI for any year was compared to BSI incidence for subjects scoring 0-1pts on the modified Triad tool and to subjects registering a change of -1 to +1 points on sleep hygiene.A total of 38 (women) and 14 (men) BSI were observed. Of 194 athlete-seasons of data, 160 included complete assessments. Women scoring 6-7 out of 12 max points on the modified Triad tool increased BSI RR 2.1 fold (95% CI 1-4.5). Men scoring 4-5 (out of 8) increased BSI RR 8.2 fold (95% CI 1.4-48). Within-season worsening of sleep hygiene by 4-5 points (17 max) independently increased BSI RR 3.2 fold (95% CI 2.0-5.1) in women, but not men.Predictive tools that incorporate sleep as a modifiable behavior may be combined with other personalized metrics to help identify endurance athletes who are at greatest risk for BSI.Refs: 1.De Souza Br J Sports Med 2014; 2.Tenforde Am J Sports Med 2017; 3.Kraus Br J Sports Med 2019; 4.Firestone Med Sci Sports Exer 2008; 5.Bender Sports Med Open 2018

Functional Characterization of Novel Lunatic Fringe Variants in Spondylocostal Dysostosis Type-III with Scoliosis *Parker Wengryn[1,] Karina Da Costa Silveira[1,] Connor Oborn[1,] Carrie-Lynn Soltys[1,] Alex Beke[1,] Inara Chacon-Fonseca[2,] Nadirah Damseh[3,] Marco Quesada Rodriguez[4,] Ramsés Badilla Porras[4,] Peter Kannu[1,] [1]University of Alberta, Canada, [2]Lakeridge Health Oshawa, Canada, [3]University of Toronto, Canada, [4]Hospital Nacional de Niños, Costa Rica

Purpose: Rare Mendelian diseases provide a unique opportunity to investigate genetic pathways contributing to normal spinal development and variability in phenotypic presentation. Spondylocostal Dysostosis Type-III (SCD3) is a rare, autosomal recessive disorder characterized by rib fusions, vertebral abnormalities, and varying degrees of scoliosis. SCD3 is caused by variants in the Lunatic Fringe (LFNG) gene encoding a ?-1-3-N-acetylglucosaminyltransferase. This enzyme transfers N-acetylglucosamine to NOTCH1 during somitogenesis to promote normal vertebral formation. We have identified compound heterozygous LFNG variants-of-uncertain-significance (VUS; the genetic variant has an unknown effect on health) in a proband with a SCD phenotype. However, the proband is taller (Height: 10th-25th%), has a longer trunk (Arm span-to-height ratio: 1.07), and more vertebrae (>20) than the six previously reported SCD3 cases. The purpose of our study is to determine whether the c.766G>A (p.G256S) and c.521G>A (p.R174H) LFNG variants lead to diminished N-acetylglucosaminyltransferase activity, protein mis-localization, and/or dysregulated pre-pro-processing. We hope that this will inform the relationship between genotype and phenotype.Methods: HEK293T cells were transiently transfected with 3XFLAG-hLFNG. Fusion protein was immunoprecipitated and assessed with a quantitative glycosyltransferase luciferase assay. NIH3T3 cells were transiently transfected with LFNG-HA, incubated with anti-HA and anti-GM130 antibodies, then assessed for signal colocalization through confocal microscopy. Finally, NIH3T3 cells were transfected with LFNG-HA and whole cell lysate was processed for protein, western blotted, and semi-quantitatively analyzed. Results: The p.G256S and p.R174H variants displayed significantly less enzymatic activity than wildtype. The p.G256S substituion was comparable to negative control whereas p.R174H was significantly more active than p.G256S. Both variants were correctly localized to the Golgi and normally pre-pro-processed.Conclusions: We have discovered the first hypomorphic (p.R174H) and report the fourth functionally null (p.G256S) LFNG variants associated with SCD3. This is the first clinically identified combination of partially active and completely inactive LFNG. This data may suggest that the hypomorphic variant partially rescued the probands height, trunk length, and vertebral number, but not segmentation defects nor scoliosis.

The Association Between 24-Hour Activity with Incident Fracture Risk in the Osteoporotic Fractures in Men (MrOS) Study *Lauren S. Roe[1,] Elsa Strotmeyer[2,] Peggy Cawthon[3,] Nancy W. Glynn[4,] Sonia Ancoli-Israel[5,] Kristine Ensrud[6,] Susan Redline[7,] Katie L. Stone[8,] Kelley Pettee Gabriel[9,] Douglas Bauer[10,] Jane A. Cauley[11,] [1], [2]University of Pittsburgh, United States, [3]San Francisco Coordinating Center, United States, [4]University of Pittsburgh School of Public Health, Department of Epidemiology, United States, [5]University of California San Diego, Department of Psychiatry, United States, [6]University of Minnesota and Minneapolis VA Health Care System, United States, [7]Brigham and Women's Hospital, United States, [8]California Pacific Medical Center, Research Institute, United States, [9]The University of Alabama at Birmingham School of Public Health, Department of Epidemiology, United States, [10]University of California, San Francisco, United States, [11]UNIVERSITY OF PITTSBURGH, United States

Lower physical activity (PA) and sleep, and higher sedentary behavior (SB) are individually associated with fractures. Time spent in these behaviors is inherently linked because there is a finite amount of time in a 24-hr period, but previous analyses examining one activity often have omitted information about all other activities. We evaluated the combined role of PA, SB, and sleep on incident fracture risk using compositional data analysis. Men (N=2,910) attending the Year 7 (2007-2009) MrOS visit (mean age 79.0+/-5.1 y) with accelerometry data (SenseWear® Pro3 Armband) were included in this analysis. PA (>1.5 metabolic equivalents of task; METs), SB (<1.5 METS), and sleep at night were measured over an average of 5.1+/-0.3 days. The 24-hr activity compositions were represented as isometric logratios (ILR). These ILRs were used as predictors in Cox proportional hazards regression models to estimate the risk of incident clinical fracture by the proportion of time in one activity relative to all other activities simultaneously. Self-reported fractures were confirmed with radiographic reports. During an average follow-up of 8.7+/-4.4 y, 669 men had any clinical fracture. Mean composition of PA, SB, and sleep was 134 min/day, 896 min/day, and 410 min/day respectively. In minimally adjusted models (age, race, clinic, season of accelerometer wear), more SB at the expense of sleep and PA was associated with greater fracture risk (hazard ratio [HR]: 1.53, 95% confidence interval [CI]: 1.12, 2.07), and more sleep at the expense of PA and SB was associated with lower fracture risk (HR: 0.71, 95% CI: 0.52, 0.97). Further adjustment for height, weight, diabetes history, health status, smoking, number of comorbidities, and number of impaired instrumental activities of daily living did not alter these associations (SB vs. PA/sleep - HR: 1.54, 95% CI: 1.14, 2.08; sleep vs. PA/SB - HR: 0.68, 95% CI: 0.50, 0.92). In contrast, no association between PA vs. sleep/SB existed with fractures in minimally or fully adjusted models. In conclusion, when accounting for the inherent co-dependence of daily activities, men with higher proportions of sleep relative to the proportion of PA and SB had a lower risk of incident fractures, while men with higher proportions of SB relative to the proportion of PA and sleep had an increased risk of fractures. Future studies should evaluate if fracture risk is lowered by increasing PA or sleep at the expense of SB.

SAT-482

The "can do, do do" framework applied to explore physical capacity, physical activity and fall risk factors in FLS patients *MERLE SCHENE[1,] Kenneth Meijer[2,] Donald Cheung[2,] Hanna Willems[3,] Annemariek Driessen[2,] Lisanne Vranken[4,] Joop van den Bergh[4,] Caroline Wyers[4,] [1]Viecuri Medisch Centrum , [2]NUTRIM School of Nutrition and Translational Research in Metabolism, Maastricht University, Netherlands, [3]Amsterdam UMC location University of Amsterdam, Internal Medicine and Geriatrics, Netherlands, [4]Department of Internal Medicine, VieCuri Medical Center, Netherlands

Physical capacity (PC) and physical activity (PA) are two associated, but distinctly separate domains of physical performance. Poor performance in these domains has been associated with an increased fall risk in older persons. Combined, PC and PA can be used to categorize physical performance into four quadrants according to the "can do, do do" framework. This cross-sectional study aims to use this framework to explore physical performance and patient characteristics including fall and fracture risk factors in patients aged >=50 years attending the fracture liaison service (FLS) for fracture risk evaluation. Physical performance of 400 fracture patients was assessed (mean age 64; female 70.8%). PC was measured by 6-minute-walking-test (6MWT) (can't do/can do) and PA by MOX accelerometer (don't do/do do) during 8 days of daily life. Following quadrants were defined based on predefined sex-specific cut-off scores for poor performance: 1."can't do, don't do"; 2."can do, don't do"; 3."can't do, do do"; 4."can do, do do". Correlation and odds ratios (ORs) between PC and PA measures were calculated and patient characteristics including fall and fracture risk factors were compared between groups. Patients performed as follows: 8.3% "can't do, don't do"; 3.0% "can do, don't do"; 19.3% "can't do, do do"; 69.5% "can do, do do". For the "can't do" group the OR for low PA was 9.76 (95%CI: 4.82-19.80), compared to the "can do" group. The "can't do, don't do" was older, had a higher proportions of osteoporosis and prevalent vertebral fractures compared to the "can do, do do" group. Moreover, both the "can't do, don't do" and "can't do, do do" group had lower physical performance on all functional tests, higher proportions of patients with fear of falling, and more patients used a walking aids, compared to the "can do, do do" group. This is the first application of the "can

do, do do" framework to explore fall and fracture risk factors among patients with a recent fracture. Of all FLS patients 20% "can't do", but "do do" while having a high prevalence of fall risk factors compared to patients that "can do, do do", which may indicate a group prone to fall. Subgroup identification following this concept provides additional insight on impaired physical performance of FLS patients and their fall and fracture risk factors and might prove useful for targeted interventions in the future.

Clinical Outcomes and Population Characteristics in Fibrodysplasia Ossificans Progressiva: A Systematic Literature Review *Hind Harrak[1], Amal Souttou[1], Xueqi Qu[2], Caitlin Knox[1]. [1]Regeneron Pharmaceuticals, Inc., United States. [2]Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, United States

Purpose: Despite efforts to better understand fibrodysplasia ossificans progressiva (FOP), a rare autosomal dominant disease characterized by progressive episodic multi-focal heterotopic ossification (HO), population characteristics and natural disease history are ill defined. This systematic literature review (SLR) assessed the current knowledge of FOP, including mortality, comorbidities, recommended management and medication use. HO formation frequency and patterns in the pediatric population were also assessed.Methods: We searched Pubmed, Embase, the Cochrane central register of controlled trials, the Trip database and NICE documents to retrieve relevant studies, restricted to humans but not by language. Studies were kept if they reported at least 1 of the following outcomes: mortality, comorbidity, medication-use pattern, standard of care, or HO in pediatric population. Clinical trials solely aiming to assess treatment of FOP were excluded to avoid potential disease-modifying effects. Two independent reviewers conducted the study selection. Data extraction was conducted by one investigator, and quality controlled by the second reviewer, using the appropriate tools by study design. The SLR was registered on Prospero (CRD42022366914).Results: Thirty-nine studies were selected. Publications were global, covering wide age groups. Study duration varied from 1 day to 33 years and sample size from 3 to 299 patients. Eight studies reported on mortality, and out of 62 reported deaths with recorded cause, 25 were due to cardiovascular or cardiorespiratory failure. Twenty-five publications included information on comorbidities, with eight studies reporting deafness and five studies reporting chronic pain as a comorbidity. The three most affected systems by order of magnitude were cardiovascular, respiratory, and skeletal. Twelve studies provided standard of care recommendations and drug utilization. Eight studies had data on pediatric HO formation.Conclusions: Despite the number of studies included in this SLR, there were important limitations: several studies used the same patient pool, lack of clear definition, outcomes, or follow-up periods. Re-use of the same patient pool meant that duplicate data cannot be ruled out, which inhibited the aggregation of the data or the estimation of background rates. Our SLR highlights the need for detailed information in published studies to allow for critical evaluation and summarization in SLRs, especially in rare diseases.

[8]Department of Molecular Endocrinology, Fujii Memorial Institute of Medical Sciences, Institute of Advanced Medical Sciences, Tokushima University, Japan. [9]Department of Internal Medicine, Kuma Hospital, Japan

Background: Fibroblast growth factor 23-related hypophosphatemic rickets/osteomalacia (FGF23-HR/HO) is a rare bone mineralization disorder characterized by high serum FGF23 and hypophosphatemia. X-linked hypophosphatemia (XLH) is the most common heritable cause, while tumor-induced osteomalacia (TIO) is a major acquired one. Due to the rarity of this disease, limited information is available regarding its treatment and prognosis. Objectives: To elucidate the clinical characteristics of XLH and TIO in Japan. Methods: A retrospective questionnaire survey of physicians belonging to the Japanese Society for Bone and Mineral Research was conducted for one year from September 2018 to identify patients diagnosed with FGF23-HR/HO. The clinical information of XLH and TIO patients was analyzed, including anthropometric data, symptoms, and laboratory data. Results: The study analyzed 104 patients (45 males and 59 females), of which 67 had XLH with confirmed PHEX mutations and 37 had TIO. Of the 67 XLH patients, 38 had a family history of the disease. Among the 40 adult patients with XLH (aXLH, age 19-72 years), 31 were diagnosed in childhood, indicating a significantly lower age of onset for XLH compared to TIO (age 32-87 years). aXLH showed significantly lower height standard deviation score (SDS) and weight-SDS, lower serum intact FGF23 (all under 200 pg/mL), and higher serum phosphate levels compared to TIO patients. Pediatric patients with XLH (pXLH, age 1.8-17 years) revealed a significantly higher prevalence of craniosynostosis and foot deformity, while aXLH had a higher prevalence of spinal ligament ossification, enthesopathy, nephrocalcinosis, and periodontitis. In contrast, in TIO, the prevalence of fracture, bone pain, joint pain, and muscle weakness was significantly higher. Regarding treatment, XLH patients received active vitamin D, phosphate, and burosumab in 62%, 47%, and 32% of cases, respectively, while TIO patients received these treatments in 73%, 38%, and 8% of cases, respectively. Tumor resection was performed in 68% of TIO patients. The utilization rate of burosumab and the dosage of alfacalcidol (μg/kg/day) were significantly higher in pXLH, followed by aXLH and TIO patients. Conclusion: aXLH patients exhibit more severe growth disturbance and may require careful prevention and management strategies for the characteristic ectopic calcifications. These findings may be helpful in improving the quality of medical care for this rare disease.

A qualitative study investigating the experiences of women living with pregnancy and lactation associated osteoporosis in the United Kingdom *Nataliya Gak[1], Ali Abbara[2], Judith Bubbear[3], Alexander Comninos[4], Richard Keen[3]. [1]Department of Rheumatology, Royal National Orthopaedic Hospital NHS Trust, Imperial College London , United Kingdom. [2]Department of Endocrinology, Imperial College London, United Kingdom. [3]Department of Rheumatology, Royal National Orthopaedic Hospital NHS Trust , United Kingdom. [4]Endocrine Bone Unit, Imperial College Healthcare NHS Trust, United Kingdom

Background: Pregnancy and lactation associated osteoporosis (PLO) is a rare and severe form of osteoporosis defined by a reduction in bone mineral density leading to fragility fractures during the last trimester of pregnancy or post-partum when lactating. Despite the severe physical and psychosocial consequences of fracturing around pregnancy, there are currently no data in this regard investigating patients with PLO in the United Kingdom. Objectives: To determine the impact of PLO on physical, emotional, and social wellbeing of women with PLO. Methods: 15 women (age range 32-60 years, mean 40 years) who attended specialist tertiary clinics in the UK, were recruited to take part in semi- structured interviews (duration from diagnosis to interview range 1-32 years, median 3 years). The in-

terviews were video recorded, transcribed verbatim and qualitative data was analysed using emergent coding and thematic analysis.Results: The main themes that emerged were: 1) lack of awareness about PLO in primary and secondary care leading to delays in diagnosis, misdiagnosis and incorrect management; 2) lack of physiotherapy and psychological support specific to PLO needs; 3) acute and chronic back pain impacting on mobility, ability to self-care and care for new-born, resulting in dependence on others (partners, parents, baby-sitters, friends); 4) grieving for the loss of motherhood, self-identity and life normality; 5) anxiety about further possible fractures and future pregnancies; 6) struggling to engaged in social activities important to wellbeing due to mobility issues, loss of self-confidence and emotional distress caused by the diagnosis of PLO.Conclusion: These data demonstrate the physical, and psychosocial impacts of PLO in women in the UK for the first time. They describe a noticeable lack of understanding about PLO and its management in the UK. Better awareness with faster diagnosis and subsequent timely treatment may partially alleviate some of the physical and psychosocial impacts. The themes identified suggest that a multidisciplinary approach with early the involvement of obstetricians, midwives, metabolic bone specialists, spinal surgeons, pain specialists, physiotherapists, and psychologists may better address the needs of women affected by PLO.

Real-World Characteristics and Disease History of Patients With X-Linked Hypophosphatemia Treated with Burosumab: A United States Claims Database Study *KATHRYN DAHIR[1], Heather Heerssen[2], Yang Zhao[2], Angie Dale[2], Ahmed Noman[3], Jeremy Kim[3], Zhiyi Li[2]. [1]Vanderbilt University Medical Center, [2]Kyowa Kirin, Inc., United States, [3]Komodo Health, United States

Purpose: X-linked hypophosphatemia (XLH) is a rare genetic disease characterized by chronic renal phosphate wasting. The clinical presentation typically begins in early childhood and progresses through adulthood. XLH is thus associated with lifetime accumulation of clinical morbidities. In 2018, burosumab became the first United States (US) Food and Drug Administration-approved therapy for treating the underlying pathophysiology of XLH. This study examined patient characteristics and disease history - including XLH-related morbidities, treatments, and procedures - among real-world patients with XLH initiating burosumab in the US.Methods: This retrospective cohort study used Komodo Health's Healthcare Map™, a real-world de-identified patient-level claims database. Included patients had >=1 claim for familial hypophosphatemia between 01/01/2015 and 06/30/2022 and >=1 claim for burosumab between 04/01/2018 and 06/30/2022 (index date was the date of first burosumab claim). The study period was the period prior to the index date and ranged from 1-7 years. Patient characteristics were measured at index while disease history was measured over the study period and stratified by age; all variables were evaluated descriptively. Results: Overall, 1,358 patients were included (mean age 23.5 +/- 19.1 years, 62% female, 41% from the southern US). Approximately half (53%) of XLH patients were <18 years of age at initiation of burosumab. Prior to receiving this treatment, patients had high levels of XLH-related morbidities, many of which appeared early and increased with age group (Figure). Most patients had received some form of conventional therapy for XLH during the study period, including high-dose calcitriol (66% of patients aged <18 years and 56% of patients >=18 years) and/or phosphate supplements (42% of patients aged <18 years and 44% of patients >=18 years), prior to burosumab. Opioid use was prevalent among XLH patients prior to burosumab treatment, and this increased with age (24% of patients aged <18 years and 51% of patients >=18 years). Physical therapy use was observed across all age groups (18% of patients aged <18 years and 40% of patients >=18 years).Conclusions: At the time of initiation of burosumab, approximately half of patients with XLH were <18 years of age and had already experienced a heavy and progressive disease burden. The prevalence of XLH-related morbidities increased with age.Sponsorship: Kyowa Kirin, Inc.

Figure. XLH-related morbidities experienced by patients with XLH prior to burosumab treatment

Association between work productivity and characteristics of adults with X-linked hypophosphatemia: an analysis of the XLH Disease Monitoring Program *Aliya Khan[1], Ben Johnson[2], Annabel Nixon[3], Jen Liu[3], Zhiyi Li[4], Alison Skrinar[5], Christy Yang[5], Angela Williams[2]. [1]McMaster University, Canada, [2]Kyowa Kirin International, United Kingdom, [3]Chilli Consultancy, United Kingdom, [4]Kyowa Kirin North America, United States, [5]Ultragenyx Pharmaceutical Inc, United States

Objective: X-linked hypophosphatemia (XLH) is a rare, progressive, phosphate wasting disorder that causes substantial musculoskeletal morbidities and functional impairment. The XLH Disease Monitoring Program (XLH-DMP; NCT03651505) is a prospective, 10-year, longitudinal, observational study of adults and children with XLH on or off any treatment. Our study examined the relationship between characteristics of adults with XLH and their work productivity, to understand the broader impact of the disease.Methods: Subjects in the XLH-DMP aged >=18 to <65 years at enrolment were included in the analysis, but those enrolled after 31 December 2019 were excluded to avoid confounding effects of the COVID-19 pandemic on work productivity. Using data collected at enrolment, relationships between work productivity and demographics, medical history, Western Ontario McMaster Universities Osteoarthritis Index (WOMAC®) scores, Patient-Reported Outcomes Measurement Information System (PROMIS) physical function score and the Timed Up and Go (TUG) assessment were evaluated using univariate analysis (ANOVA, chi-squared) to guide the selection of variables for multivariate analyses (multinomial logistic regression). Results: The analysis included 281 adults (75.4% female), with a mean (SD) age of 39.9 (12.3) years; 80.8% were from the USA, 8.5% from Brazil, 7.1% from Canada, and 3.6% from Chile; 53.4% were employed full-time, 15.3% employed part-time and 31.3% not employed. Subjects had undergone a mean (SD) of 3.9 (4.7) surgeries and had mean WOMAC scores of 32.5 (22.5) for pain, 43.3 (24.8) for stiffness and 29.1 (22.8) for physical function, and a mean PROMIS physical function T-score of 41.6 (8.8). Multivariate analysis identified number of surgeries and PROMIS physical function score as significantly associated with work status: subjects with fewer surgeries (odds ratio [OR] 0.88; 95% confidence intervals [CI] 0.82-0.95; p<0.01) and those with better PROMIS physical function scores (OR 1.09; 95% CI 1.02-1.16; p<0.01) were more likely to be in full-time employment compared with being unemployed.Conclusion: Full-time employment levels are low in adults of working age with XLH, suggesting that the disease has a substantial impact on work productivity. Patients' physical function and history of surgery are likely to influence work productivity.

SAT-499

Eagle syndrome: [18F]NaF PET/CT and in-depth tissue analysis *Ruben de Ruiter[1], Sanne Treurniet[1], Björn Busse[5], Jan Jaap Hendrickx[3], Berend Teunissen[4], Adriaan Lammertsma[4], Marelise Eekhoff[1], Felix Schmidt[5]. [1]Department of Endocrinology and Metabolism, Amsterdam University Medical Centers, Vrije Universiteit, Amsterdam Movement Sciences, Netherlands, [5]Department of Osteology and Biomechanics, University Medical Center Hamburg-Eppendorf, Germany, [3]Department of Otolaryngology, Head and Neck Surgery, Amsterdam University Medical Centers, Vrije Universiteit, Netherlands, [4]Department of Radiology and Nuclear Medicine, Amsterdam University Medical Centers, Vrije Universiteit, Netherlands, [5]Department of Osteology and Biomechanics, University Medical Center Hamburg-Eppendorf, Netherlands

Purpose: Eagle syndrome is a rare medical condition, characterized by elongation and calcification of the styloid process. Various theories have been proposed towards the etiology of this styloid calcification, varying from congenital elongation of the styloid process to metaplastic changes following a traumatic stimulus. To elucidate the pathophysiology of Eagle syndrome we performed [18F]NaF PET/CTs in 6 patients presenting with Eagle syndrome followed by detailed bone quality analysis after surgery.Methods: Six patients (age: 36 - 57 years old, men/women: 3/3) were included presenting with Eagle syndrome. Pre-operatively a [18F]NaF PET/CT was performed to evaluate active areas of bone formation, in particular in the stylohyoid region. The styloid process was surgically removed and further analyzed by micro-CT (?CT), quantitative backscattered electron imaging (qBEI) and histopathology including bone histomorphometry.Results: Four out of the six patients showed increased [18F]NaF uptake on the PET/CT scan at the base of the elongated styloid process. Histopathology of the biopsies revealed both cortical and trabecular bone tissue with bone marrow tissue present. Osteoid appeared at the tip in three out of six specimens, indicating the occurrence of longitudinal growth. Three specimens exhibited signs of past fractures (2/6 callus formation and 1/6 pseudoarthrosis). Volumteric tissue mineral density (vTMD) in the styloid processes was compatible with the mineralization of cranial, cortical bone as a control. Following ?CT analysis, qBEI measurements (CaMean, CaPeak, CaLow, CaHigh, StdDev) showed a large mineralization variability in the Eagle sample set significantly different from cortical controls.Discussion: Morphological analysis of the removed calcified tissue obtained from Eagle syndrome patients, revealed cortical and trabecular bone

with cartilage tissue. Growth of the styloid process appeared to be taking place at the tip. The variation in 18F-uptake uptake on the PET/CT may indicate that growth of the styloid process is not occurring at a fixed rate or is a relatively slow process. Elongation of the styloid process may be a result of mechanical forces produced by the stylohyoid ligament, which can also vary over time. Intense uptake on the PET/CT may be the result of a recent fracture as the styloid process appears to heal "normally" with callus formation.

[7]Ultragenyx Pharmaceutical Inc., United States. [9]Ultragenyx, United States. [9]Ultragenyx,

Setrusumab is a recombinant, fully human monoclonal antibody that selectively binds to and inhibits sclerostin, thereby increasing anabolic bone activity and decreasing bone resorption; setrusumab is in development for the treatment of osteogenesis imperfecta (OI). A Phase 2b study in adults with OI showed increases in bone formation, bone density and bone strength with setrusumab across OI Types I, III, and IV (ASTEROID; NCT03118570) and a pivotal Phase 2/3 study is ongoing to determine the effects of setrusumab on dose, efficacy and safety in pediatric and young adults with OI (Orbit; NCT05125809).This abstract describes the study design of Cosmic, an open-label, randomized, active-controlled, Phase 3 study of setrusumab compared with bisphosphonates in pediatric subjects 2 to <7 years of age with OI Types I, III or IV (NCT05768854). The primary objective is to evaluate the effect of setrusumab vs intravenous bisphosphonates (IV-BP) therapy on reduction in fracture rate, including morphometric vertebral fractures. Participants will receive either setrusumab or IV-BP for up to 24 months during an active-control period. All participants will then enter an extension period for a minimum of 12 months, with those initially assigned to IV-BP transitioning to setrusumab, if desired.The primary endpoint is the annualized rate of all radiographically-confirmed fractures, including morphometric vertebral fractures. Secondary endpoints include the annualized rate of radiographically-confirmed fractures, excluding morphometric vertebral fractures; change from baseline in POSNA-PODCI Sports/Physical Functioning and Pain/Comfort Subscale Scores; serum setrusumab concentration; and the subject incidence of TEAEs, SAEs, and AEs of special interest.Key inclusion criteria include a clinical diagnosis of OI Types I, III, or IV; a history of >=1 fracture in the past 12 months, >=2 fractures in the past 24 months, or >=1 femur, tibia, or humerus fracture in the past 24 months; and prior or current IV-BP. Exclusion criteria includes a history of skeletal malignancies, bone metastases or neural foraminal stenosis; clinical manifestations of Chiari malformation or basilar invagination; current uncontrolled concomitant diseases that may impact bone metabolism; any skeletal condition (other than OI) leading to bone deformity and/or increased risk of fractures; and cardiovascular disease.The Cosmic study is being initiated in the second quarter of 2023.

A PTH Receptor Inverse Agonist (PTH-IA) in Patients with Jansen's Metaphyseal Chondrodysplasia: Rationale and Design for a Phase 1/2 Clinical Trial *Smita Jha[2], Anisha Ninan[2], Rachel Gafni[4], Kelly Roszko[4], Carlos Ferreira[4], Richa Lomash[5], Rodica Stan[5], Elizabeth Ottinger[5], Thomas Gardella[6], Lee Weinstein[2], Harald Jueppner[6], Michael Collins[7]. [2]NIDDK, . [2]NIDDK, United States. [4]National Institutes of Health, United States. [4]National Institutes of Health, . [5]NCATS, United States. [6]Massachusetts General Hospital, United States. [7]NIDCR, United States

Jansen's Metaphyseal Chondrodysplasia (JMC) is a rare disease with ~30 patients currently identified worldwide. JMC is caused by germline, heterozygous gain-of-function pathogenic variants of the parathyroid hormone 1 receptor (PTH1R), the receptor for PTH and PTHrP that lead to its constitutive activation. Phenotypic features of JMC are heterogenous and include short-stature, scoliosis, fractures, bone pain, mineral-ion abnormalities (typically hypercalcemia and hypercalciuria despite low PTH), hypertension, nephrocalcinosis and chronic kidney diseases. There are currently no approved therapies for JMC. We previously demonstrated that PTH-IA, an inverse agonist at PTHR1 suppresses Jansen's PTH1R variant signaling in vitro and in vivo. We propose to evaluate the safety and efficacy of PTH-IA in a Phase 1/2 open-label, first-in-human, dose-escalating, safety and efficacy study. PTH-IA will be administered twice daily subcutaneously. Phase 1 will enroll at least one adult with JMC; Phase 2 will enroll up to five patients?3 years of age. Each phase is divided into three periods: baseline, dose-finding, and treatment (Figure 1). At baseline, patients will undergo blood and urine tests, imaging studies including 18F-NaF PET/CT, and biopsy of dysplastic bone tissue. During dose finding, the dose of PTH-IA will be escalated, and blood and urine sampled serially (for tests including calcium, phosphorus, PTH, PK, bone turnover markers and 1,25(OH)2 vitamin D). The optimal dose will be the minimum dose at which the mean of the two highest PTH values increases to 30-40 pg/mL (in patients with a baseline PTH ?20 pg/mL) in the absence of dose-limiting toxicity. In patients with a baseline PTH >20 pg/mL, the optimal dose will be the dose at which the mean of two highest PTH increases to 55-65 pg/mL. Patients will remain on their optimal dose for the duration of the treatment period (total drug exposure <=28 days) and obtain a second 18F-NaF PET/CT at end of the period. The primary and secondary endpoints of the study are: i) dose limiting toxicities and incidence, severity, seriousness, and causality of all treatment-emergent adverse events ii) pharmacokinetics iii) absolute levels and percentage change from baseline in serum PTH and fractional excretion of calcium iv) optimal dose range of PTH-IA v) change in overall and sentinel skeletal lesion metabolic activity and density on 18F-NaF PET/CT and vi) change in bone turnover markers. We anticipate that the results will inform our understanding of mineral-ion homeostasis and clarify the therapeutic potential of PTH-IA.

CALIBRATE: A Phase 3, Randomized, Open-Label Study Evaluating the Efficacy and Safety of Encaleret (CLTX-305) Compared to Standard of Care in Participants with Autosomal Dominant Hypocalcemia Type 1 [NCT05680818] *Michael Mannstadt[1], Lars Rejnmark[2], MARIA LUISA BRANDI[3], Keiichi Ozono[4], Peter Tebben[5], Arun Mathew[6], Mary Scott Roberts[7], Scott Adler[7], Rachel Gafni[8]. [1]Massachusetts General Hospital Harvard Medical School, United States. [2]Aarhus University Hospital, Denmark. [3]FONDAZIONE FIRMO, Italy. [4]Osaka University Graduate School of Medicine, Japan. [5]Mayo Clinic, United States. [6]BridgeBio Pharma, . [7]Calcilytix, United States. [8]National Institutes of Health, United States

Autosomal dominant hypocalcemia type 1 (ADH1), caused by pathogenic gain-of-function calcium-sensing receptor gene (CASR) variants, is characterized by low parathyroid hormone (PTH) levels, hypocalcemia, hypercalciuria, hyperphosphatemia and hypomagnesemia. Current standard-of-care (SoC) (calcium and active vitamin D)?worsens hypercalciuria, which may result in renal complications.Encaleret is an oral calcilytic that functions as a negative allosteric modulator of the calcium-sensing receptor and is under investigation as a potential treatment for ADH1. A phase 2b study [NCT04581629] in 13 adults with ADH1 showed that encaleret led to sustained normalization in mean blood levels of intact PTH, albumin-corrected calcium (cCa), phosphorus, magnesium and 24-hr urine calcium (UCa) excretion over 24 weeks compared with baseline. Encaleret was well-tolerated with no serious adverse events reported.CALIBRATE is a global phase 3 study designed to evaluate the efficacy and safety of encaleret compared to SoC in approximately 60 participants with ADH1. Eligible participants >=16 years-old with ADH1 will enter a

screening period with a SoC optimization and maintenance period (Period 1 [P1]) prior to randomization. Participants will then be randomized 2:1 (encaleret:SoC) into a 20-week dose titration period (Period 2). Doses of encaleret or SoC will be titrated to achieve target cCa concentrations while minimizing UCa excretion. Participants will then enter a 4-week maintenance period (Period 3 [P3]) where doses of encaleret or SoC are intended to be fixed. The primary efficacy endpoint is a composite endpoint: a) cCa within 8.3-10.7 mg/dL AND b) 24-hr UCa within reference range (men: < 300 mg/day; women: < 250 mg/day). Participants who meet both criteria will be considered responders. The primary analysis will be a within-patient comparison of the proportion of responders at the completion of P3 (encaleret) with the proportion of responders at the end of P1 (SoC). Key secondary endpoints include between-treatment arm comparisons as well as the evaluation of mineral homeostasis parameters, renal health, bone health, and patient-reported outcomes. Following completion of P3, eligible participants will have the option to enter a long-term extension (LTE) period with continued access to encaleret.CALIBRATE is recruiting study participants in 12 countries: USA, Canada, Brazil, Netherlands, Belgium, Denmark, France, Italy, Czech Republic, Taiwan, Australia, and Japan.

Health Assessments of Normotopic Bone in Individuals with Fibrodysplasia Ossificans Progressiva *Robert J. Pignolo[1], Mona Al Mukaddam[2], Geneviève Baujat[3], Angela M. Cheung[4], Carmen De Cunto[5], Edward Hsiao[6], Richard Keen[7], Rose Marino[8], Andrew Strahs[8], Frederick S. Kaplan[2]. [1]Mayo Clinic, United States. [2]University of Pennsylvania, United States. [3]Université Paris Cité, France. [4]University of Toronto, Canada. [5]Hospital Italiano de Buenos Aires, Argentina. [6]University of California San Francisco, United States. [7]Royal National Orthopaedic Hospital, United Kingdom. [8]Ipsen, United States

Purpose: Fibrodysplasia ossificans progressiva (FOP) is an ultra-rare, genetic disorder characterized by cumulative and irreversible heterotopic ossification (HO) in soft and connective tissues. HO progressively restricts movement, leading to cumulative disability and a shortened life expectancy in individuals with FOP. While FOP has been shown to impact bone health, limited studies have investigated normotopic bone health parameters. Here, bone mineral content (BMC), bone mineral density (BMD), and bone strength of the normotopic skeleton were evaluated in individuals with FOP enrolled in a non-interventional natural history study (NHS; NCT02322255). Methods: Individuals with FOP aged <=65 years, with a confirmed ACVR1R206H mutation, were enrolled (N=114) in the NHS. During the study, low-dose whole-body computed tomography (WBCT; excluding head) was performed to assess HO. The accuracy of routine bone assessments using standard techniques in individuals with FOP is limited due to excess bone formation and ankyloses throughout the skeleton. Therefore, WBCT scans obtained at Baseline were evaluated post hoc using a novel computational method, biomechanical computed tomography (BCT; VirtuOst® software), to calculate BMC, BMD, and bone strength at the spine (L1, L2, or adjacent vertebrae) in individuals with FOP aged <18 and >=18 years. BMD z-scores were calculated where normative data were available. Results: BMC, BMD, and bone strength at Baseline are presented (Table). Mean (standard deviation) BMD z-score for individuals aged >=18 years was ?3.0 (1.55; n=33) at Baseline, suggesting that BMD may be lower in adults with FOP compared with unaffected individuals. Normative BMD data were not available for individuals aged <18 years. Conclusion: This is the first time that BCT has been used to evaluate BMC, BMD, and bone strength from WBCT scans in individuals with FOP. BCT could increase our understanding of bone health in individuals with FOP; however, further studies are required to understand the reproducibility of these measurements and their clinical significance for fracture risk and other comorbidities.

Table: Mean (SD) computationally estimated BMC, BMD, and bone strength at Baseline.

	<18 years (n=61)	≥18 years (n=40)
Vertebral body BMC (g)	3.8 (1.96)	5.3 (1.51)
Mid-vertebral BMD (mg/cm^3)	112.1 (31.13)	91.2 (39.11)
Vertebral strength (N)	4,276.1 (1,508.69)	4,872.4 (1,591.22)

BMC: bone mineral content; BMD: bone mineral density; SD: standard deviation.

Real-world utilization of burosumab in patients with tumor-induced osteomalacia: data from a French national registry *JULIEN PACCOU[1], Guillaume Couture[2], Pascale Guillot[3], Nadia Mehsen-Cetre[4], Caroline Morizot[5]. [1]Lille University Hospital, France. [2]Rheumatology Department, CHU de Toulouse, France. [3]Rheumatology Department, CHU de Nantes, France. [4]Rheumatology Department, CHU de Bordeaux, France. [5]Rheumatology Department, CHU de Nancy, France

Tumor-induced osteomalacia (TIO) is a rare paraneoplastic syndrome due to a phosphaturic tumor, which overproduces Fibroblast Growth Factor 23 (FGF-23), causing hyperphosphaturia, hypophosphatemia, low 1,25(OH)2D and osteomalacia. Surgical complete resection is the recommended treatment choice and the standard of care but some tumors cannot be found and others cannot be removed resulting in a persistence or recurrence of the disease. In those difficult situations, burosumab, a fully human monoclonal antibody targeted against FGF-23, is a treatment option. An early access to burosumab, has been set up for TIO patients in France since July 2022. Before that, Kyowa Kirin France had provided access to burosumab at no cost on compassionate grounds for a few number of patients. We retrospectively evaluated patients with definite diagnosis of TIO referred to tertiary Rheumatology Centers between July 2022 and March 2023, investigating clinical and biochemical characteristics before burosumab initiation as well as disease outcome following 2 months of treatment. We included 6 patients: 4 (66.7%) were females, mean age (+/- standard deviation) was 54 +/- 8 years, and mean weight was 74.7 +/- 23.3 kg. Tumor localizations: lower limbs (n=1), lower limbs and chest (n=2), head and neck (n=1), spinal canal (n=1), no localization (n=1). Among these 6 patients, 3 were already under burosumab before July 2022 due to compassionate use. Biochemical data were: serum phosphorus 0.7 +/- 0.3 mmol/L (Reference Range: 0.8-1.5), PTH 65.6 +/- 48.0 ng/mL (RR: 12-50), intact FGF-23, 279.3 +/- 114.4 pg/mL (RR: 25-45). On a scale of 1-100, mean pain was 43 +/- 32 before burosumab initiation (starting dosage 0.5 +/- 0.3 mg/kg rounded to the nearest 10 mg every 4 weeks (20 to 70 mg/4w)). Evaluation of 5 patients was available after 2 months of treatment. Mean pain was 38 +/- 22, mean phosphorus 0.9 +/- 0.4 mmol/L, and burosumab dosage 0.6 +/- 0.3 mg/kg every 4 weeks (30 to 70 mg/4w)). Burosumab was generally well tolerated. Those preliminary findings following burosumab early access for TIO patients in France support benefits in terms of efficacy, safety and ease of treatment. For patients not eligible or refractory to surgery, burosumab appears to be a promising option.

SAT-515

Real-life Experience of Burosumab in Two Adult Sisters with X-linked Hypophosphatemia (XLH) from Argentina *Laura Maria Schiro[1], Evangelina Giacoia[1]. [1]Hospital Nacional Prof A Posadas, Argentina

The aim of this presentation is to show the clinical, biochemical and quality of life evolution of two sisters with XLH, under treatment with burosumab.Since the approval of fibroblast growth factor 23 (FGF-23) monoclonal antibody, burosumab, as a treatment for XLH, there are few real-life reported cases of adult patients on the drug. These two sisters were diagnosed in adulthood, having gone through multiple surgical interventions, with erroneous diagnoses. In this way they accumulated sequelae of the disease.At first consultation in 2015, VS, 55 years old, height 4'00", weight 132,3 Lb, SJ, 60 years old, height 4'39",weight 119 Lb. Both suffer from musculoskeletal pain and stiffness, short stature, bowed lower limbs, fractures and pseudofractures due to osteomalacia, and enthesopathy. The variant ChrX:22,196,490 CAG>C was identified in heterozygosity. Since diagnosis, they were replaced with conventional treatment, but they had never achieved proper phosphorus levels, remaining between 1,8 and 2,1 mg/dl (RR2,5-4,5), and showed no clinical or radiographic improvement, leading to lack of compliance. Until the possibility of treatment with burosumab arose, which was initiated in April 2021, at a dose of 50 mg every 4 weeks. After two years of treatment, the phosphorus reached an average between 2.7 and 3.2 mg/dl, in addition to a clear radiological improvement, since it prevented the development of osteomalacia and pseudofractures, prevented the appearance of dental complications and improved the consolidation of previous fractures. The assessment of quality of life using the WOMAC scale was not able to show significant changes in these patients. Depression, which often accompanies chronic diseases, can significantly impact the individual's perception of their quality of life, making it challenging to evaluate the overall effectiveness of the treatment. Regarding the adverse effects, one of the sisters presented vertigo that disappeared after a few weeks.In conclusion, this real life experience highlights the promising efficacy and safety of this new therapy in adult patients with XLH. It is important to highlight that the normal values of phosphatemia were maintained throughout the treatment. Assessing quality of life in individuals with XLH requires a comprehensive approach that includes patient-reported outcomes, biochemistry, clinical evaluations, and monitoring of both physical and mental health parameters.

Novel Clinical and Molecular Evidence in CYP26B1-Related Disorder *Karina da Costa Silveira[1], Inara Chacon Fonseca[2], Connor Oborn[1], Parker Wengryn[1], Alexander Beke[1], Carrie-Lynn Soltys[1], Oswaldo Artigalas[3], Eric Campos[4], Denise Cavalcanti[5], Peter Kannu[1]. [1]Department of Medical Genetics, University of Alberta, Canada. [2]Clinical Genetics, Durham Region Cancer Centre, Lakeridge Health Oshawa, Canada. [5]Skeletal Dysplasia Group, University of Campinas, Brazil

Introduction: CYP26B1, a P450 cytochrome family member, metabolizes retinoic acid (RA) in the developing embryo to control RA levels. So far, a few individuals with CYP26B1 variants featuring mild to lethal phenotypes have been reported. Here we report two families with CYP26B1-related disorder and describe the functional study of novel pathogenic variants in CYP26B1.Methods: Research-based exome sequencing was performed in family 1 and phenotype-driven Sanger sequencing in family 2. A minigene assay assessed splicing defects. Using a CYP26B1 expression vector (construct), luciferase (DLR) assay analyzed the enzymatic activity of mutant constructs after adding exogenous RA; immunofluorescence (IF) determined if mutant constructs were localized in the endoplasmic reticulum (ER).Results: Siblings from family 1 (11yo and 15yo) present a mild skeletal phenotype including brachycephaly without craniosynostosis, distinctive facial features, arachnodactyly, reduced radioulnar joint movement, conductive hearing loss, and a learning disability. CYP26B1 compound heterozygous variants were identified: p.Pro118Leu; p.Arg234Gln. The stillborn fetus from family 2 presents a lethal phenotype with spina bifida occulta, hydrocephalus, poor skeletal mineralization, joint synostosis, limb defects, and a homozygous point variant in CYP26B1. Minigene assay analysis shows this variant creates an in-frame deletion by introducing a new splice site which excludes part of exon 5 (p.Val361_Asp382del).DLR reveals that the p.Val361_Asp382del variant results in a significantly reduced ability to metabolize exogenous RA (˜3.5 fold decrease compared to the wild-type). The two other variants cause a partial loss of activity with a 1.7 (p.Pro118Leu) and 2.3 (p.Arg234Gln) fold decrease. IF suggests that the CYP26B1 mutant constructs are still localized in the ER.Conclusions: We report here two additional families with pathogenic variants in CYP26B1 including the very first description of a splicing variant causing a lethal phenotype. The splicing variant in family 2 led to a partial deletion of the protein drastically affecting function (but not protein folding) and creating the most severe phenotype reported. The phenotype in family 1 was much milder than what has been previously reported. Our report adds to the genotypic and phenotypic spectrum seen in CYP26B1-related skeletal dysplasia. A complete review of the CYP26B1 mutation phenotype is described in Fig 1.

[9]Amsterdam UMC, location VU University Medical Center, Amsterdam, The Netherlands, Netherlands

Background: Fibrodysplasia Ossificans Progressiva (FOP) is an autosomal dominant, invalidating disorder marked by severe heterotopic ossifications (HO), severe ankylosis and early death. There are currently no approved treatments in the world except Canada. AZD0530 (saracatinib) was identified by our team as a potent inhibitor of the ALK2-kinase which, through a R206H mutation, causes this rare bone disease. AZD0530 was effective in FOP mouse models. The purpose of this study is to investigate the repositioning of AZD0530, originally designed for ovarian cancer treatment, to treat patients with FOP. This study is funded by the Innovative Medicines Initiative and supported by IFOPA.Methods: The Saracatinib Trial to Prevent FOP (STOPFOP) is a phase 2a, multicentre, 6-month double blind randomized controlled trial of AZD0530 versus placebo, followed by a 12 month trial comparing open-label extended AZD0530 treatment with control data from a previous trial. Due to COVID the study is delayed, but presently we are including 16 otherwise healthy FOP patients, aged 18-65 years, with the classic FOP mutation (R206H). Endpoints are objective change in heterotopic bone volume measured by low-dose whole-body computer tomography, [18F] NaF PET activity and patient reported outcome measures such as the FOP-IADL questionnaire.Discussion: Drug repositioning - using existing, previously researched but unapproved drugs for the treatment of a different disease - is especially useful in rare diseases with limited study populations. It represents an ideal solution for limiting risks in early clinical studies. Using existing pre-clinical and clinical knowledge may also allow more affordable pricing once an indication is approved. With positive study outcome, AZD0530 may provide a rapidly translatable therapy for FOP due to the availability of extensive safety data from over 600 patients in more than 28 registered clinical trials using AZD0530. At the time of writing, 5 patients have already completed the study and all of them elected to continue the medication in an extended study phase, waiting for more results to be analysed once the study is complete.

Background: BMP signaling is critical for normal gut development and function. Fibrodysplasia ossificans progressiva (FOP) is a severe genetic condition that leads to inflammatory flare-ups and heterotopic ossification. 95-98% of patients with FOP show a highly recurrent ACVR1R206H mutation, resulting in increased BMP signaling and abnormal response to Activin A. Patients exhibit a surprising spectrum of bone formation and functional loss, suggesting environmental variables may contribute to phenotypic variability. Patients also report multiple gastrointestinal (GI) symptoms like food selectivity, intermittent bloating, and nausea/vomiting. We previously showed that patients with FOP have significant increases in their clinical and molecular inflammatory responses. We hypothesize that patients with FOP may have microbiota-related inflammatory drivers that contribute to their disease progression.Objective: We assess baseline GI symptoms, and characterize and quantify the gut microbiome in FOP patients vs. siblings living in the same household.Methods: Seven patients with FOP and seven siblings were enrolled and completed surveys on their food preferences, eating habits, and GI symptoms. Shotgun metagenomic sequencing was performed on all stool samples at enrollment (baseline, n=7 pairs) and at one-year follow-up (n=6 pairs).Results: Patients with FOP had significantly more emesis (p=0.01) and were more likely to avoid food requiring chewing (p=0.02). Microbiome analysis at baseline revealed that patients with FOP had significantly lower microbial diversity at the phylum level in community composition (p=0.04) and richness (p=0.03). We detected a higher abundance of Firmicutes and lower abundance of Bacteroidetes (p=0.026) in patients with FOP. Notably, a higher Firmicutes:Bacteroidetes ratio is reportedly related to gut dysbiosis. FOP patients also exhibited a higher abundance of Candidatus Saccharibacteria (p=0.07), which has been associated with inflammatory mucosal diseases, such as inflammatory bowel disease. Conclusion: Patients with FOP show GI symptoms related to their FOP disease manifestations of spinal/esophageal curvatures and jaw ankylosis. Gut microbiomes in patients with FOP showed differences in bacterial composition. Further evaluation is needed to identify if these changes in the microbiome are associated with FOP flare activity or inflammatory status, and if manipulating the microbiome impacts the disease course of patients with FOP.

Clinical and treatment characteristics of pediatric and adult patients with familial hypophosphatemia compared with demographically matched controls *Zhiyi Li[1], Elizabeth H. Marchlewicz[2], Danae Black[2], Hana Schwartz[2], Yang Zhao[3], Erik Imel[4], Nicole Princic[2]. [1]Kyowa Kirin, United States. [2]Merative, United States. [3], United States. [4]Indiana University School of Medicine, United States

Purpose: Familial hypophosphatemia (FH) is characterized by renal phosphate wasting, rickets, osteomalacia and other musculoskeletal consequences. Understanding of disease progression by age of patients with FH is limited. This study examined the clinical and treatment characteristics of patients with FH across age groups, compared to demographically matched non-FH control patients.Methods: Patients from Merative® MarketScan® Commercial and Medicare claims databases with >1 diagnosis code for FH (ICD10=E83.31) between 1/1/2018-12/31/2021 were included if they had 12 months of continuous enrollment pre- and post-index. Patients treated with burosumab during the study period were excluded. The index date was defined as the date of first FH diagnosis code. FH patients were demographically matched 1:3 to non-FH control patients from MarketScan databases based on age, sex, geographic region, payer, and index year and were stratified by age (0-11, 12-17, 18-29, 30-39, 40-49, 50-64, 65+ years). Clinical and treatment characteristics were assessed in the 12-month follow-up period.Results: Matched FH patients (n=570) and controls (n=1,710) were 57.0% female and had a mean age of 47 years; pediatric patients comprised 10.4% of included FH cases. The most common clinical characteristics associated with FH differed by age: for ages 0-11 years, delayed growth/walking (26.7% FH vs. 0.0% controls), lower limb deformity (26.7% vs. 0.0%), and rickets (20.0% vs. 0.0%); for ages 30-39 years, arthralgia (22.9% vs. 5.7%), kidney disease (21.4% vs. 0.5%) and fractures (11.4% vs. 0.5%); and for ages 65+ years, kidney disease (57.1% vs. 9.5%), osteoarthritis (39.0% vs. 15.2%), and arthralgia (36.4% vs. 16.0%) (all P<0.001). Charlson Comorbidity Index was significantly higher among FH patients and increased with age (0-11 years: 1.1 vs. 0.1; 65+ years: 4.0 vs. 0.6, both P<0.001). Calcitriol (16.7% vs. 1.5%) and oral phosphate supplements (97.9% vs. 0.0%) were prescribed to more FH patients than controls (both P<0.001). Laboratory tests (71.9% vs. 11.6%), physical therapy (31.8% vs. 8.9%), and use of a wheelchair or other walking assistance device (9.3% vs. 0.9%) were more common among FH patients than controls (all P<0.001).Conclusions: Among FH patients, compared to non-FH control patients, the clinical characteristics of the disease are more frequent even among children and young adults and increase with age, suggesting a progressive accumulative disease.

ENPP1 enzyme replacement therapy improves brain calcification but does not rescue skeletal phenotype in a mouse model for craniometaphyseal dysplasia *Ernst Reichenberger[1], Kevin O'Brien[5], Ayano Hatori[1], Thomas Carpenter[3], Koen van de Wetering[4], Lisa Flaman[5], Jennifer Howe[5], Daniel Ortiz[5], Yves Sabbagh[5], I-Ping Chen[1]. [1]University of Connecticut Health, United States. [5]Inozyme Pharma, . [3]Yale University School of Medicine, United States. [4]Thomas Jefferson University, United States. [5]Inozyme Pharma, United States

Craniometaphyseal dysplasia (CMD), a rare genetic bone disorder, is characterized by progressive thickening of craniofacial bones and flared metaphyses of long bones. Patients with CMD often suffer from obstruction of neural foramina and neurological symptoms, such as facial palsy, blindness, deafness, or severe headache. Mutations in ANKH (mouse ortholog ANK), a transporter for small molecules such as citrate and ATP, have been identified for autosomal dominant form of CMD. Knock-in (KI) mice carrying an ANKF377del mutation (AnkKI/KI) replicate many features of human CMD. Mutant ANK protein is rapidly degraded and pyrophosphate (PPi) levels in plasma and bone are significantly reduced in AnkKI/KI mice. PPi is a potent inhibitor of mineralization. To examine the extent to which restoration of circulating PPi levels can prevent the development of a CMD-like phenotype, we treated AnkKI/KI mice with the human recombinant ENPP1-Fc protein IMA2a. ENPP1 is an enzyme that hydrolyzes ATP into AMP and PPi. Male and female Ank+/+ and AnkKI/KI mice (n>=6 per group) were subcutaneously injected with IMA2a (5 mg/kg) or vehicle once a week for 13 weeks, starting at the age of 1 week. PPi and ENPP1 activity levels in plasma were determined at the end point. ENPP1 activity was significantly increased in AnkKI/KI mice injected with IMA2a (Vehicle / IMA2a: 28.15+/-1.65 / 482.7+/-331.2 mOD/minute; p<0.01), which resulted in the successful restoration of plasma PPi levels (Ank+/+ / AnkKI/KI vehicle treatment / AnkKI/KI IMA2a: 0.94+/-0.5 / 0.43+/-0.2 / 1.29+/-0.8 ?M; p<0.01). We examined the skeletal phenotype by Faxitron and ?CT. IMA2a treatment of AnkKI/KI mice did not significantly correct CMD features in femurs, mandibles, and skulls, including the abnormal shape of femurs, increased cortical porosity, hyperostotic mandibles, or narrowed foramina magnum. Calcified nodules were noted in the brain stem of AnkKI/KI mice by ?CT. Interestingly, treatment of AnkKI/KI mice with IMA2a significantly reduced the volume of calcified nodules found in the brain. Brain calcification has not been reported in CMD patients and the extent to which it can induce neurological dysfunction in CMD mice or patients remains unknown. Our data demonstrate that IMA2a is sufficient to restore plasma PPi levels and reduce brain stem calcification but does not rescue the skeletal abnormalities in AnkKI/KI mice in this treatment regimen.

Prrx1Cre-Alplfl/- (PAKO) Mice, a Model to Study Adult HPP Metabolic Phenotypes *VICTORIA DEMAMBRO[1], Jennifer Daruszka[1], Samantha Costa[2], Jose Luis Millan[3], Michael Whyte[4], Anyonya Guntur[1], Dr. Clifford ROsen[5]. [1]MaineHealth Institute for Research, United States. [2]MaineHealth Institute for Research , United States. [3]Sanford Burnham Prebys, United States. [4]Shriners Hospital for Children, United States. [5]Maine Medical Center, United States

Hypophosphatasia (HPP) is caused by loss-of-function mutations in the tissue-nonspecific alkaline phosphatase (TNAP) gene (ALPL) resulting in rickets, bone fragility, muscle weakness and lean body mass when severe in children. Adult HPP has broad expressitivity ranging from simple dental abnormalities to fractures, osteomalacia, chronic muscle weakness/pain as well as chronic fatigue with an estimated carrier prevalence of 1/300. We have reported on the role of TNAP in adipogenesis and mitochondrial function utilizing an Alplko model. Alpl-/- pups exhibited decreased fat mass, adipogenesis, lipid accumulation and mitochondrial function. However, Alpl-/- pups die by postnatal D21 preventing study of these changes into adulthood. We next reported on Prrx1Cre-Alplflfl (Crefl/fl) strain as a model of adult HPP. Prrx1 is highly expressed in the limb bud mesenchyme thus targeting long bones, muscle and the inguinal fat depot (IWAT). Crefl/fl mice exhibited classic bone HPP phenotypes, a 50% reduction in serum TNAP, reduced BMAT and lean mass. Differentiated Crefl/fl BMSCs exhibited no mineralization as well as reduced adipogenesis and mitochondrial function in vitro. However, no significant differences were noted in Crefl/fl IWAT weights, adipocyte size and in vitro adipogenesis despite a 70% decrease in Alpl expression vs. controls. We then hypothesized that TNAP endogenous levels may be affecting the adipogenic phenotype as Prrx1 is highly expressed in IWAT. To test this premise and reduce TNAP levels further we created a Prrx1Cre-Alplflfl X Alpl+/- (PAKO) strain by introducing a null allele into the PrrxCre-Alplflfl colony. Here we report that Crefl/- mice have a 75% reduction in serum TNAP vs. +/f controls coupled with reduced IWAT weight, adipocyte size and BMAT. Interestingly, Crefl/- mice had significantly reduced energy expenditure (EE) vs. controls coupled with reduced running wheel activity and speed. No significant differences were noted in resting EE. However, EE during periods of increased activity was significantly reduced. ANCOVA analysis revealed no significant covariance between body composition, wheel activity or speed with the reduced EE observed in the Crefl/- mice. We surmise that the reduced wheel activity and speed maybe indicative of muscle wasting and fatigue phenotypes. Our data suggest that the PAKO mice are a good model for adult HPP allowing the study of adipogenesis, chronic muscle wasting and fatigue phenotypes with age.

Role of fibroblast activation protein in fibrous dysplasia *Luis Fernandez De Castro Diaz[1], Zachary Michel[2], Layne Raborn[2], Alison Boyce[3]. [1]NIDCR, United States. [2]NIDCR (NIH), United States. [3]National Institutes of Health, United States

Fibrous dysplasia (FD) is a mosaic skeletal disorder arising from de novo activating GNAS mutations during embryogenesis, resulting in expansile fibro-osseous lesions and leading to fractures, pain, and disability. FD tissue is characterized by the replacement of normal bone and marrow by fibrous tissue containing varying amounts of curvilinear trabeculae of poorly mineralized hypercellular woven bone.Fibroblast activation protein (FAP) is a membrane-bound serine protease originally identified in carcinoma-associated fibroblasts (CAFs) in the stroma of most solid tumors. It is associated with tissue remodeling, and growing evidence suggests it plays a role in fibrotic and inflammatory diseases. FAP inhibition was developed for cancer treatment but has not yielded sufficient therapeutic outcomes. However, since FAP is widely expressed by CAFs, a radiolabeled FAP inhibitor has demonstrated to be an effective pan-tumoral tracer, suggesting its potential application for FD nuclear imaging. Moreover, FAP can be detected in serum, and it correlates with disease burden in several disorders, so it could serve as a biomarker in FD. Lastly, due to the high specificity of FAP proteolytic target peptide sequence, and its expression generally confined to fibrotic lesioned tissue, FAP represents a good target candidate for local pro-drug activation, by which a drug coupled to an inactivating peptide can be locally activated upon FAP-mediated cleavage. FD, as a mosaic disease, could significantly benefit from such therapeutic approach, to avoid off target effects of systemically administered drugs.In this study, we measured the expression of FAP in human and mouse FD BMSCs, as well as in tissue treated or not with anti-RANKL therapy. We also measured FAP concentration in FD patient serum and healthy volunteers. We found that (1) in mouse BMSC cultures, expression of the FD-causing G?sR201C resulted in a 2-fold increase of FAP release to the media; (2) cultured human FD BMSCs overexpress FAP in comparison to WT BMSCs; (3) FAP is increased in FD tissue in comparison to normal bone in mice, and decreases with anti-RANKL in both mice and humans; and (4) plasma levels of circulating FAP in FD patients are higher than in healthy volunteers, and it correlates with disease burden.These data support the potential of FAP as a biomarker and imaging radiotracer in FD and open the notion of this protease as a pro-drug activation target in FD.

Effects of Voxelotor Analog GBT1118 on Bone in Sickle Cell Disease Mice *Liping Xiao[1], Wei He[1], Marja Marie Hurley[2]. [1]UConn Health, United States. [2]UCONN Health School of Medicine, United States

Voxelotor is a sickle hemoglobin (HbS) polymerization inhibitor and has been approved by the FDA for the treatment of hemolytic anemia in sickle cell disease (SCD). Since bone loss is common in SCD, we assessed the effect of GBT1118, an analog of voxelotor on bone in SCD. Four months old female healthy control (Ctrl) and Townes SCD mice were fed with control chow (Teklad 2020 Diet, Veh) or GBT1118 chow (Teklad 2020 Diet with 4 g/kg GBT1118) for 2 months. Dual-energy X-ray absorptiometry analysis showed no significant effect of GBT1118 on bone mineral density. However, micro computed-tomography (uCT) analysis showed that GBT1118 significantly increased femur metaphyseal trabecular thickness (Tb.Th) and decreased trabecular spacing (Tb.Sp) in SCD mice. GBT1118 enhanced bone volume fraction (BV/TV) and trabecular number (Tb.N) in SCD mice, however these changes were not significant. Mid-diaphyseal uCT showed that the enlarged marrow area (Ma.Ar) in SCD mice was reduced with GBT1118 and the drug reversed the decline caused by SCD in cortical area/total area (Ct.Ar/Tt/Ar). Cortical thickness (Ct.Th) was significantly lower in SCD-Veh group vs. Ctrl-Veh, there was a trend increase with GBT1118 treatment. GBT1118 did not alter Tt.Ar or Ct.Ar in SCD mice. There was no difference in serum calcium, phosphate among groups. GBT1118 did not alter serum parathyroid hormone or 1,25 dihydroxyvitamin D level in SCD mice. Serum bone turnover markers Osteocalcin, P1NP, and CTX-1 were not altered by GBT1118 in SCD mice. Von Kossa staining showed the decreased mineralized trabecular number in SCD mice was rescued by GBT1118 (Fig.1A). Bone histomorphometry (Fig.1B-H) showed that there was a significantly decreased mineral apposition rate (MAR), bone formation rate (BRF) and inter-label thickness (Ir.LTh) in SCD-Veh group vs. Ctrl-Veh, which was rescued with GBT1118. Mineralization surface/bone surface (MS/BS) was lower in SCD-Veh vs. Ctrl-Veh, with no rescue by GBT1118. Osteoclast surface/bone surface (Oc.S/BS) and osteoclast number/bone surface (N.Oc/BS) were significantly higher in SCD-Veh group vs. Ctrl-Veh, which was reduced with GBT1118. qPCR analysis of whole tibia showed that GBT1118 inhibits Sost and Trap mRNA expression in SCD mice. We conclude that these are promising results that GBT1118 might be beneficial in SCD-related bone pathology but treating the mice with higher doses of the drug or for longer periods of time at the current dose may be necessary.

Broad Spectrum Antibiotic Treatment of PDGFR?-cre/ACVR1R206H FOP Mice Improves Survival and Decreases Chronic Heterotopic Ossification *Liam Lam[1], Camille Fang[7], Ariane Zamarioli[3], Aditi Sharma[4], JESSICA PIERCE[5], Michael Hohl[6], Daniel Perrien[6], Edward Hsiao[7]. [1]UCSF, United States. [7]University of California, San Francisco, . [3]Department of Orthopedics and Anesthesiology, Ribeirao Preto Medical School, University of Sao Paulo, Brazil., Brazil. [4]UC San Francisco, . [5]Emory University School of Medicine, United States. [6]Emory University, United States. [7]University of California, San Francisco, United States

Background: Fibrodysplasia ossificans Progressiva (FOP) is a highly penetrant genetic disease that leads to heterotopic ossification (HO) of skeletal muscle due to inflammatory flares caused by a highly recurrent ACVR1R206H mutation that causes Activin A to be misinterpreted as a bone morphogenetic protein (BMP) signal. We previously found that patients with FOP may have alterations in their gut microbiota and that ablation of microbiota reduces injury-induced HO in FOP mice. Pdgfra-cre/Acvr1R206H mice expressing Alk2R206H in fibro-adipoprogenitors spontaneously develop HO resembling that of human patients, leading to reduced muscle function, loss of mobility, and death by 9 weeks old. Here, we tested the ability of broad-spectrum antibiotic ablation of the microbiome to reduce spontaneous, non-injury-induced, HO and improve survival in Pdgfra-cre/Acvr1R206H FOP mice.Methods: At weaning, FOP mice were assigned to ABX or No ABX groups (n=12 each). Mice were given standard drinking water (No ABX) or water containing an established antibiotic cocktail (1.0 g/L Ampicillin, 0.5 g/L Vancomycin, 0.5 g/L Metronidazole,

and 0.5 g/L Neomycin) (ABX) to deplete the microbiota from weaning. Mouse mortality was determined using humane endpoints defined by UCSF-IACUC as >15% weight loss, moribund, or death. HO volume was measured by microCT.Results: Kaplan-Meier curve analysis showed that ABX FOP mice survived longer than No ABX FOP mice (Median odds of survival 54.5 days vs. 41 days, p = 0.048). ABX Wean FOP mice also recovered their body weight, returning to similar levels as WT mice. MicroCT analyses showed a trend toward less HO in ABX Wean mice (45.8% reduction vs. No ABX, p=0.20 by t-test) and a significant 12.7% decrease in tissue mineral density of HO vs. No ABX FOP mice (p=0.11). Conclusion: These results show that ablation of the microbiota with broad spectrum antibiotics started at weaning could improve survival of Pdgfra-cre/Acvr1R206H FOP mice, possibly by decreasing HO and improving body weight. Future investigations are needed to identify the mechanisms by which antibiotic ablation of microbiota mitigates mortality and HO in FOP mice, understand how spontaneous vs. injury-induced HO differ, and elucidate if these effects extend to patients with FOP.

SAT-531

Protein Kinase A: a Promising Therapeutic Target of Fibrous Dysplasia *Zhongyu Liu[1], Ding Bai[1], Xuefeng Zhao[2]. [1]State Key Laboratory of Oral Diseases, National Clinical Research Center for Oral Diseases, Department of Orthodontics and Paediatrics, West China Hospital of Stomatology,Sichuan University, China. [2], China

Fibrous dysplasia (FD) is a skeletal disease caused by postzygotic activating mutations of GNAS. Its symptoms include bone fractures, deformities, and pain. And currently, there is no cure for this disease. The cAMP-dependent protein kinase, also known as protein kinase A (PKA) plays critical roles in metabolism, gene regulation, and disease. However, the role of PKA in FD is unknown. To test our hypothesis that PKA is a therapeutic target for FD, we generated a tetracycline-inducible transgenic mouse model expressing consecutive activating mutation of catalytic subunit alpha of PKA in skeletal stem cell linage (tet-PkacaW197R/Prrx1-Cre). The tet-PkacaW197R/Prrx1-Cre mice developed robust FD-like lesions a few days following administration of doxycycline. Utilizing the PKA inhibitor gene PKI and the FD mouse model (tet-GNASR201C/Linker/Prrx1-Cre) we developed previously, we created a mouse model in which the expression of PKA was effectively suppressed while GNAS-cAMP signaling was elevated (tet-GNASR201C/tet-PKI/Prrx1-Cre). Encouragingly, the tet-GNASR201C/tet-PKI/Prrx1-Cre mice failed to develop FD-like bone lesions, demonstrating that the FD lesion was developed in a PKA-dependent fashion. Furthermore, we found that lesions of FD mice were largely restored following the treatment of small molecular inhibitors of PKA (H89 and rp-cAMPs). Together, these findings suggest that PKA is necessary and sufficient for the initiation and development of FD, making it a promising therapeutic target for FD.

Generation of a Col1a1 conditional knock-in mouse model for the study of osteogenesis imperfecta *Roy Morello[1], Milena Dimori[1], Charles O'Brien[2]. [1]University of Arkansas for Medical Sciences, United States. [2]Univ of Arkansas for Medical Sciences, United States

Several mouse models are available to study the pathophysiology of osteogenesis imperfecta (OI). Some of these have been genetically modified to introduce a mutation in Col1a1 or Col1a2 to mimic classic dominant OI while others, carrying mutations in other genes, are mimicking rarer, recessive forms of the disease. While these models have been very useful to better understand the disease, they express the underlying mutation in all tissues and thus prevent the study of its potential effects in a tissue-specific manner. To address this important limitation, we designed the first conditional knock-in allele for Col1a1 and generated mice that express the p.Gly1146Arg mutation, known to cause severe OI in human subjects, but only after Cre-specific recombination of the floxed allele. To validate our design we then crossed our Col1a1Gly1146Arg-Floxed/+ mice with the EIIA-Cre mouse strain to verify that offspring with global expression of the mutation exhibit an OI phenotype. Analysis of mice from several litters at 9 weeks of age revealed the presence of runted mice that upon genotyping harbored the recombined allele, Col1a1Gly1146Arg-Floxed/+;EIIA-Cre+. By digital X-ray these mice showed multiple fractures, including bilateral pelvic fractures and severe kypo-scoliosis. Both DEXA and microCT analysis showed severely reduced BMD and BMC, with dramatic reduction of trabecular bone and thinning of cortical bone. Importantly, these mice also showed severe morphological lung defects, confirming our findings in other OI mouse models. In conclusion, we successfully generated a conditional knock-in allele for Col1a1 and verified that its global expression using EIIA-Cre mice causes severe OI. We are breeding these mice with mice expressing Cre in all lung fibroblasts to assess the role of an OI mutation on respiratory function in the context of a healthy skeleton, and with mice expressing Cre in osteocytes to determine whether osteocytes play a significant role in OI disease manifestations compared to osteoblasts. We will also use these mice to study the impact of a severe type I collagen mutation in other tissues as well as during different developmental time points using an inducible Cre.

The Microbiome Contributes to Endochondral Heterotopic Ossification in FOP Mice by Promoting Maturation of Cartilage and Endochondral Bone *JESSICA PIERCE[1], Leslie McCauliff[2], Kela Johnson[2], Michael Hohl[2], Rheinallt Jones[2], Camille Fang[3], Liam Lam[3], ROBERTO PACIFICI[4], Edward Hsiao[5], Daniel Perrien[2]. [1]Emory University School of Medicine, United States. [2]Emory University, United States. [3]University of California San Francisco, United States. [4]EMORY UNIVERSITY, United States. [5]University of California, San Francisco, United States

Endochondral heterotopic ossification (EHO) in Fibrodysplasia Ossificans Progressiva (FOP) is driven by adverse wound healing responses in skeletal muscles, including hyperinflammation, caused by mutations in the Type 1 BMP receptor ACVR1/ALK2. Inflammatory responses to skeletal muscle injury are also modulated by changes in the gut microbiome, and we previously showed that microbiome ablation via an established broad-spectrum antibiotic cocktail (ABX; 1.0 mg/mL ampicillin, 1.0 mg/mL neomycin, 1.0 mg/mL metronidazole, and 0.5 mg/mL vancomycin) significantly reduced injury-induced EHO in tamoxifen-inducible R26creERt2;ALK2R206H-FlEx/w (FOP) mice. This was mediated, in part, by reduced total immune cells and proinflammatory monocytes and macrophages in the injury site, suggesting an indirect contribution of the microbiome to EHO. Here we report the effect of microbiome ablation on the later progression of FOP lesions and muscle repair by analyzing the tissue composition in hindlimb muscles of FOP mice 21 days post-injury (dpi). Twenty-four-day-old FOP mice were given sterile water (CON) or water containing ABX from 10 days before pinch injury of the lower hindlimb muscles until sacrifice at 21 dpi. Ex vivo microCT analysis revealed that median EHO volume in the hindlimbs of ABX-FOP mice (2.44 [1.36,5.65] mm3) was significantly less than in CON-FOP (7.51 [2.59,17.25] mm3, p=0.042 by Mann-Whitney). To further assess soft tissue composition of the FOP lesions, the areas of mature EHO, prehypertrophic and hypertrophic cartilage, fibroproliferative tissue, and regenerating muscle were measured in representative H&E-stained cross-sections of the decalcified hindlimbs. As expected, this confirmed the reduction of mature bone and total lesion size in ABX-FOP mice. The lesions in ABX-FOP mice also contained significantly more cartilage (median=0.18 [0.06,0.37] mm2) compared to CON-FOP mice (0.07 [0.01,0.12] mm2, p=0.049), but significant differences in the relative areas of fibroproliferative tissue and regenerating muscle were not detected. While our previous report demonstrated that microbiome ablation reduced immune cell infiltration at the early stages of FOP lesions, these findings suggest that it may also impair EHO maturation in FOP mice. Future studies are needed to determine whether this is a secondary effect of reduced inflammation in the early lesion or occurs via a direct effect of the microbiome on endochondral bone formation.

Electrocardiogram Changes in an Osteogenesis Imperfecta Murine Model (oim) *Krish Sardesai[1], Brittany Lafaver[2], Julian Vallejo[1], Li Lee[3], Lixin Ma[3], Charlotte Phillips[4], Michael Wacker[5]. [1]University of Missouri-Kansas City, School of Medicine, United States. [2]Department of Biochemistry, University of Missouri, United States. [3]Department of Radiology, University of Missouri, United States. [4]University of Missouri-Columbia, United States. [5]University of Missouri-Kansas City School of Medicine, United States

Osteogenesis imperfecta (OI), also known as "brittle bone disease", is a heritable collagenopathy involving the formation of type I collagen, occurring once every 15,000 - 20,000 births. Its pathogenesis is largely due to mutations in COL1A1 and COL1A2 genes. OI is characterized by decreased bone mineral density and increased susceptibility to bone fractures, given that type I collagen is the major structural protein found in bone. Beyond brittle bones, collagen type I contributes to cardiac extracellular matrix and is found in heart valves, interventricular septum, chordae tendineae, and annuli fibrosi; hence, downstream cardiovascular pathologies are a primary cause of mortality in OI, though the specific pathogenesis is largely unstudied. We hypothesize that OI contributes to electrophysiological abnormalities in mice even as young as 4 months concomitant with changes in cardiac structure and function.The osteogenesis imperfecta murine (oim) model replicates OI type III through a homozygous gene mutation of the COL1A2 gene. 4-month old wild-type (WT) and oim (oim/oim) mice underwent conscious electrocardiogram testing (ECG) wherein heart rate variability (HRV), QRS interval, PR interval, ST segment, and corrected QT interval were measured over 20 minutes. Additionally, cardiac function was assessed by in vivo cardiac 7T cine MRI providing parameters such as left ventricular blood volumes and ejection fraction. ECG analysis demonstrated oim mice (combined sexes) exhibit an increase in SD Rate HRV

(18 +/- 4 for WT vs. 25 +/- 6 bpm oim, p<0.05; n=14; female mice alone p=0.058; n=7). Oim mice did not exhibit a significant alteration in conscious heart rate or other ECG parameters. These results are surprising given that oim displayed changes in cardiac structure and function with increased blood volumes in male oim of 21.7% and 60.54%, diastolic and systolic end volumes, respectively with a corresponding decrease in male oim ejection fraction of 16.4% compared to WT littermates (p<0.05; n= 9). It is possible that the high heart rate and variability with conscious mice complicated observing additional differences. While HRV prolongation is normally associated with enhanced vagal tone, studies suggest an increased HRV may also be associated with an increased bone fracture risk, potentially explaining prolongation in oim mice (Stein et al., 2021). These preliminary results suggest understanding changes in ECG may provide additional clinical tools for OI care.

A new chemical chaperone rescues cell homeostasis and improves bone collagen content in osteogenesis imperfecta *Nadia Garibaldi[1], Roberta Besio[2], Julen Fernandez[1], Francesca Tonelli[2], Filippo Doria[2], Cecilia Masiero[2], Antonella Forlino[2], Alessandra Carriero[1]. [1]The City College of New York, United States, [2]University of Pavia, Italy

Classical osteogenesis imperfecta (OI) is associated to intracellular collagen accumulations that impairs bone cellular homeostasis and extracellular matrix. We recently focused on the chaperone 4-phenylbutyrate (4-PBA) as a potential OI treatment, but its short half-life and lack of bone specific targeting constitute major limitations. Molecular modeling starting from 4-PBA structure and focused on improving drug stability allowed the identification of a new potentially more stable derivative, MOD-4-PBA. Here, we evaluate MOD-4-PBA efficacy in counteracting OI bone cells stress, and its ability to improve bone matrix properties.To this aim, after its synthesis, we tested MOD-4-PBA efficacy first in vitro in primary osteoblasts (OBs) isolated from the OI murine model Brtl using qPCR-based arrays, western blot, immunofluorescence, thioflavin T labelling of intracellular protein aggregates and protein secretion. We then tested MOD-4-PBA efficacy in improving bone quality in vivo in the Chihuahua zebrafish model of OI, where we evaluated cranial bones mineralization using Alizarin Red in larvae. In adult zebrafish we quantified vertebral length and bone volume using synchrotron microtomography, as well as collagen content, fibers orientation and continuity using second harmonic generation microscopy. MOD-4-PBA administration was well tolerated and non-toxic in Brtl cells. It proved to reduce apoptosis, as confirmed by the low cleaved caspase 3 expression and to modulate the Unfolded Protein Response pathway. The increased expression of the endoplasmic reticulum quality control proteins in treated OBs suggests an attempt of these cells to strongly react to intracellular collagen accumulation. The MOD-4-PBA administration reduced intracellular protein aggregates and increased proteostasis favoring protein secretion (Fig. A). In vivo, in zebrafish larvae, an optimized dose of MOD-4-PBA increased the level of mineralization of cleithrum and branchiostegal ray 3 in both WT and Chihuahua mutants. In adult zebrafish, we observed same vertebral length and bone volume with increased collagen content and fibers continuity even in disoriented fibers (Fig. B). In summary, MOD-4-PBA administration ameliorated cellular homeostasis and proteostasis in OI murine OBs and improved bone collagen content and mineralization in the OI zebrafish Chihuahua, thus paving the way for an innovative approach to complement the current OI therapies.

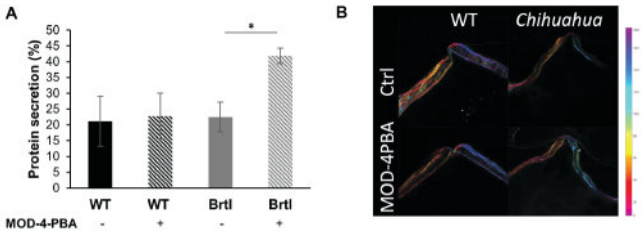

Figure A: Graph representing protein secretion evaluated by radioactively labelling proteins with ^{35}S-L-Methionine and ^{35}S-L-Cysteine in absence or presence of MOD-4-PBA. The experiment was performed in three independent cell preparations. *p<0.05 **B**: Fiber orientation in WT and *Chihuahua* zebrafish vertebral endplates with/out MOD-4-PBA treatment.

Potent Parathyroid Hormone 1 Receptor Antagonists Suppress Receptor Activation and Downstream Pathways in Human Primary Osteoblasts *Jonathan Shintaku[1], Elizabeth Rico-Bautista[1], Joe Pontillo[1], Shimiao Wang[1], Anel Castellanos[1], Julie Nguyen[1], Kelsey Retting[1], Beth Fleck[1], Sameer Urgaonkar[1], Stephen F. Betz[1], Stacy Markison[1]. [1]Crinetics Pharmaceuticals, Inc., United States

Parathyroid hormone (PTH) regulates calcium homeostasis by direct and indirect targeting of bone, kidney, and intestine. In bone, PTH stimulates cAMP generation and PKA signaling, which alters expression of genes such as RANKL and OPG. RANKL secretion from osteoblasts activates osteoclasts to promote bone resorption and calcium release from the bone matrix. Primary hyperparathyroidism (PHPT) is diagnosed in about 100,000 people in the United States every year and is characterized by over-secretion of PTH, usually due to parathyroid adenomas or hyperplasia. Approximately 20% of individuals with PHPT are symptomatic, exhibiting skeletal, renal, gastrointestinal, and/or neurological manifestations and increased mortality. Medical intervention seeks to normalize blood calcium levels, increase bone mineral density (BMD) to lower the risk of bone fractures, and reduce the risk of kidney stones. While the first line therapy of partial to total parathyroidectomy is sufficient to treat most individuals, surgery is either declined or insufficient in 10-15% of symptomatic PHPT patients. Alternatives to surgery include calcimimetics, which reduce circulating calcium but have no effect on BMD, or bisphosphonates, which can improve BMD but have no effect on circulating calcium. We hypothesize that targeting PTH action via a PTH1 receptor (PTH1R) antagonist could effectively treat both symptoms of PHPT. Using an iterative medicinal chemistry approach, Crinetics has identified potent non-peptide PTH1R antagonists. In CHO-K1 cells heterologously expressing human PTH1R, compounds demonstrated good potency in functional antagonist assays (IC50<100 nM). Select compounds were then evaluated in normal human primary osteoblasts and human osteosarcoma cells to gauge their therapeutic potential for improving calcium homeostasis and increasing BMD. In both human cellular models, antagonists suppressed PTH-dependent activation of PTH1R in a concentration-dependent manner, with potency comparable to the heterologous system. Antagonist action was also evaluated downstream of PTH1R via expression of functionally relevant genes such RANKL and OPG. The compounds' potent PTH1R antagonist activity in normal human primary osteoblasts strengthens our confidence in their ability to regulate PTH1R activity in patients with PHPT.

Bone tissue structure and composition of oim middle ear ossicles *MAIALEN UGARTEBURU[1], Luis Cardoso[2], Claus-Peter Richter[3], Alessandra Carriero[2]. [1], [2]The City College of New York, United States, [3]Northwestern University , United States

Hearing loss is a common clinical hallmark of people with Osteogenesis Imperfecta (OI, or brittle bone disease). To date, pathophysiological mechanisms of hearing impairment in OI are uncertain, and structural and compositional properties of the middle ear bones in OI remain poorly studied. In a recent study on the ossicles morphology in the oim mouse model of OI, we found consistent fractures of the incus in the oim middle ear [1]. To explain the mechanism of these fractures, here we investigate the bone tissue structural and compositional properties of the oim middle ear ossicles. We examined bone composition in oim and WT mouse (14 w.o.) ossicles using Raman spectroscopy. On the same bones, we quantified collagen content orientation, continuity, and number of clusters of collagen fibers using second harmonic generation microscopy and a custom-made MATLAB code [2]. On the contralateral ears, we performed synchrotron microtomography to determine ossicular bone tissue porosity at the vascular and cellular level. Bone tissue from the oim ossicles showed no differences in the mineral compositional parameters (mineral-to-matrix ratio, carbonate substitution, and crystallinity) compared to healthy bone. However, they exhibited a decrease in collagen content, as well as in fibers organization and continuity, with an increased number of fibers clusters, and higher lacunar, but not vascular, density volume. These results suggest that potential causes for bone fragility in the oim middle ear bones are to be searched in the collagen organization within the tissue, and in its cellular porosity. These both represent defects within the bone tissue, where a crack can start and easily propagate [3, 4]. Interestingly, structural changes resemble the ones we found in the long bones [3], but not the compositional properties [4], possibly because the middle ear mineralizes during ossification, with no subsequent remodeling. Furthermore, tissue porosity in the ossicles is in contrast with those found in the otic capsule [5], showing that under pathological conditions, different bones of the same hearing system may have different properties according to their physiological function.[1] Ugarteburu, M., et al. ARO 2022[2] Muñoz A., et al. NEBEC 2022[3] Carriero A., et al. Bone 2014[4] Carriero A., et al. JBMR 2014[5] De Paolis, A., et al. JSB 2021

Activating Gcm2 variant enhances tumorigenesis in a cyclin D1-driven mouse model of primary hyperparathyroidism *Jessica Costa-Guda[1], Justin Bellizzi[2], Callie Burke[2], Christina Titarenko[2], Sharon Yaqoob-Krysztofiak[2], Andrew Arnold[3]. [1]University of Connecticut Health Center, United States. [2]UConn Health, United States. [3]University of Connecticut School of Medicine, United States

Germline missense variants in the glial cells missing 2 gene (GCM2) have been associated with familial and sporadic parathyroid tumors, but population-based penetrance is low for most and their potential roles in pathogenesis or clinical management remain unclear. Further, functional evidence has thus far been restricted to demonstrating increased activity in in vitro transcription assays without direct relevance to a parathyroid tumor phenotype, causing difficulty in rigorously classifying the variants e.g. as low-penetrance predisposition alleles, modifiers, pathogenic drivers, variants of uncertain significance (VUS) etc. We therefore evaluated, in a functionally relevant murine system, the ability of one main variant, Gcm2 Y392S (equivalent to human GCM2 Y394S), to accelerate parathyroid tumorigenesis in cooperation with an established parathyroid tumor-driver. Genetically engineered mice harboring Gcm2 Y392S, originally developed at NIDDK on a C57BL/6 background and generously provided by Dr S Agarwal, were crossed with PCD mice, an established model where parathyroid-specific cyclin D1 overexpression (driven by a PTH-CCND1 transgene on an FVB background) causes primary hyperparathyroidism (PHPT). Serum calcium increased over time in both Gcm2Y392S/PCD and PCD mice. By 12 months of age, significantly more Gcm2Y392S/PCD mice had elevated serum calcium compared with PCD mice and by 18 months, serum calcium levels in Gcm2Y392S/PCD mice were significantly higher than in PCD mice. Parathyroid cell proliferation, measured by Ki67 immunostaining, was also significantly higher in Gcm2Y392S/PCD mice than in PCD mice. In contrast, serum calcium levels and parathyroid proliferation in mixed background littermates positive for Gcm2Y392S alone were similar to those of non-transgenic littermates. Thus, in this murine model, Gcm2 Y392S cooperatively enhanced cyclin D1's parathyroid tumorigenic phenotype, but alone was insufficient to cause parathyroid neoplasia or primary hyperparathyroidism. Our observations seem consistent with reports of reduced penetrance for the corresponding human variant GCM2 variant Y394S, further suggesting that Y394S may function more as a modest predisposition allele than as a strongly penetrant germline cause of PHPT. More functional evidence as described here is needed and should also be considered when studying the potential implications or role of germline activating GCM2 variants in genetic counseling and clinical decision-making.

Single cell transcriptome analysis of FD/MAS skeletal lesions reveals unique osteoblastic and fibroblastic cell clusters and a gene expression signature that is preserved across multiple cell types *KELLY WENTWORTH[1], Edward Hsiao[2], Fernando Fierro[3], Bryan Le[3], Tania Moody[2]. [1]University of California-San Francisco, Zuckerberg San Francisco General Hospital, United States. [2]University of California, San Francisco, United States. [3]University of California, Davis, United States

Fibrous dysplasia (FD) is a rare skeletal dysplasia characterized by expansile, fibrotic bone lesions that cause significant morbidity. FD exists on a spectrum and can affect one or more bones or occur as part of McCune-Albright Syndrome (MAS), which is defined by polyostotic FD, café-au-lait skin lesions, precocious puberty and various endocrinopathies. FD/MAS is a somatic, mosaic disease caused by a postzygotic activating mutation in GNAS (p.R201H/C), resulting in constitutive Gs-signaling in affected tissues. The precise mechanisms by which this altered signaling causes the FD skeletal phenotype remains unknown, and a more detailed understanding of the cell types present in FD lesions and their transcriptomic profile is needed. Here we report a comprehensive single cell RNA sequencing (scRNAseq) analysis of FD bone lesions (n=4) and compare them to bone from osteoarthritis patients undergoing joint replacement (n=4). Bone fragments obtained from surgical samples were digested and enriched for viable and non-hematopoietic cells. Single cell suspensions were processed for scRNAseq using 10x Chromium technology and sequenced. Following QC and normalization of sample gene expression matrixes, FD and control samples were combined into one dataset for analysis. Integration of the FD and control samples revealed the presence of 3 major cell groups: stromal cells, endothelium, and smooth muscle cells. Each group contained a significant number of genes that were differentially expressed (DE) in FD v. control cells (10638-16384, $p<0.05$), highlighting the significant transcriptomic differences seen in FD cells. Upon subclustering the stromal compartment, 14 cell clusters were identified, including fibroblasts, osteoblasts (OBs), chondrocytes, and skeletal stem/progenitor cells. Intriguingly, FD lesions harbor a unique cluster of OB-like cells that are nearly absent in controls (613 v.10 cells, respectively) and 2 clusters of ECM-producing fibroblasts that are enriched for FD cells (259 v. 14 and 1962 v. 135, respectively). We also identified a significant number of DE genes in FD v. control samples (ranging from 3207-13603 genes per cluster, $p<0.05$), many of which were consistently upregulated in FD across multiple cell types. Altogether, our scRNAseq analysis sheds new light on the altered cellularity and transcriptomic profile of human FD lesions and identifies possible biomarkers and pathways that could be targeted for therapeutic intervention. Progressive Loss of Bone Density in Patients with Esophageal Cancer *Miles Cameron[1], Sarah Judge[1], Andrew Judge[1]. [1]University of Florida, United States

Background: Changes in body composition are common in esophageal cancer (EC). More than 60% of patients, regardless of stage, display signs of cachexia, including weight loss, skeletal muscle atrophy and fat wasting. In the current study, we questioned whether bone density also decreases in patients with EC and associates with oncologic outcomes. Methods: We performed a retrospective review of all patients that received esophagectomy between 2015 and 2020 at University of Florida Health. Patients with pre-existing cardiac disease were excluded. Body composition was measured using PET/CT scans, and patients were classified as having cachexia/myopenia if having an L3 skeletal muscle index below sex- and BMI-dependent cutoffs. A p-value less than 0.05 was considered statistically significant.Results: Bone density was significantly reduced in patients with cachexia relative to those with normal muscle mass (108+/-37.2 HU v. 146+/-55.0 HU, p=0.003). Furthermore, bone density correlated with muscle mass ($p<0.0001$, R=0.5055) and muscle quality/radiodensity (p=0.0002, R=0.4736). Mean rate of bone loss was -12.0+/-27.9 HU/100d between initial and re-staging imaging studies after neoadjuvant therapy. Patients with regional lymph node metastases at surgery (N1-3) had more bone loss than those with N0 disease (-26.6+/-30.8 HU/100d v. -2.71+/-22.1 HU/100d, p=0.03). Similarly, progressive loss of bone was observed in patients with positive lymphovascular (LV) invasion (-41.8+/-32.6 HU/100d v. -3.53+/-20.1 HU/100d, p=0.005) and positive perineural (PN) invasion (-29.8 +/- 32.4 HU/100d v. -3.12 +/- 21.1 HU/100d, p=0.01).Conclusion: Reduced bone mineral density is a key component of cachexia in patients with EC. We demonstrate herein that osteopenia in EC patients associates with several cachexia measures and that progressive loss of bone may predict a worse response to neoadjuvant therapy and a tumor's early metastatic potential. Bone density may serve as a strong predictor of survival and stratification tool for clinical trials. These findings further highlight the need to study mechanisms that lead to bone wasting in tumor bearing hosts.

Higher High-sensitivity Cardiac Troponin I is Associated with Fall and Fracture-Related Hospitalizations in Older Women *Abadi Kahsu Gebre[2], Marc Sim[2], Jack Dalla Via[2], Cassandra Smith[2], Alexander Rodriguez[3], Jonathan Hodgson[2], Catherine Bondonno[2], Wai Lim[4], Elizabeth Byrnes[5], Peter Thompson[4], Richard Prince[6], Joshua Lewis[2]. [2]Edith Cowan University, Australia, [2]Edith Cowan University, , [3]Monash University, , [4]The University of Western Australia, Australia, [5]PathWest Laboratory Medicine, Queen Elizabeth II Medical Centre, Australia, [6]University of Western Australia,

Background: Emerging evidence indicates that individuals with subclinical and clinical cardiovascular disease (CVD) are at increased risk of muscle function decline, falls, and fractures. However, it is unclear if there is an association between high-sensitivity cardiac troponin I (hs-cTnI), a biomarker for myocardial injury, and muscle function decline, injurious fall and fracture-related hospitalizations.Methods: This prospective cohort study included 1179 healthy community-dwelling older women (>=70 years of age) with subclinical plasma levels of hs-cTnI (<15.6 ng/L, in quartiles) measured at baseline (1998). Hand grip strength (HGS) and the timed up-and-go (TUG) test were assessed at baseline. Hip bone mineral density (BMD) was measured by dual-energy X-ray absorptiometry at baseline or year 1 (1999). Data on fall and fracture-related hospitalizations over 14.5 years were obtained from linked health records. Cox proportional hazards regression model was used to determine the association of hs-cTnI (in quartiles) with fall and fracture-related hospitalizations.Results: Compared to women in the lowest quartile of hs-cTnI (Q1), those in the highest quartile (Q4) were older, had higher prevalent chronic diseases, and slower TUG performance (10.3 vs 9.5 seconds, p=0.03). There was no difference in average HGS (Q1 vs Q4;19.9 vs 21.2 kg, p=0.06) or BMD (0.80 vs 0.83 mg/cm2, p=0.58) between the groups. Women in Q4 were more likely to experience injurious falls (43% vs 36%) and fracture-related hospitalizations (30% vs 26%) compared to those in Q1. In a multivariable-adjusted model that accounted for prevalent falls and CVD risk factors, women in Q4 had higher risk of fall-related hospitalization (HR 1.46 95% CI 1.08-1.98) compared to those in Q1. They also had higher risk of fracture-related hospitalization (HR 1.52 95%CI 1.05-2.19), independent of hip BMD.Conclusion: Higher hs-cTnI,a biomarker of myocardial injury, was associated with poorer mobility, and a greater risk of fall and fracture-related hospitalizations in community-dwelling older women.These data indicate the importance of considering cardiac health when assessing musculoskeletal health.

SAT-548

Association of progression free survival with metabolic activity and radiodensity of the psoas muscle evaluated by preoperative 18F-FDG PET-CT in patients with non-metastatic breast cancer *Yun Kyung Jeon[1], Keunyoung Kim[2]. [1]Pusan National University Hospital, Republic of Korea, [2]Nuclear Medicine, Pusan National University Hospital, Republic of Korea

Background: This study aimed to evaluate the associations of metabolic activity and radiodensity of the psoas muscle measured derived from clinically acquired 18F-fluorodeoxyglucose (F-18 FDG) positron emission tomography/computed tomography (PET/CT) at diagnosis with progression free survival (PFS) in nonmetastatic breast cancer. Methods: This observational study included 249 women from January 2014 and December 2014 in Pusan National University Hospital. All patients undergone surgical resection for stages I-III invasive ductal carcinoma of the breast. Both maximum standardized uptake value (SUVmax) and Hounsfield Unit (HU) of the bilateral psoas muscles were extracted from preoperative performed F-18 FDG PET/CT. We calculated hazard ratios to evaluate the associations between progression free survival with SUVs or HU of psoas muscle using Cox proportional hazard model.Results: Median (range) age of 249 women included in this study was 53 (29-82) years, and median follow-up was 72.5 months (1.9-83.1); 19 patients (7.6%) presented with disease progression. Univariate analyses identified a higher T stage, higher N stage, estrogen receptor negativity, progesterone receptor negativity, human epidermal growth factor receptor 2 positivity, triple-negative breast cancer and higher SUVmax psoas muscle were significantly related to progression free survival (PFS). Lower radiodensity of psoas muscle alone was not significantly related to PFS. Multivariate Cox regression analysis revealed that higher level of N stage (hazard ratio [HR] = 2.240, confidence interval [CI]; 1.349 - 3.716, P = 0.002) and SUVmax (HR = 4.202, CI; 1.488 - 11.863, P = 0.007) as an independent factor for disease progression. Conclusions: Measures of metabolic status of psoas muscle from clinically acquired preoperative F-18 FDG PET/CT scans in nonmetastatic patients provide significant information for PFS.

Pole Walking Intervention and Fall Risk Factors in Retirement Communities: A Pilot Feasibility Trial *Mohsen Keramati[1], Mahdi Rostami Haji Abadi[1], Saija Kontulainen[1]. [1]College of Kinesiology, University of Saskatchewan, Canada

The effectiveness of exercise interventions in reducing fall and fracture risk in care home residents is unknown. Our purpose was to assess changes in physical function and other fall risk factors, and to explore safety and feasibility of pole walking intervention in retirement care home residents. We recruited 19 residents (mean age 83.8 years; 84% female; 53% with positive fall history) from 4 retirement communities in Saskatoon, Canada to participate in this patient-oriented, multi-site, single-arm pilot feasibility trial. Individually-tailored, supervised group intervention sessions (20-60 min) were offered 3 times/week for 12 weeks at each site. Sessions consisted of posture and balance warm-up, pole walking, strengthening exercises, and stretching. We measured body composition and areal-BMD (DXA), physical function (timed “up & go” [TUG], 6-min walk, 30-s chair stand [30CST], and handgrip strength), health-related quality of life (36-item short-form survey [SF-36]), and fear of falling (falls efficacy scale). We assessed safety by recording adverse events, and feasibility via recruitment, retention and attendance rates, as well as participant-reported intervention acceptability, appropriateness, and feasibility scores. Progression criteria to future RCT were recruitment rate >=1 participant/site/month; retention rate>=80%; mean attendance rate>=70%; mean participant-reported scores >=4.0; and no intervention-related serious adverse event. We assessed changes from baseline to 12-weeks using paired t-tests. Participants improved their mobility (mean change in TUG: -1.5 s; 95% CI: -2.6 to -0.4), lower limb muscle strength (30-CST: 2.5 reps; 1.3 to 3.6), and SF-36 physical functioning score (11.8; 2.9 to 20.7). There were no intervention-related serious adverse events. Recruitment, retention, and mean attendance rates were 2.7 participants/site/month, 84%, and 91%, respectively. Participant-reported acceptability, appropriateness, and feasibility scores were >4.0. In conclusion, pole walking intervention pilot in retirement communities was feasible. Participants improved their physical function over 12 weeks. These findings guide the design of an RCT to examine the efficacy of this intervention in improving fall and fracture risk factors in retirement communities.

Circulating resistin level as a potential biomarker for sarcopenia in older adults *Mi Kyung Kwak[1], Hee-Won Jung[2], Eunju Lee[3], Ji Yeon Baek[4], Il-Young Jang[4], So Jeong Park[5], Jin Young Lee[5], Beom-Jun Kim[3]. [1]Hallym University Dongtan Sacred Heart Hospital, Republic of Korea, [2]Asan Medical Center, , [3]Asan Medical Center, University of Ulsan College of Medicine, Republic of Korea, [4]Division of Geriatrics, Department of Internal Medicine, Asan Medical Center, Republic of Korea, [5]Asan Institute for Life Sciences, Asan Medical Center, Republic of Korea

Background: It is well known that muscles weaken with age, and a situation in which the amount, strength, or performance of muscles is reduced can be referred to as sarcopenia. On the other hand, resistin, which is secreted by adipocytes, myocytes and leukocytes and is known to be pro-inflammatory, is known to directly inhibit myogenesis. However, there are few human studies and only some measurements in a specific group. Therefore, this study investigated the relationship between resistin levels and sarcopenia in older adults.Methods: Blood samples were collected from 247 participants who underwent muscle assessment in a geriatric clinic and resistin levels were measured. Serum resistin levels were measured by enzyme-linked immunosorbent assay (ELISA). Sarcopenia and related parameters were determined using cutoff values for the Asian population.Results: In this study, serum resistin levels were statistically significantly higher in the sarcopenia group than in the non-sarcopenia group (10.65 +/- 5.46 vs. 7.90 +/- 4.22, P<0.001). We observed an association of serum resistin levels with muscle-related parameters, and higher serum resistin levels were significantly associated with lower gait speed (? = -0.205, p=0.001), higher chair-stand time (? = 0.171, p=0.007), and lower Short Physical Performance Battery (? = -0.184, p=0.004). These results were similar in the age- and sex-adjusted model and in the age-, sex-, and BMI-adjusted model. The odds ratio (OR) for sarcopenia increased with each unit increase in serum resistin level, both before and after adjustment (OR=1.10 to 1.13, p=<0.001 to 0.006). In addition, the OR for low muscle mass or strength showed a similar pattern (OR=1.09 to

1.14, p=<0.001 to 0.007). In addition, serum resistin levels were examined by dividing the groups according to sarcopenia status or abnormalities in sarcopenia-related parameters. As a result, resistin levels were statistically significantly higher in cases with sarcopenia, low muscle mass, low muscle strength, and poor physical performance (p=<0.001 to 0.033). Conclusions: Serum resistin levels were associated with sarcopenia or sarcopenia parameters in older adults.

Figure 1. Differences in serum Resistin levels according to sarcopenia status and abnormalities in sarcopenia-related parameters unadjusted (a), adjusted for age and sex (b), adjusted for age, sex, and BMI (c). The estimated means with 95% confidence interval were presented using analysis of covariance. ASM, appendicular skeletal muscle mass; BMI, body mass index; BW, body weight.

SAT-551

Depression is more associated with osteosarcopenia than with other musculoskeletal phenotypes. Data from the SARCOS study *ALBERTO FRISOLI JUNIOR[1], Amanda Kimura[2], Angela Paes[2]. [1]UNIVERSIDADE FEDERAL SAO PAULO, . [2]Universidade Federal Sao Paulo, Brazil

Studies have shown that depression is associated with osteoporosis and sarcopenia. However, the heterogeneity of the latter two conditions and the overlap between them may cause some misinterpretations in the association with depression. To clarify this issue, we assessed the association between depression and osteosarcopenia phenotypes by two different diagnoses of sarcopenia, in older adults. Methods: SARCOS is a prospective cohort study on the association between sarcopenia and osteoporosis and difficult outcomes in older adults with cardiovascular disease. Population: subjects aged > 60 years from the cardiovascular disease outpatient clinic. All patients underwent DXA analysis for appendicular muscle mass, bone mineral density, in addition, handgrip strength and walking speed were measured. Sarcopenia was diagnosed following the EWGSOP II (EW) and SDOC recommendations. Osteoporosis was diagnosed according to the WHO guidelines. Osteosarcopenia was categorized into four phenotypes (osteosarcopenia-OPSAR, sarcopenia-only-SAR, osteoporosis-only-OP, and robust-ROB) for each sarcopenia diagnosis. Depression was considered if the Geriatric Depression Scale was >= 7 points. Regression analyses were adjusted for significant variables for Osteosarcopenia SDOC (Age>80, female sex, previous falls, dementia, diabetes mellitus, previous fracture) and Osteosarcopenia EWGSOPII (female sex, Age>80, Diabetes mellitus, previous fracture, and hospitalizations). Results: In this study, 409 patients were evaluated. The mean age was 77.87(7.6) years, female gender 57.5%(235). Depression occurred in 18.6%(76); osteosarcopenia phenotypes: OPSAR-SDOC:17.8%(73), SAR-SDOC:26.7%(109), OP-SDOC:11.5%(47); p<0.001; and OPSAR-EW:9.5%(39); SAR-EW:8.1%(33); OP-EW:19.8%(81);p=0.337. In patients with depression, 34.2% had OPSAR-SDOC, 28.2% OPSAR-EW; 22% SAR-SDOC, 21.2% SAR-EW; 4.3% OP-SDOC and 19.8% OP-EW. In regression analyses, depression showed odds ratio for OPSAR-SDOC: 3.59 (1.73-7.47; 0.001), SAR-SDOC: 2.05 (1.03-3.96; 0.040); OP-SDOC 0.21 (0.04-0.96;0.045), while for phenotypes with EW, the OR for OPSAR-EW: 2.33 (1.01-5.35; 0.045); SAR-EW: 1.51 (0.59-3.86; 0.382); OP-EW: 1.05 (0.54-2.05;0.862). Conclusions: In our study depression showed greater association with the Osteosarcopenia phenotype than as the other phenotypes, regardless of sarcopenia diagnosis. Implications: These results highlight the importance of differentiating osteosarcopenia phenotypes in clinical practice.

SAT-552

Preliminary Analysis of Weight Loss Associated Musculoskeletal Changes as Assessed by Computed Tomography in the INVEST in Bone Health Trial *Delanie Lynch[5], Allison Avery[2], Caitlyn Dwyer[2], Peggy Cawthon[3], Marjorie Howard[4], Kristen Beavers[2], Ashley Weaver[5]. [5]Wake Forest University School of Medicine , . [2]Wake Forest University, United States. [3]California Pacific Medical Center, United States. [4]Wake Forest University School of Medicine, United States. [5]Wake Forest University School of Medicine , United States

Weight loss improves many obesity-related comorbidities; yet, remains controversial for older adults due to associated musculoskeletal declines and increased fracture risk. Computed tomography (CT) provides accurate, high-resolution measurement of weight loss-associated muscle and bone loss. The purpose of this study is to begin to examine how CT-derived muscle and bone change over 6 months in a geriatric weight loss study.We analyzed a convenience sample of 24 older (68.0+/-4yrs) predominantly white (75.0%) women (66.7%) living with obesity (33.8+/-3kg/m2) and participating in the ongoing INVEST in Bone Health trial (NCT04076618). All participants received caloric restriction targeting 10% weight loss over 6 months (n=24), with some randomized to additional resistance training (n=8) or weighted vest use (n=8). At baseline and 6-months, participants underwent a CT of the trunk and mid-thigh. In each CT, a phantom was imaged to calibrate volumetric bone mineral density (vBMD). Trabecular and cortical vBMD were measured for the total hip and femoral neck. Mid-thigh muscle and intermuscular fat areas were segmented from a single CT slice. Statistical analyses were performed with paired t-tests and partial Pearson's correlations (adjusted for age, sex and weight).Body weight decreased by 11% (-10.3+/-6kg; p<0.01) over 6 months. From baseline, mid-thigh muscle area declined 5% (-6.8+/-6cm2; p<0.01) and intermuscular fat area declined 16% (-1.9+/-3cm2; p=0.01). Trabecular vBMD was not significantly changed (<2% change) for the total hip or femoral neck. Cortical vBMD increased from baseline by 0.6% at the total hip (4.5+/-9mg/cm3; p=0.03) and by 1.9% at the femoral neck (12.9+/-21mg/cm3; p=0.01). Muscle and vBMD changes were not significantly correlated, with the strongest trends between changes in intermuscular fat and hip vBMD (r= -0.34;p=0.14).Significant 6-month weight loss was associated with declines in muscle and intermuscular fat area, while cortical vBMD increased. Only modest correlations were observed between change in muscle and bone outcomes, potentially indicating no causal relationship. However, full interpretation of these results is limited due to the small sample size and lack of analysis by interventional assignment (i.e. resistance training or weighted vest use), which remains blinded at this time. Future work will explore these muscle and bone outcomes longitudinally (i.e. 12-months) in the entire study cohort (n=150).

SAT-553

ANALGESIC ACTIVITY OF NSAIDs AND PARACETAMOL IN EXPERIMENTAL OSTEOARTHRITIS AND HYPOTHYROIDISM *ROKSOLANA POVOROZNYUK[1], Vladyslav Povoroznyuk[2], Dmytro Nosivets[3], Nataliia Dzerovych[2]. [1], Ukraine. [2]D.F. Chebotarev Institute of Gerontology NAMS of Ukraine, Ukraine. [3]Oles Honchar Dnipro National University, Ukraine

Separate nosological forms of osteoarthritis (OA) and hypothyroidism (HT) differ in their etiology; however, the issue of comorbidity gains the utmost importance for these diseases, which are insufficiently explored in the literature. Analgesics may affect the hormonal activity of the thyroid gland through a direct influence on the synthesis and secretion of hormones or their metabolism, clearance and absorption by tissues. However, an important and unexplored issue is the study of the processes of interaction of analgesics with the hormone

replacement therapy drug L-thyroxine, their ability to affect pain of varying intensity. The aim was to conduct a comparative analysis of the influence of experimental pathologies (OA and HT) on the state of the nociceptive system and the influence of the use of NSAIDs and paracetamol on antinociceptive mechanisms in experimental rats.Materials and Methods. Experimental studies were performed on 240 white mature nonlinear rats of both sexes. Experimental OA was reproduced by a single intra-articular injection of 0.1 ml of Iodoacetic acid solution into the knee joint, which was prepared at the rate of 3 mg of reagent per 50 ?l of sterile saline. Experimental HT was performed by enteral administration of 0.02% carbimazole solution, which was prepared at the rate of 5 mg per 250 ml of saline. The analgesic potential of the studied drugs was evaluated by studying their antinociceptive activity based on the effect on the pain threshold of rats after a single administration of NSAIDs and paracetamol and against the background of a 5-day administration of L-thyroxine using the method of electrical stimulation of the tail root of rats and recording the nociceptive response (vocalization reaction. Conclusions. Hypothyroidism leads to hypoalgesia against the background of OA, which is evidenced by a decrease in the threshold of pain sensitivity by 17% ($p<0.05$) in the comorbid condition versus 24% ($p<0.05$) in OA. Experimental pathological conditions - OA and HT significantly change the antinociceptive activity of drugs. Under the conditions of OA and HT against the background of hormone replacement therapy with L-thyroxine, it was established that these drugs are ranked as follows by the intensity of antinociceptive action: diclofenac sodium (+212%) (p ibuprofen (+144%) (p nimesulide (+134%) (p paracetamol (+116%) (p meloxicam (+104%) (p celecoxib (+93%) ($p<0.001$), which reflects the highest antinociceptive activity of diclofenac sodium.

The Relationship between Diet Quality and Sarcopenia: an Analysis of the National Health and Nutrition Examination Survey *Sikarin Upala[1], Moya Alfonso[1], Steven Hecht[1], Darin Ruanpeng[2]. [1]Nova Southeastern University, United States. [2]St Luke's Hospital, United States

Introduction: Sarcopenia is a skeletal muscle disease associated with morbidity and mortality. Factors related to sarcopenia include aging, systemic diseases, physical inactivity, and inadequate energy intake. Limited evidence shows that the levels of sarcopenia symptomology might be better with adherence to healthier diets. However, it is unclear whether the relationship between diet quality and sarcopenia is unique and independent of factors that associate with sarcopenia. This dissertation study aims to determine whether diet quality has a unique relationship with sarcopenia symptomology independent of physical activity and energy intake using publicly available data from the National Health and Nutrition Examination Survey (NHANES) 2011-2012 and 2013-2014. Methods: Eligibility criteria included adult participants aged 18 and older with levels of sarcopenia symptomology (grip strength and appendicular skeletal muscle mass; ASMI) measurement, first 24-hour recall dietary data, physical activity, and energy intake data. Diet quality was assessed using the Healthy Eating Index-2015 (HEI) score. Simple and multiple linear regression analysis was used to determine the relationship between the component of HEI-2015 and levels of sarcopenia symptomology. Energy intake and physical activity were used as covariates. Results: The results from 5,302 participants eligible for this study demonstrated that total HEI-2015 score and scores of the components of HEI-2015 were associated with grip strength and ASMI, but the direction of relationship differs based on the components. Total protein foods had a positive linear relationship with grip strength and ASMI independent of physical activity and total energy intake. The magnitudes of the unique relationship differ based on gender and race and ethnicity. Conclusions: Adequate energy intake and physical activity are essential practice to maintain skeletal muscle strength and skeletal muscle mass. Dietary protein may have a unique beneficial role on these levels of sarcopenia symptomology. Findings from this dissertation study can be applied to practice and further research in the fields of nutrition and sarcopenia.

Lactobacillus Reuteri improved skeletomuscular properties through modulating bile acid profile and vitamin D metabolism in mature male mice *Wen-Xuan Yu[1], Siu-Wai Wan[1], Chun Au-Yeung[1], Yayi Shen[1], Tsz-Hung Kong[1], Liping Zhou[1], Kam-Wah Mok[1], Man-Sau Wong[1]. [1]The Hong Kong Polytechnic University, China

Probiotic supplements have been reported as potential strategies for ameliorating skeletomuscular dysfunction and osteosarcopenia. However, the underlying mechanisms are currently unknown. The present study aimed to compare the effects of probiotics on muscular properties in male mice and explore the role of gut-derived bile acids in modulating vitamin D metabolism and myogenesis.Four-month-old C57BL/6 male mice were randomly assigned to 4 groups and orally administrated with sterile water, 3 x 108 CFU Lactobacillus Reuteri, Bifidobacterium Longum, or Streptococcus Salivarius 3 times per week for 8 weeks. Muscle strength was determined by forelimb and four paws grip strength. Muscular properties were evaluated by measuring muscle mass and fibre cross sectional area of tibialis anterior. Circulating level of 1,25(OH)2D3, the bioactive form of vitamin D, was determined to evaluate its correlation with muscular properties. Serum bile acid profile was determined by targeted metabolomic approach. The effects of selected gut-derived bile acids on myogenesis were further evaluated in mouse myoblast C2C12 cells.The results showed L. Reuteri significantly improved forelimb grip strength ($P<0.05$) and 4 paws grip strength ($P<0.05$) in male mice. S. Salivarius only improved forelimb grip strength ($P<0.05$). Fibre cross sectional area of tibialis anterior was increased by 33.39% ($P<0.01$) in mice treated with L. Reuteri compared to control group. Gastrocnemius and quadriceps mass positively correlated with circulating 1,25(OH)2D3 level ($P<0.05$) which was markedly upregulated in L. Reuteri treated mice ($P<0.01$). There was an evident conversion of primary bile acids into secondary bile acids after administration of probiotics. Relative abundance of secondary bile acids was elevated from 44.95% to 57.82% by L. Reuteri. Among the bile acid profile, deoxycholic acid (DCA) and lithocholic acids (LCA), the typical gut-derived bile acids, were markedly increased in L. Reuteri treated mice. In addition, DCA and LCA further increased myogenesis of C2C12 cells in terms of myoblast number ($P<0.05$) and mean myoblast area ($P<0.05$).In summary, our results indicated that the actions of L. Reuteri in regulating skeletomuscular properties might be associated with bioactivation of vitamin D. As the major gut-derived metabolites, secondary bile acids play an important role in mediating myogenesis. These findings improved our understandings of skeletomuscular-gut axis.

Type 1 diabetes (T1D) is associated with an increased risk of hip fracture, but the factors underlying skeletal fragility in older adults with T1D are not well understood. This study assessed regional differences in bone mineral density (BMD) and strength of cadaveric femora from postmenopausal women with longstanding T1D and non-diabetic controls. Whole femora were acquired post-mortem from female Joslin Medalists with T1D >=50yrs (n=11); age and sex-matched non-diabetic control femora were obtained from a tissue bank (n=10). Femora were scanned via axial computed tomography (CT, Siemens). CT scans were analyzed using Medical Image Analysis Framework (MIAF)-Femur, with cortical thickness (Ct.Th) and volumetric BMD (total=Tt; trabecular=Tb) assessed at the total hip (TH) and femoral neck (FN). FN volumes were further divided into quadrants: superior anterior (SA) and posterior (SP) as well as inferior anterior (IA) and posterior (IP). Femoral strength and DXA-equivalent TH and FN areal BMD (aBMD) and T-score were calculated using Biomechanical CT analysis (BCT, O.N. Diagnostics). Individuals were considered high fracture risk if they had either low aBMD (T-score<=-2.5) or fragile bone strength (<=3000N). The ratio of fall force to femoral strength was computed using a soft-tissue attenuated fall force and femoral strength from BCT. Wilcoxon rank sum tests assessed group differences; percent differences are between group medians.The T1D group had an average (mean+/-SD) BMI=25.1+/-3.4kg/m2, HbA1c=8.3+/-0.9%, T1D duration=65+/-5yrs, age at onset=13+/-8yrs, and age at death=78+/-10yrs; age and BMI were not different between groups. 73% of T1D and 40% of controls were considered high risk (p=0.2). TH Tt.BMD and aBMD did not differ between groups. FN aBMD (p=0.07) and Tb.BMD (p=0.06) were lower in T1D (Table). Within the FN, women with T1D had Tb.BMD deficits that were larg-

est in the SP (-35%, p=0.04) and SA (-35%, p=0.10) quadrants. Ct.Th did not differ between groups at any site. Women with T1D also had lower femoral strength (-26%, p=0.03), but similar fall force (p=0.25), resulting in a greater load-to-strength ratio (+28%, p=0.04).These findings reveal deficits in femoral BMD and strength and greater load-to-strength ratio in older women with T1D, indicating increased susceptibility to hip fracture. As hip fractures may initiate in the superior FN, trabecular bone deficits in this region may contribute to the high risk of hip fracture in older adults with T1D.

In Patients with Glucocorticoid-Induced Osteonecrosis Severity of Disease Predicts Bone Loss *Olivia Blumberg[1], Alison Heilbronner[2], Alexandra Krez[1], Douglas Mintz[1], Jeri Nieves[3], Donald McMahon[4], Gail Roboz[5], Pinkal Desai[5], Derek Hansen[1], Joseph Lane[1], Richard Bockman[6], Emily Stein[1]. [1]Hospital for Special Surgery, United States. [2], United States. [3]Columbia University and Hospital for Special Surgery, . [4]Columbia University College of Physicians and Surgeons, . [5]Weill Cornell Medical College, United States. [6]Hospital for Special Surgery, Weill Cornell Medical College, United States

Osteonecrosis (ON) and osteoporosis are well-recognized harmful sequelae of glucocorticoid (GC) exposure. However, whether shared factors govern patient susceptibility to both conditions is not well understood. Few studies have investigated the concurrent development of ON and bone loss. This prospective study investigated relationships between patient characteristics, ON severity and progression, and bone loss over 12 months in a cohort with GC-induced ON. We hypothesized that patients with more severe and progressive ON would have greater bone loss by DXA. 28 individuals were enrolled and followed with imaging at baseline, 6 and 12 months including MRI of the bilateral hips, knees and shoulders to diagnose/classify ON and DXA of the spine, hips and forearm. Changes between baseline and 12-month imaging were investigated. Mean age of subjects was 44+/-17 years, 50% women. The most common indications for GC treatment were systemic lupus erythematosus (25%) and acute lymphoblastic leukemia (25%). Mean number of joints with ON at baseline was 4 (range 1 to 6). 23% of joints with ON exhibited collapse. Mean DXA Z-scores at baseline were within the normal range at the spine (0.0), total hip (-0.2), femoral neck (-0.1), 1/3 radius (0.3). Patients with more severe ON at baseline, defined as the number of joints with ON, were younger (r=-0.44, p=0.02) and had higher cumulative oral (r=0.37, p=0.05) and IV GC exposure (r=0.58, p=0.001). Patients with more severe ON at baseline also had more bone loss at the spine (r=-0.57, p=0.002, Figure) and the 1/3 radius (r=-0.37, p=0.05), and tended to have more bone loss at the total hip (r=-0.36, p=0.07) and femoral neck (r=-0.32, p=0.11). Based upon 12-month change in MRI appearance (increased size of lesion, increased edema, joint collapse), ON was classified as progressing in 43% of the cohort. Progression of ON over the course of the study was not significantly related to age, GC exposure or bone loss. No new joints with ON were identified over the 12-month follow-up. In summary, our findings suggest that patients with more severe ON had more ongoing bone loss by DXA on follow-up imaging. Relationships were strongest at the spine, the site known to be most reflective of the harmful skeletal effects of GCs. Future work is needed to investigate the individual and synergistic factors that govern susceptibility to the skeletal effects of GCs and to develop therapeutic approaches to prevent these devastating complications.

Adolescent girls with type 1 diabetes develop changes in bone prior to evidence of clinical neuropathy *RACHEL USALA[1], IVANA SHEN[2], Mahshid Mohseni[3], Trinity Tedtsen[4], Mary Bouxsein[4], Deborah Mitchell[4], Erica Scheller[5]. [1]Washington University in St. Louis, . [2], . [3]Washington University School of Medicine, United States. [4]Endocrine Unit, Massachusetts General Hospital and Harvard Medical School, United States. [5]Washington University, United States

Neuropathy and skeletal disease are prevalent complications in patients with type 1 diabetes (T1D). However, it remains unknown whether neuropathy directly causes bone disease in patients with T1D or if changes in nerve and bone develop independently. To address this, we conducted a single-centered cross-sectional study. Thirty-three girls aged 12-18 years with and without T1D were enrolled (n=12 control, n=21 T1D). Groups were well matched for age, height, and physical activity. All control and T1D participants had healthy neural exams without clinical neuropathy as assessed by the Michigan Neuropathy Screening Instrument. Participants with T1D had significantly higher Z-scores for weight and BMI. Therefore, bone outcomes were adjusted for BMIz. There were no significant differences in bone mineral density by DXA between control and T1D participants. Differences in bone microarchitectural parameters between groups were observed with high-resolution scans with XtremeCT-II. Among adolescent girls with T1D, there was a decrease in trabecular bone volume fraction at both the distal radius (-5.5%, p=0.095) and the tibia (-7.1%, p=0.017). This was driven predominantly by decreases in trabecular thickness at both sites (-4.2% radius, p=0.007; -5.1% tibia, p=0.034). Cortical parameters including thickness, perimeter, and area remained largely unchanged after adjusting for body size (BMIz) with two exceptions. In the tibia (only), volumetric BMD was increased by 5.8% (p=0.024) and porosity was decreased from 2.1+/-1.6% in the control group to 1.3+/-1.1% with T1D (p=0.012). Predicted failure load trended lower in the T1D tibia relative to control, but was not statistically significant (-9.1%, p=0.242). Biochemically, participants with T1D had lower circulating levels of both CTX (a marker of bone resorption, -34%, p=0.035) and osteocalcin (a marker of bone formation, -25%, p=0.057) compared to controls, identifying a low bone turnover state among young persons with T1D. Our study demonstrates that deficits in trabecular bone microarchitecture, decreased cortical porosity in the tibia, and suppression of bone turnover occur in adolescents with T1D early in the course of disease, prior to the onset of clinical neuropathy. This informs our understanding of the rapid clinical onset and progression of skeletal disease in young girls with T1D and suggests that development of early management strategies for adolescents may help to prevent fracture and related co-morbidities.

Glucose dysregulation is associated with lower bone mineral density in adults with cystic fibrosis *Lucia Gonzalez Ramirez[1], Joseph Kindler[2], Elizabeth Ivie[1], Pichatorn Suppakitjanusant[1], William Hunt[1], Vin Tangpricha[1], Tanicia Daley[1], Arlene Stecenko[1], Richard Lewis[2], Thomas Ziegler[1], Jessica Alvarez[1]. [1]Emory University, United States. [2]The University of Georgia, United States

Diabetes and bone disease are common complications of cystic fibrosis (CF). In adults without CF, bone fragility is a concerning complication of diabetes, but the diabetes-bone connection in CF is understudied. This study determined associations between glucose dysregulation and bone mineral density (BMD) in adults with CF. This was a cross-sectional study of 61 adults with CF ages 18-50 years (31% female, 28% Black). Total body BMD was assessed via dual-energy X-ray absorptiometry (DXA), and Z-scores were calculated. During a 2-hour oral glucose tolerance test (OGTT), glucose was assessed at fasting and min 120. OGTT and DXA were performed on the same day. Subjects were classified as having impaired fasting glucose (IFG; fasting glucose >100 mg/dL), impaired glucose tolerance (IGT; 2-hour glucose >140 mg/dL), diabetes (fasting glucose >126 mg/dL or 2-hour

glucose >200 mg/dL), or normal glucose control (fasting glucose <100 mg/dL and 2-hour glucose <140 mg/dL). Linear regression was performed to determine associations between glucose control indices and total body BMD Z-score. Additional analyses included race/ethnicity, sex, age, and body mass index (BMI) as covariates. Twenty-three percent had normal glucose; 34% and 36% had IFG and/or IGT, respectively; and 34% had diabetes. In unadjusted analyses, fasting glucose (p=0.039; Fig 1) but not 2-hour glucose was inversely associated with BMD Z-score. In adjusted analyses, fasting glucose and 2-hour glucose were inversely associated with BMD Z-score (both <0.05). BMD Z-score was significantly lower in those with IFG vs. without IFG (p=0.02; Fig 1), and this difference was maintained after adjusting for covariates (p=0.010). Compared to those with normal glucose control, people with diabetes had lower BMD Z-score (0.74+/-1.42 vs. -0.10+/-1.01), but this difference was not significant (p=0.057). BMD Z-score did not differ between those with both IFG and IGT vs. normal glucose control (p=0.61). In line with studies in non-CF populations, glucose dysregulation is associated with having lower BMD in people with CF. The International Society for Clinical Densitometry recommends assessing hip and spine BMD for clinical evaluations, but unfortunately these measures were not completed for this study. Accordingly, these results highlight the need for additional research focused specifically on diabetes-related bone deficits in people with CF.

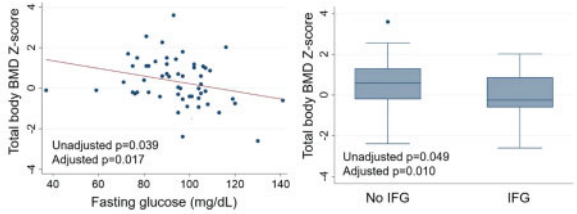

Fig. 1. The inverse association between fasting blood glucose and BMD Z-score (left) and differences in total body BMD Z-score between adults with IFG vs. no IFG (right) in people with CF. Adjusted analyses control for age, sex, race/ethnicity, and BMI. BMD, bone mineral density; IFG, impaired fasting glucose; BMI, body mass index.

Associations of Endothelial Function with Bone Perfusion and Microstructure in Patients with Type 2 Diabetes *Maximilian T. Loeffler[1], Po-hung Wu[2], Amir M. Pirmoazen[3], Gabby B. Joseph[4], Isra Saeed[4], Jing Liu[4], Thomas M. Link[4], Galateia Kazakia[5]. [1]UCSF Radiology and Biomedical Imaging, United States. [2]University of California - San Francisco, . [3]University of Florida Jacksonville, United States. [4]UCSF, United States. [5]University of California, San Francisco, United States

Background: Skeletal fragility is a known complication of type 2 diabetes (T2D). Chronic hyperglycemia promotes endothelial dysfunction, a root cause of micro- and macrovascular complications in T2D. We hypothesize that endothelial dysfunction assessed by pulse amplitude tonometry (PAT) plays a role in the development of diabetic bone disease. The purpose of this study was to investigate the association of PAT with bone perfusion and changes in bone microstructure in T2D patients and non-diabetic controls.Methods: We included 79 participants in this cross-sectional study (39 T2D and 40 age- and sex-matched controls). Inclusion criteria were age 50-70 years, DXA T-score -2.5-0, and no bone disease or use of bone active drugs. HR-pQCT was performed at the distal radius and tibia. Intracortical bone perfusion was assessed using dynamic contrast-enhanced MRI in the distal tibia. Reactive hyperemia index (RHI) was measured by PAT at the index finger. T2D and control participants were compared. Associations between RHI and bone parameters were calculated in linear regression models adjusting for HbA1c.Results: RHI did not significantly differ between T2D participants and controls (p=0.105, Fig. 1). Maximum perfusion slope was 21% higher in T2D (p=0.044). Increasing RHI (=better endothelial function) was significantly associated with longer transition time in the combined group and in T2D participants, but not in controls (Table 1, Fig. 2). RHI was associated with lower Ct.BMD and Ct.Th in the tibia and radius, and with lower Tb.Th and Tb.Sp and higher Tb.N in the tibia in the combined group. Associations were significant for Tb.N and Tb.Sp in T2D participants and for Ct.BMD in controls (Fig. 3). Only in controls, RHI was associated with higher Ct.Po in the tibia and with lower Tb.BMD in the tibia and radius.Conclusion: Better endothelial function was strongly associated with longer transition time in T2D, consistent with neovascularization. This may indicate that those with endothelial dysfunction were unable to mount an adequate response to perfusion demands. Surprisingly, better endothelial function was associated with bone structural decline including decreased cortical BMD and increased porosity in controls. This inverse relationship in the bone-vascular axis could reflect physiologic bone turnover supported by healthy endothelium. A dysregulation of bone remodeling is suggested by the lack of association of RHI with cortical microstructure in T2D.

Table 1: Associations of RHI (marker of endothelial function) with intracortical perfusion in the tibia and bone parameters in the radius and tibia.
